optimum b-jet selection criteria. The best jet reconstruction performance is observed for the jet cone algorithms with the cone size of  $\Delta R = \sqrt{\Delta\eta^2 + \Delta\phi^2} = 0.4$ , compatible with the performance of the  $k_T$  algorithm for the same cone size. After a jet is selected as described, the b-tagging algorithm is performed to determine whether the jet originates from the b-quark. The minimum  $p_T$  value of 20 GeV is required for each b-jet in order to reduce the contribution of the calorimeter noise and of the mistagged light- or c-jets. The rejection of light- and c-jets is essential for the suppression of the  $Z + jet$  background. One could extend the lower  $p_T$ -bound down to  $\sim 15$  GeV without a large change of the rejection rate. However, the impact on the final signal significance will be rather small, while the agreement between the full and the fast simulation is shown to decrease.

Several b-tagging algorithms have been studied in order to define the optimum selection of the low- $p_T$  b-jets coming from the signal. The best rejection is obtained by IP3DSV1 [27], which is based on the information obtained from the transverse and longitudinal impact parameter significances of the tracks and from the reconstructed secondary vertex. The distribution of the b-tagging weight obtained by this algorithm is shown in Figure 4 for the b-jets and the light jets in the  $b\bar{b}A$  signal sample at 200 GeV and in the  $t\bar{t}$  background sample. The arrow indicates the optimum cut value of 4. Figure 5 shows the obtained b-tagging efficiency for the  $b\bar{b}A$  signal sample, in dependence on the b-jet  $E_T$  (Figure 5a) and  $\eta$  (Figure 5b)). The kinematic cuts of  $p_T > 20$  GeV and  $|\eta| < 2.5$ , as well as the IP3DSV1 weight-cut of 4 have been applied for the b-jet selection. The resulting b-tagging efficiency is  $(64.1 \pm 0.81)\%$  for the  $b\bar{b}A$  signal sample, with a light-jet rejection of  $(80 \pm 1)$  for the  $Z + jet$  sample. Systematic detector-related

Figure 4: Distribution of the b-tagging weight for the b-jets and the light jets in the  $b\bar{b}A$  signal and  $t\bar{t}$  background sample, obtained by the IP3DSV1 b-tagging algorithm. The arrow indicates the optimum cut value of 4, which is used for the selection of the b-jets in the analyses.

Figure 5: B-tagging efficiency in dependence of b-jet transverse energy  $E_T$  (a) and pseudorapidity  $\eta$  (b), evaluated for the  $b\bar{b}A$  signal sample at  $m_A = 200$  GeV and  $\tan\beta = 30$ . IP3DSV1 b-tagging weight cut of  $>4$  has been applied.

uncertainties are not included here.

The final important reconstruction object is the missing transverse energy ( $E_T^{miss}$ ), which allows for the suppression of the  $t\bar{t}$  background. In the signal processes, there is no neutrino contribution, such that the measured  $E_T^{miss}$  value is dominated by the experimental resolution. The reconstruction algorithm for the calculation of the missing transverse energy is described in detail in Ref [28]. The distributions of  $E_{T(x,y)}^{miss}$  components in the signal samples have a Gaussian part with a width  $\sigma = (7.8 \pm 0.1)$  GeV, while the non-Gaussian tails (above  $5\sigma$ ) are found to contribute less than 1.5% to the overall distribution.  $E_T^{miss}$  is sensitive to pile-up effects, as will be described in the next subsection.

## 4.2 Reconstruction performance under influence of pile-up and cavern background

In the following, the detector performance related to the analysis is evaluated in dependence on the pile-up at luminosities of  $10^{33} \text{ cm}^{-2}\text{s}^{-1}$  and cavern background (five times higher than the expectation). In

Figure 6(left), the efficiency and the fake rate of the muon reconstruction is shown for the  $b\bar{b}A$  signal sample simulated without and with the pile-up contribution as a function of the pseudorapidity. The corresponding momentum resolution is shown in Figure 6(middle). Similar results are obtained also for the background samples. As can be seen from the plots, muon reconstruction is only marginally

Figure 6: Efficiency and the fake rate (left) and resolution (middle) of the muon reconstruction as a function of the  $|\eta|$  (for  $p_T > 20$  GeV), with and without the pile-up contribution in the  $b\bar{b}A$  signal sample with  $m_A=200$  /GeV. The right plot shows the corresponding dimuon mass distribution.

influenced by pile-up. Consequently, the dimuon invariant mass also remains unaffected, as shown in Figure 6(right) for  $m_A=200$  GeV.

On the contrary, the reconstruction of the missing transverse energy is substantially affected by pile-up in the calorimeter. The degradation of the  $E_T^{miss}$ -resolution mainly affects the selection of events with a small true missing energy (signal and the  $Z$  background) as shown in Figure 7(left);  $t\bar{t}$  events, characterized by a large missing energy, are rather insensitive to pile-up (see Figure 7(right)). This

Figure 7: Missing transverse energy distribution for the  $b\bar{b}A$  signal at 200 GeV (left) and the  $t\bar{t}$  background (right), with and without pile-up.

effect must be taken into account during the optimization of the event selection criteria. For instance, an event selection cut at  $E_T^{miss} < 30$  GeV, which is reasonable without pile-up, would reject too many signal events, once the pile-up contribution is included. Therefore, this analysis cut should rather be set to at least 40 GeV in the realistic LHC environment.

The change of the calorimeter response under the influence of pile-up affects also the jet reconstruction. Due to a higher calorimeter activity, one expects an increase in the number of reconstructed jets. This can be observed in Figure 8(left), showing the jet multiplicity in the  $Zb\bar{b}$  background events.

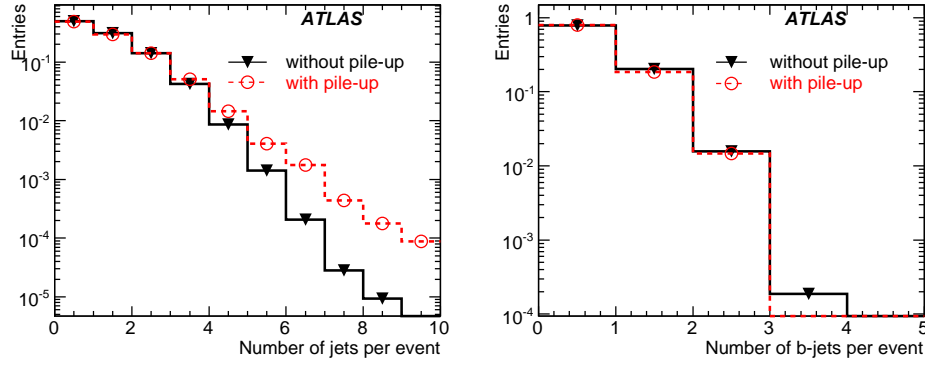

Figure 8: Total number of jets per event (left) and the number of b-jets (right) in the  $Zb\bar{b}$  background sample, with and without the pile-up contribution.

No significant impact of the pile-up is observed on the b-tagging (see Figure 8(right)), due to the additional tracking and vertex information.

## 5 Event selection

The search for the MSSM Higgs bosons can be performed by several different approaches, related to the number of jets one requires to be present in the final state. As mentioned before, due to a large signal production rate in the associated production mode, the presence of the b-jets in the final state can help to suppress the Drell-Yan background. On the contrary, the remaining events with 0 b-jets provide for a high signal rate on top of the smoothly distributed background, even at low integrated luminosity.

The event selection methods are optimized separately for the two cases:

- Signatures with 0 b-jets in the final state.
- Signatures with at least one b-jet in the final state.

The two mentioned final states are uncorrelated and therefore complementary. In the case of 0 b-jets in the final state, the dominant background is the Drell-Yan  $Z$  boson production, while in the case of at least one b-jet the  $t\bar{t}$  background has the biggest contribution, especially for Higgs masses above 130 GeV, which are further away from the  $Z$  resonance.

Before describing the selection criteria, the preselection of the events is discussed, common to the two signatures above. The preselection is defined by the kinematic cuts on muon  $p_T$  and  $|\eta|$ , together with the muon isolation criteria.

### 5.1 Preselection

The main characteristics of the signal signatures is the presence of two isolated muons of opposite charge in the final state. The  $p_T$ -distribution of the muons is shown in Figure 9 for the signal and background processes. The signal is characterized by the relatively high- $p_T$  muons, while the background has muons

Figure 9: Distribution of the muon transverse momentum  $p_T$  for the muons in the signal and background events.

of lower momenta. The muon  $p_T$  distribution in the signal is highly correlated to the Higgs boson mass. Therefore, the lower bound on the muon  $p_T$  is kept at a relatively low value, in order to allow for a general search in a broad Higgs mass range. At preselection level, both muons are required to have a  $p_T > 20$  GeV and to be in the pseudorapidity range  $|\eta| < 2.7$ .

The selected high- $p_T$  muons are required to be isolated, in order to reject the processes in which the muons originate from the hadronic decays. The applied isolation criteria require the calorimeter energy  $E_T$  deposited in a cone of size  $\Delta R = 0.4$  around a given muon, divided by the muon  $p_T$  to be lower than 0.2. The distribution of this isolation variable is shown in Figure 10(left) for different signal and background processes.

The isolation criteria significantly decrease the  $t\bar{t}$  background, where one of the muons comes from the b-decays. The power of rejection of the non-isolated muons originating from the b-quarks in the  $t\bar{t}$  background is shown in Figure 10(right) for the standard calorimeter isolation ( $E_T^{cone0.4}$ ), and for the isolation normalized by the muon  $p_T$ .

Due to the high muon momenta, the signal can be efficiently triggered by the single high- $p_T$  muon trigger. The efficiency of the trigger selection for the dimuon signal events is shown to be around 95% for all studied mass points. The detailed study of the trigger selection efficiency for events which pass all offline event selection criteria will be presented in Section 5.3. In the following, the results of the event selection without the trigger requirement are presented at first.

## 5.2 Signatures with 0 b-jets and with at least one b-jet in the final state

The large Z boson background contribution can be reduced by requiring that the jets which are present in the final state are tagged as b-jets. Therefore, assuming a fully performing b-tagging algorithm, the following set of selection criteria can be applied:

Figure 10: (left) Muon isolation variable  $E_T^{cone0.4}/p_T(\mu)$ , shown for different signal and background processes. Here, the  $E_T^{cone0.4}$  is the energy measured in the calorimeters in cone  $\Delta R = 0.4$  around a given muon. (right) Rejection of the non-isolated muons originating from the b-quarks in  $t\bar{t}$  events as a function of the selection efficiency for isolated muons, shown for the two isolation variables described in the text. The filled circle indicates the working point with the isolation cut at  $E_T^{cone0.4}/p_T(\mu) < 0.2$ .

- Events are required to pass the preselection criteria and to have a missing transverse energy  $E_T^{miss} < 40$  GeV. This cut is particularly effective in rejecting the  $t\bar{t}$  and  $WW$  background, which are characterized by a high missing energy due to the presence of neutrinos in the final state (see Figure 11(left)).

Figure 11: (left) Missing transverse energy, (middle) distribution of the b-tagging IP3DSV1 weight after requiring  $p_T > 20$  GeV and  $|\eta| < 2.5$  and (right) the multiplicity of reconstructed b-jets per event, after applying the  $p_T$ - and  $\eta$ -cuts and requiring the b-tagging IP3DSV1 weight greater than 4. Distributions for the  $bbA$  signal ( $m_A = 200$  GeV) and for the major background processes are shown. Arrows indicate the cuts applied in the analysis.

- Subsequently, the number of b-jets is counted in each event, requiring  $p_T > 20$  GeV,  $|\eta| < 2.5$  and the b-tagging IP3DSV1 weight greater than 4. The distribution of the b-tagging weights before

and the b-jet multiplicity after applying the weight-cut are shown in Figure 11. As shown in the middle plot, the b-tagging weight is effective in reducing the background from  $Z + \text{light jets}$ , at the expense of a significant loss of the signal. This cut is scarcely effective against the  $t\bar{t}$  background, which, however, can be reduced by the additional cuts discussed below. Therefore, the analysis is divided into a channel with 0 b-jets (in which the  $Z$  background is dominant) and the channel with at least one b-jet (in which the  $t\bar{t}$  background plays an important role and can be further suppressed).

- Further  $t\bar{t}$  rejection criteria have been studied for the channel with at least one b-jet.
  - Two muons originating from the decay of the same particle (Higgs boson) tend to be emitted back-to-back, especially if this particle has a low transverse momentum. As opposed to that, the muons originating from the two different particles (as in the  $t\bar{t}$  events) are not correlated and can be separated by any angle. Therefore, the cut is applied on the angle  $\Delta\phi_{\mu\mu}$  between the two muons by requiring  $|\sin\Delta\phi_{\mu\mu}| < 0.75$ . The  $|\sin\Delta\phi_{\mu\mu}|$  distributions for the signal and background processes are shown in Figure 12(a).
  - In addition, several discriminating variables related to the hadronic activity in the events have been studied: the  $p_T$  distribution of the b-jets, the number of jets per event, or a sum of the transverse momenta of all jets in the event ( $\sum p_T^{\text{jet}}$ ). The distributions of two of these variables are shown in Figure 12(b) and c). The latter is shown to provide the highest rejection against the  $t\bar{t}$  background, while at the same time remaining relatively robust under the influence of pile-up. A cut at  $\sum p_T^{\text{jet}} < 90$  GeV is required.

Figure 12: Discriminating variables against the  $t\bar{t}$  background: a)  $|\sin\Delta\phi|$  shown for the  $b\bar{b}A$  signal ( $m_A=200$  GeV) and for the major background processes, b) the maximum  $p_T$  of the b-jet, and c)  $\sum p_T^{\text{jets}}$ -distribution for the signal and background processes. Arrows indicate the cuts applied in the analysis.

- The final number of events which is used for the calculation of the signal significances is evaluated in a mass window  $\Delta m = m_A \pm 2\sigma_{\mu\mu}$  around the  $A$  boson mass, where  $\sigma_{\mu\mu}$  is the expected  $m_A$ -dependent width of the dimuon resonance (see Table 2).

The signal and background event rates after each of the cuts described above are shown in Tables 3 and 4.

A signal selection efficiency of 7-10% is reached for the channel with at least one b-jet in the final state. The dominant background processes are almost equally the  $Z + \text{jet}$  and the  $t\bar{t}$  events. The signal

Table 4:  $\sigma \times BR$  for the background processes obtained after each event selection cut. The upper limits are evaluated at 90% CL. Numbers in brackets represent the statistical error on the last digit.

events are mainly lost due to the limited b-jet reconstruction efficiency, as discussed previously. This is in agreement with a much larger signal selection efficiency of 40-50% in the case of the channel with 0 b-jets. Here, the  $Z$  background is observed to have a dominant contribution. The invariant dimuon mass distributions obtained for the two channels are shown in Figure 13.

In the initial phase of the detector running, the b-tagging algorithms still may not have the optimum performance. Therefore, the discovery potential has also been evaluated for the case where no b-tagging requirement is imposed on the reconstructed jets. Due to the large  $Z$  background, the signatures with no b-tagging requirement will provide a similar discovery potential as the analysis with 0 b-jets in the final state.

### 5.3 Trigger selection

Previously calculated event selection efficiencies have been obtained assuming that each analysed event can be triggered. In this Section, a realistic trigger description is included to evaluate the effect of the

Figure 13: Invariant dimuon mass distributions of the main backgrounds and the  $A$  boson signal at masses  $m_A=150, 200$  and  $300$  GeV and  $\tan\beta = 30$ , obtained for the integrated luminosity of  $30 \text{ fb}^{-1}$ . B-tagging has been applied for the event selection. The production rates of  $H$  and  $A$  bosons have been added together. a) for the 0 b-jet final state and b) for the final state with at least 1 b-jet.

limited trigger efficiency on the final event selection.

Since the signal processes are characterized by the two high- $p_T$  muons in the final state (see Figure 9), the most reliable trigger item is a single high- $p_T$  muon with  $p_T > 20$  GeV. The single-muon trigger efficiency is mostly limited by the geometrical acceptance of the trigger chambers in the muon spectrometer, as discussed in detail in [29]. The efficiency of the trigger selection for events passing all previously described event selection criteria is shown in Table 5 for the signal at 200 GeV and for the background samples. A very similar trigger selection efficiency can be observed for all signal and

Dataset	L1	High level trigger
$bbA$ , 200 GeV	97.2	95.0
$t\bar{t}$	97.1	95.1
$bbZ$	97.1	94.8

Table 5: Trigger selection efficiency (%) of events which pass all event selection criteria described in Section 5.2. The results are listed for the signal and the two background processes.

background samples. The relatively high final trigger selection efficiency of  $\sim 95\%$  corresponds to the decrease of the signal significance by 2-3% compared to the previously shown results. It has been shown that the observed efficiencies are effectively stable to a level of about  $\pm 0.5\%$  at any level of the event selection, since the selection criteria are not affecting the muon kinematics. Furthermore, the trigger selection does not induce any bias to the dimuon invariant mass distribution.

The studies described above have been performed under the assumption that the trigger threshold for

a single high- $p_T$  muon is 20 GeV. If this threshold should be higher, some of the signal events might be lost by the trigger selection. In order to evaluate the sensitivity of the signal selection on the varying trigger thresholds, a dedicated study has been performed. New trigger thresholds of 20, 26 and 30 GeV are emulated by the requirement that at least one reconstructed muon with a  $p_T$  above the given threshold exists in the event. This muon is also required to have a matching L1 region-of-interest in the muon spectrometer, in order to take into account the holes in the geometrical trigger acceptance. The trigger selection efficiencies for the new trigger thresholds are shown in Figure 14 for events remaining after each of the analysis cuts applied on the  $b\bar{b}A$  signal with mass  $m_A=200$  GeV. No visible degradation of the

Figure 14: Trigger selection efficiency of the  $b\bar{b}A$  signal events ( $m_A=200$  GeV) in dependence on the offline analysis selection. Different curves show the results obtained for different trigger thresholds.

final signal selection is observed for the trigger threshold variations of up to 30 GeV. Similar behavior is observed also for the signal at other mass points. This result can be explained by a rather high muon momenta in the signal samples, such that there is only a small fraction of signal events in which both muons have a  $p_T$  below 30 GeV. The dependence of the  $t\bar{t}$  and  $Zb\bar{b}$  background selection on the trigger threshold of up to 30 GeV is shown to be smaller than 2% after all analysis cuts.

## 6 Systematic uncertainties

Several sources of systematic uncertainties can affect the total yields of both the signal and the background events after applying the selection criteria specified in the previous Section. In this Section, the influence of the theoretical and the detector-related systematic uncertainties is evaluated.

### 6.1 Theoretical uncertainties

As mentioned previously, the Higgs boson production in association with the b-quarks has been simulated with PYTHIA and SHERPA Monte Carlo generators and the obtained differential distributions are scaled to the Feynhiggs NNLO cross-sections. It is important to remark that no cuts have been applied on the transverse momenta of the generated b-quarks, since also the event topologies with less than two

observed b-jets are studied in the presented analyses. (An outgoing b-quark can be considered as observable if its momentum is above  $\sim 15$  GeV). Therefore, the corresponding NNLO cross-sections also have to be calculated in an inclusive way, with no constraints on the kinematics of the b-quarks.

As discussed in Section 2, the total theoretical uncertainty on the inclusive cross-section amounts to  $\sim 17\%$ , depending on the Higgs boson mass. In addition, since the experimental search distinguishes between the final states with 0 and those with 1 or more b-jets (with  $p_T > 20$  GeV), it is important to show that the proportion between the mentioned different event topologies which is obtained from the Monte Carlo generators also agrees with theory predictions. For this purpose, the fraction of generated events is calculated which have *exactly* one b-quark with  $p_T > 15$  GeV and  $|\eta| < 2.5$  in the final state (before hadronization). This number is then compared to the ratio of the MCFM cross-section calculated for the  $bg \rightarrow bH$  process with the same cuts on the b-quarks, divided by the inclusive cross-section. The result of the comparison is shown in Figure 15, being comparable to the 20% uncertainty. The SHERPA

Figure 15: Fraction of events  $\sigma_{1b}$  with exactly one b-quark with  $p_T > 15$  GeV and  $|\eta| < 2.5$ , relative to the total inclusive cross-section  $\sigma_{total}$ , shown in dependence on the Higgs boson mass  $M_H$ . The lines show the theory prediction as the ratio between the MCFM  $bg \rightarrow Hb$  and  $b\bar{b} \rightarrow H$  cross-sections. Solid line: MRST2004 pdf set, dashed line: MRST2002 pdf set. Circles: result from SHERPA 1.0.9. Triangles: PYTHIA 6.4  $gg \rightarrow b\bar{b}H$  process.

prediction is about 20% higher than PYTHIA and agrees better with the theory calculation with the MRST2004 pdf set. The MRST2002 pdf set gives a better compatibility with PYTHIA. Taking into account the theory uncertainties mentioned above, one can conclude that the samples produced with both generators can reproduce the NLO predictions from a single b-quark rate.

The observed differences between SHERPA and PYTHIA are visible also in the differential b-quark distributions. The differential  $p_T$  and  $\eta$ -distributions of the leading b-quark, as obtained by the PYTHIA and SHERPA generators are compared in Figure 16 for the signal at the mass of 200 GeV. The comparison is performed on a parton level, before hadronization. A slightly harder transverse momentum spectrum and a more central pseudorapidity of the b-quarks is observed in the SHERPA events.

## 6.2 Detector-related systematic uncertainties

Systematic uncertainties related to the muon and the jet reconstruction, as well as the uncertainties on the b-tagging performance have been evaluated with rather conservative estimates on the level of under-

Figure 16: Differential  $p_T$  and  $\eta$  distribution of the leading b-quark, obtained by SHERPA (gray histogram) and by the PYTHIA  $gg \rightarrow b\bar{b}H$  calculation (solid line). All histograms have been normalized to unity.

standing of the detector performance. This level is assumed to correspond approximately to an integrated luminosity of  $1 \text{ fb}^{-1}$ . For each of the above effects, the corresponding change of the reconstructed missing transverse energy is taken into account. Further more, systematic effects due to the differences between the fast and the full simulation are taken into account by means of the comparison between the full and fast simulation.

**Muon reconstruction** uncertainties are treated separately for the reconstruction efficiency, muon momentum resolution and the muon momentum scale. The efficiency of the muon identification is assumed to be known with an accuracy of  $\pm 1\%$ , based on the results of the tag-and-probe method for the muon efficiency measurement from the real data [30]. Systematic errors of the muon momentum scale are taken to be  $\pm 1\%$ , arising for instance from the non-perfect knowledge of the magnetic field. The incomplete understanding of the material distributions inside the detector, as well as possible residual detector misalignment can lead to an additional smearing of the muon momentum resolution. Based on early detector calibration, the additional smearing is expected to be  $\sigma(\frac{1}{p_T}) = \frac{0.011}{p_T} \oplus 0.00017$  (in  $1/(\text{GeV})$ ). The first term enhances the effect of the Coulomb scattering, while the second enhances the contribution from the misalignment.

**Jet reconstruction** uncertainties are estimated by the jet performance group [25]. In the pseudo-rapidity region below  $|\eta|=3.2$ , the jet energy scale uncertainty of  $\pm 3\%$  and a resolution uncertainty of  $\sigma(E) = 0.45 \cdot \sqrt{E}$  are assumed. For  $|\eta| > 3.2$ , the corresponding values are  $\pm 10\%$  and  $\sigma(E) = 0.63 \cdot \sqrt{E}$  respectively.

**b-tagging** efficiency and the fake rate are crucial for the described analysis. Conservative relative uncertainty of  $\pm 5\%$  on the b-tagging efficiency and  $\pm 10\%$  uncertainty on the rejection of the light jets have been assumed.

The results obtained after implementing each of the above systematic uncertainties separately into the analysis are shown in Table 6 for the signal at  $m_A=150 \text{ GeV}$  and for the backgrounds within the corresponding mass window. Signals at different mass points are affected by a similar amount. The background uncertainties are also rather independent of the dimuon mass region, but from one exception. The muon momentum scale mostly affects the background in the lower mass region, close to the Z resonance, while the deviations become smaller for the higher signal masses, i.e. one observes  $\pm 11\%$ ,  $\pm 5\%$  and  $\pm 3\%$  for the Higgs masses of 110, 130 and 200 GeV respectively.

Systematic uncertainty [%]	Signal	$t\bar{t}$	Z+ b jet	Z+light jet
Muon efficiency	$\pm 2$	$\pm 1$	$\pm 2$	$\pm 2$
Muon $p_T$ scale	$\pm 2$	$\pm 3$	$\pm 3$	$\pm 5$
Muon resolution	-2	-4	3	3
Jet energy scale	$\pm 1$	$\pm 5$	$\pm 2$	$\pm 2$
Jet energy resolution	-1	-3	-1	-1
b-tagging efficiency	$\pm 4$	$\pm 3$	$\pm 4$	$\pm 2$
b-tagging fake rate	$\pm 1$	$\pm 0$	$\pm 0$	$\pm 6$
Full-Atfast corrections	0	+8	-10	+5
Total	$\pm 5$	$\pm 12$	$\pm 12$	$\pm 11$

Table 6: Relative deviation of the selection efficiency in % for the signal at  $m_A=150$  GeV and for the background events after imposing each of the systematic uncertainties separately, as described in the text. The total deviation is given as quadratic sum of the separate contributions, including the one-sided corrections.

## 7 Background estimation based on the measured data

As previously discussed, theoretical and experimental uncertainties can lead to systematic errors in determination of the background rates. Additional information on the shape and the size of the background contributions can be collected from the real data. As shown before, two major backgrounds surviving all event selection criteria are the  $Z + jet$  and the  $t\bar{t}$  processes. Two strategies to estimate their contributions from the measured data shall now be described.

The first method makes use of the fact that the branching ratio for  $A/H$  boson decays into two electrons is negligible compared to the dimuon decay channel. Therefore, since one doesn't expect any signal in the dielectron final state, one can use this signature to determine the total background contribution. Additionally, the signatures with one electron and one muon in the final state provide the contribution of the  $t\bar{t}$  background alone, since the  $Z + jet$  processes do not contribute to this final state. Thus, one can separately measure the two background contributions. The background estimation based on the  $e^+e^-$ -channel has been discussed in detail in [31]. Good agreement has been demonstrated between the dilepton invariant mass distributions for the  $Z \rightarrow \mu\mu$  and the  $Z \rightarrow ee$  processes. In this paper, the emphasis is given to a similar procedure for the determination of the  $t\bar{t}$  background.

The goal of the second method is to define a set of event selection criteria which allow for the higher selection efficiency for the particular background process, while simultaneously rejecting all other signal and background contributions. Such background-enriched control sample can be used to better understand the shape of the invariant dimuon mass distribution.

### 7.1 Background estimation based on the $e^+e^-$ and $\mu^\pm e^\mp$ signatures

The estimation of the  $t\bar{t}$  background is important for the analysis channel with at least one b-jet in the final state. A study is performed using fast simulation of the  $t\bar{t}$  background, in order to obtain a reliable statistical accuracy. The detector performance given by the fast simulation has been adjusted such to reproduce the performance obtained with the full simulation, as mentioned previously. Based on the studies in [31], the shape of the dilepton invariant mass distribution obtained for the  $\mu^+\mu^-$ ,  $e^+e^-$  and  $\mu^\pm e^\mp$  final state in the  $t\bar{t}$  process are expected to be very similar. The total number of background events selected in each of the three final states will be different due to different reconstruction efficiencies for muons and electrons. However, since these efficiencies can be experimentally measured with an accuracy

of better than 1%, this effect can be corrected for rather precisely. Additional differences may occur due to an additional calorimeter activity in presence of electrons. This can be taken into account by rejecting all reconstructed jets which overlap with reconstructed electrons.

Figure 17: (a) The  $\mu^+\mu^-$  invariant mass distribution (stars) of the  $t\bar{t}$  background, and its estimates obtained from the  $e^+e^-$  (triangles) and  $\mu^\pm e^\mp$  (full circles) final states. (b) Corresponding ratios of estimated and actual  $\mu^+\mu^-$  invariant mass distributions.

Figure 17(a) shows the invariant mass distributions obtained for the  $\mu^+\mu^-$ ,  $e^+e^-$  and  $\mu^\pm e^\mp$  final states in  $t\bar{t}$  events. The dielectron distribution has been scaled down by a factor  $0.84^2$ , to account for the difference between the electron and muon reconstruction efficiency. Similarly, the  $\mu^\pm e^\mp$ -distribution has been scaled down by  $0.5 \times 0.84$ . Figure 17(b) shows the corresponding ratios of estimated and actual  $\mu^+\mu^-$  invariant mass distribution. The subtraction of the  $\mu^\pm e^\mp$  sample from the total background is illustrated in Figure 18 for  $\mathcal{L} = 30 \text{ fb}^{-1}$ , for the analysis requiring identification of at least one b-jet.

Figure 18: Invariant dimuon mass as in Figure 13(b), after the subtraction of the  $t\bar{t}$  background estimated in the  $\mu^\pm e^\mp$  final state. The distributions correspond to an integrated luminosity of  $\mathcal{L} = 30 \text{ fb}^{-1}$ .

## 7.2 Background estimation from the control samples

In analyses with 0 b-jets in the final state the dominant background is the  $Z + jet$  process. Since the topology of this process is very similar to the signal topology, it is rather difficult to define a set of selection criteria which would allow for the extraction of the  $Z$  background and simultaneous rejection of the signal.

Contrary to that, the  $t\bar{t}$  process is characterized by a relatively high missing transverse energy and a high jet activity. Since this background is important for the analysis with at least one jet in the final state, the event selection criteria of this analysis are modified by selecting only events with a missing transverse energy above 60 GeV and by removing the cut on the  $\sum p_T^{jet}$ -variable. All other selection criteria remain the same. The purity of the  $t\bar{t}$  control sample obtained after the described event selection is shown in Figure 19(a). All remaining processes are suppressed to a negligible amount. Figures 19(b) and (c)

Figure 19: (a)  $t\bar{t}$  control sample (stacked histogram) obtained as described in text. Full circles indicate the actually measured  $\mu^+\mu^-$  invariant mass distribution for the  $t\bar{t}$  background, after applying the standard analysis selection cuts. (b) The measured (full circles) and the control  $t\bar{t}$  distributions (open squares), normalized to the same number of events. (c) The ratio of normalized distributions from (b).

show the  $t\bar{t}$  background obtained with the selection criteria described in Section 5.2 for at least one b-jet in the final state ( $t\bar{t}$  measured) compared to the distribution obtained from the  $t\bar{t}$  control sample. Both distributions are normalized to the same number of events. The shape of the  $t\bar{t}$  background can be estimated by the described procedure with an accuracy of 10-20%.

## 7.3 Fit function for the parametrization of the background

The background can be parametrized by the function  $f_B$  consisting of a Breit-Wigner and an exponential contribution,

$$f_B(x) = \frac{a_1}{x} \cdot \left[ \frac{1}{(x^2 - M_Z^2) + M_Z^2 \Gamma_Z^2} + a_2 \cdot \exp(-a_3 \cdot x) \right], \quad (1)$$

where  $x$  is the running dimuon mass, while  $a_1$ ,  $a_2$  and  $a_3$  are the free parametrization parameters. The mean  $M_Z$  and the width  $\Gamma_Z$  of the Breit-Wigner distribution describe the  $Z$  resonance. The parameters  $a_{2,3}$  describing the exponential part can be determined by the fit on the background estimated from data, as described in the previous subsection. The overall normalization factor  $a_1$  is determined by the fit on the side bands of the dimuon mass distribution. Figure 20 shows the result of the fit on the background distribution obtained after all analysis cuts for the case with at least one b-jet in the final state. The

two dashed lines correspond to the errors on the  $a_{2,3}$  parameters, as obtained from the  $e^+e^-$  data at an integrated luminosity of  $10 \text{ fb}^{-1}$ .

Figure 20: Fit (full line) of the background function  $f_{bkg}$  (see Eq. 1) on the background distribution (full circles) resulting from the analysis with at least one b-jet in the final state. The dashed lines represent the shape variations given by the errors on the  $a_2$  and  $a_3$  parameters, from the fit on the  $e^+e^-$  data.

The accuracy of the background parametrization by the described method has been tested by means of large number of toy Monte Carlo experiments at different integrated luminosities  $\mathcal{L}$ . Typical results of the background extraction in the mass window from 188-212 GeV are shown in Figure 21 for an integrated luminosity of  $15 \text{ fb}^{-1}$  (left) and  $3 \text{ fb}^{-1}$  (right). The empirically evaluated expected uncertainty of

Figure 21: Normalized difference of the expected number of background events ( $BKG_{expected}$ ) in the mass window from 188-212 GeV, and the number ( $BKG_{fitted}$ ) obtained from the fit method described in the text (left) for an integrated luminosity of  $=15 \text{ fb}^{-1}$  and (b)  $=3 \text{ fb}^{-1}$ .

the background determination from the fit to data is  $\sim 8\%/\sqrt{\mathcal{L}[\text{fb}^{-1}]}$ . The variation of the exponential shape, due to the errors on the fit parameters  $a_2$  and  $a_3$ , plays a non-marginal role only for dimuon masses above 300 GeV, decreasing the relative uncertainty to  $\sim 10\%/\sqrt{\mathcal{L}[\text{fb}^{-1}]}$ . Conservatively the latter expression will be used in the analyses discussed below. Similar fit procedure has been performed also for the analysis with 0 b-jets in the final state. Due to the larger amount of background, a smaller background uncertainty of  $\sim 2\%/\sqrt{\mathcal{L}[\text{fb}^{-1}]}$  can be obtained in this case, including the systematic uncertainty on the shape parameters  $a_2$  and  $a_3$ .

## 8 Evaluation of the signal significance

Two approaches have been applied to evaluate the statistical significance of the observed signal. The "fixed mass" approach provides the significance based on the number of signal and background events which are expected in a given range of the dimuon invariant mass. However, the location of the signal mass peak can be determined only if the signal rates are sufficiently high, or if the signal is already discovered in the  $A/H/h \rightarrow \tau\tau$  decay channel. In a more general "floating mass" approach, no constraints are applied on the dimuon invariant mass.

The number of signal and background events can be determined from the fit of the function  $f_{SB}$  to the data,

$$f_{SB}(x) = p_0 \cdot f_B + p_1 \cdot f_S = p_0 \cdot f_B + p_1 \cdot \frac{1}{\sigma_A \sqrt{2\pi}} \cdot \exp\left(-\frac{(x - p_2)^2}{2\sigma_A^2}\right), \quad (2)$$

where  $f_S$  is the Gaussian distribution describing the signal.  $p_2$  is the mass of the signal (which can be fixed or left as a free, "floating" parameter) and  $\sigma_A$  is the width of the Higgs resonance.  $p_0$  is the background scale and  $p_1$  the total number of signal events. The number of signal ( $N_S$ ) and background ( $N_B$ ) events used for the calculation of the signal significance is extracted from the fit, by integration in a window of  $\pm 2\sigma_A$ . The signal significance is evaluated by means of the profile likelihood method [32], using the obtained number of signal and background events as an input and taking into account the background uncertainty ( $10\%/\sqrt{\mathcal{L}[\text{fb}^{-1}]}$ ) as discussed in Section 7.3 above.

The results obtained for the signal significance have been cross-checked by the large number of Monte Carlo pseudoexperiments for several different integrated luminosities. The pseudoexperiments are based on the Monte Carlo distributions and are divided into the "background-only" experiments ( $BO$ ), containing only background contributions, and the "signal-plus-background" experiments ( $SpB$ ) having both the signal and the background contribution. In addition to the profile likelihood calculation in each of these experiments, the signal significance can be estimated also from the log-likelihood ratios. The log-likelihood ratio  $\ln Q_{BO}$  and  $\ln Q_{SpB}$ , both defined as  $(N_S + N_B) \ln \frac{N_S + N_B}{N_B} - N_S$ , are evaluated for each  $BO$ - and  $SpB$ -pseudoexperiment. The signal significance is obtained from the probability of a Type-II error, defined by the fraction of  $BO$  pseudoexperiments which have a log-likelihood ratio  $\ln Q_{BO}$  larger than the median of the  $\ln Q_{SpB}$ -distribution. The probability of a Type-I error, i.e. the number of  $SpB$ -pseudoexperiments which fall below the median of the  $\ln Q_{BO}$ -distribution, was used to determine the 95% CL limits.

Figure 22(left) shows the comparison of the signal significances obtained in the fixed-mass approach. The solid line shows the results of the profile likelihood method, while the dots are the results given by the Type-II error probabilities obtained in the pseudoexperiments. At very low luminosities, the profile-likelihood estimation based on average values seems to slightly overestimate the significance. However, at luminosities close to those needed for the  $5\sigma$ -significance, the two calculations give equivalent results. Figure 22(right) shows the degradation of the signal significance observed once the floating-mass approach is applied in which the Higgs mass is left as a free parameter of the fit (usually referred to as a look-elsewhere effect). In general, the ratio of the Type-II error probabilities obtained from the fixed-mass and the floating-mass approaches is constant and approximately equal to the explored mass range divided by the signal mass width. Correspondingly, the ratio of signal significances is lower at low luminosities, while the difference between the two approaches is reduced to 5% or less at the luminosities close to those needed for a  $5\sigma$ -discovery.

### 8.1 Influence of the systematic uncertainties on the signal significance

In order to include the systematic uncertainties in the calculation of the signal significance, one should perform additional large number of pseudoexperiments for each of the systematic effects. However, the

Figure 22: (left) Signal significance obtained in the fixed-mass approach for the signal at  $m_A=200$  GeV and  $\tan\beta=30$ , as a function of integrated luminosity. The full line corresponds to the results obtained by the profile likelihood method using the average number of expected signal and background events, while the dots show the results obtained from the Type-II error probability from a large amount of pseudoexperiments. Both estimations include the background uncertainty from the  $f_{SB}$ -fit. (right) Ratio of signal significances obtained with the floating- and the fixed-mass approach, as a function of the integrated luminosity.

difference between the signal significance in the floating-mass and in the fixed-mass approach is small compared to the effect of the additional systematic uncertainties. Thus, in the following the fixed-mass approach is used and the full treatment of the look-elsewhere effect is left for the future studies.

By means of the background estimation from the data, the amount of the background events underneath the signal can be determined with an accuracy of  $\sim 10\%/\sqrt{\mathcal{L}[\text{fb}^{-1}]}$ , as described in Section 7. This can be achieved independently of the systematic uncertainties discussed in Section 6.

Therefore, the influence of the systematic uncertainties on the signal significance is given by the corresponding changes in the expected number of signal and background events. The numbers entering the significance calculation are therefore changed accordingly, taking into account that the systematic uncertainty is different for different background processes. The signal significance is calculated separately for each systematic effect and the deviations from the original signal significance are added in quadrature. Figure 23 shows the signal significance obtained for two different masses  $m_A$ , as a function of  $\tan\beta$ . The contributions of the uncertainty in the background determination from the fit to data and of the experimental systematic uncertainties to the expected significance are shown separately.

## 9 Discovery potential and the exclusion limits

The previously described methods for the evaluation of the signal significance and of the exclusion limits have been applied to all mass points studied. Table 7 summarizes the signal significances obtained for different signal mass points at  $\tan\beta=30$  and  $\mathcal{L}=10 \text{ fb}^{-1}$ , for the analysis with 0 b-jets and with at least one b-jet in the final state. The luminosities needed to reach the  $5\sigma$  signal significance and the 95% CL exclusion limit are given in Table 8, for different signal masses at  $\tan\beta=30$ . The results shown so far do not include the possible degradation due to the influence of pile-up and cavern background. The degraded resolution of the missing transverse energy is expected to cause a  $\sim 15\%$  change in the final selection of the signal and the Z background. The  $t\bar{t}$  background is characterized by a large  $E_T^{\text{miss}}$  and is therefore somewhat less sensitive to the  $E_T^{\text{miss}}$  performance under pile-up ( $\sim 10\%$  change in the selection

Figure 23: Signal significance as a function of  $\tan\beta$  for the integrated luminosity of  $10 \text{ fb}^{-1}$  and  $m_A=150 \text{ GeV}$  (left) and  $m_A=300 \text{ GeV}$  (right). The dotted curves are obtained assuming a negligible error of the background determination. The dashed curves show the result once the background uncertainty is taken into account, as obtained from the fit to the data. The solid curves additionally include the systematic uncertainties. The width of the solid curves indicates the errors in the background shape parametrization.

400	0.5	0.8	0.5	0.8	0.4 - 0.5	0.7 - 0.9	0.4 - 0.5	0.7 - 0.9

Table 7: Signal significance for signal at different mass points, with  $\tan\beta=30$  and  $\mathcal{L}=10 \text{ fb}^{-1}$ . The numbers are shown for different levels of the background uncertainty. For degenerate  $A$ ,  $H$  and  $h$  boson states with the same mass, the production rates have been summed.

efficiency). Table 9 summarizes the results obtained with pile-up effects taken into account. Only small changes are observed compared to the previous results.

The results shown in Tables 7 and 8 can be extrapolated to other  $\tan\beta$  values. The only difference which occurs for the a given signal mass point when changing the  $\tan\beta$  value is the change of the production rates and of the natural width of the  $A/H/h$  bosons. In the  $(m_A - \tan\beta)$  plane which is of interest for this analysis, the resolution of the mass measurement is mostly dominated by the experimental resolution. Nevertheless, the variation of the natural Higgs width is taken into account in the calculation by increasing the background contribution correspondingly to the expected change of the mass window.

Using the previously described production cross-sections and branching ratios, the  $5\sigma$ -discovery curves are obtained as shown in Figure 24(left) separately for the analysis with 0 and with at least one b-jet in the final state. The luminosity needed for the exclusion of the signal hypothesis at a 95% confidence level is shown in Figure 24(right).

The signatures with the b-jets in the final state allow for the highest discovery potential. The 0 b-jet final state plays nevertheless an important role. Since the search in this final state is uncorrelated to the

Table 9: Luminosity needed for the  $5\sigma$  signal significance (no systematics) and the 95% CL exclusion of the signal hypothesis (with systematics), obtained for the combined analyses, with the pile-up effects taken into account. The results are shown for  $\tan\beta=30$ .

Figure 24:  $\tan\beta$  values needed for the  $5\sigma$ -discovery (left) and for the 95% CL exclusion of the signal hypothesis (right), shown in dependence on the  $A$  boson mass.

previous one, one can quadratically add the signal significances obtained from the two analyses. The  $5\sigma$ -discovery curves obtained from the combination of both analyses, as well as the combined 95% CL exclusion limits are shown in Figure 25. At an integrated luminosity of  $10 \text{ fb}^{-1}$ , the discovery can be reached for  $m_A$  masses up to 350 GeV with  $\tan\beta$  values between 25 and 60. For  $m_A$  masses below 110 GeV the sensitivity drops rapidly as shown in Ref [5], due to the increasing Drell-Yan background

Figure 25: Combined analyses results: (left)  $\tan\beta$  values needed for the  $5\sigma$ -discovery at  $\mathcal{L}=10\text{ fb}^{-1}$  and  $\mathcal{L}=30\text{ fb}^{-1}$ , shown in dependence on the  $A$  boson mass and (right) combined 95% CL exclusion limits.

close to the pole mass of the  $Z$  boson. The  $\tan\beta$  values above  $\sim 16$  can be excluded already with  $10\text{ fb}^{-1}$  of integrated luminosity in case of the Higgs boson masses up to 200 GeV.

## 10 Conclusions

In this note, the potential for the discovery of the neutral MSSM Higgs boson is evaluated in the dimuon decay channel. As opposed to the Standard Model predictions, the decay of neutral MSSM Higgs bosons  $A$ ,  $H$  and  $h$  into two muons is strongly enhanced in the MSSM. In addition, the  $\mu^+\mu^-$  final state provides a very clean signature in the detector.

The event selection criteria are optimized in the signal mass range from 100 to 500 GeV, separately for the signatures with 0 b-jets and with at least one b-jet in the final state. The obtained combined result shows that an integrated luminosity of  $10\text{ fb}^{-1}$  allows for the discovery for  $m_A$  masses up to 350 GeV with  $\tan\beta$  values between 30 and 60. Three times higher luminosity allows for an increased sensitivity down to  $\tan\beta=20$ . The theoretical and detector-related systematic uncertainties are shown to degrade the signal significance by up to 20%. This takes into account that the background contribution can be estimated from the data with an accuracy of  $\sim 2\text{--}10\%/\mathcal{L}[\text{fb}^{-1}]$ .

# Sensitivity to an Invisibly Decaying Higgs Boson

## Abstract

Many extensions of the Standard Model include Higgs bosons decaying predominantly or partially to non-interacting particles such as the SUSY Lightest Supersymmetric Particle (LSP). To set limits on the production cross-section times the branching fraction to invisible decay products of such Higgs bosons with the ATLAS detector requires an examination of specific production modes such as the associated production ( $ZH$ ) or the vector boson fusion (VBF) process. The predominant Standard Model backgrounds for these processes are  $ZZ \rightarrow \ell\ell\nu\nu$  for the  $ZH$  channel and jets from QCD processes and  $W^\pm$  or  $Z$  bosons produced in association with jets for the VBF channel. The sensitivity to an invisibly decaying Higgs boson is investigated in this paper using fully simulated ATLAS data for both signal and background. The ATLAS potential for triggering these events is also discussed.

## 1 Introduction

Some extensions of the Standard Model predict that Higgs bosons could decay into stable neutral weakly interacting particles, leading to invisible Higgs boson decays. The Higgs boson decay products could be for example neutralinos, gravitinos, gravitons or Majorons [1-3]. In the case of the Minimal Supersymmetric Standard Model (MSSM), if R-parity is conserved, Higgs bosons decaying into a pair of neutralinos may in some cases even dominate [1]. Being the lightest supersymmetric particles, neutralinos would be stable and would leave the detector without decaying, remaining invisible. If R-parity is violated, then Higgs bosons could decay into Majorons, which would interact too weakly to allow detection [2]. Some theories with extra dimensions also predict invisible Higgs boson decays, and have the added advantage of generating neutrino masses [3]. This search is sensitive to any boson coupling to  $Z$  or  $W$  and decaying invisibly. The combined LEP Higgs boson mass limit in this channel is 114.4 GeV [4].

At the Large Hadron Collider, Higgs boson production could occur through several mechanisms. To select and identify events with an invisibly decaying Higgs boson one must be able to trigger on a signature that is visible in the event. This is possible for channels such as Vector Boson Fusion (VBF)  $qqH$  [5],  $t\bar{t}H$  [6] and the associated production processes,  $ZH$  and  $W^\pm H$  [7, 8]. Although gluon fusion has a much higher Higgs boson production cross-section than these modes [9], it is not possible to trigger on these events when the Higgs boson decays invisibly.

In this paper, the ATLAS sensitivity to an invisibly decaying Higgs boson is determined in a way that does not depend on a specific extension of the Standard Model. The analysis uses the variable  $\xi^2$  which is defined as,

$$\xi^2 = BR(H \rightarrow inv.) \frac{\sigma_{BSM}}{\sigma_{SM}} \quad (1)$$

where  $\sigma_{BSM}$  represents the “Beyond the Standard Model” cross-section and  $\sigma_{SM}$  represents the Standard Model cross-section. In the case for which the Higgs boson decays entirely to the invisible mode,  $\xi^2$  is the ratio between the non-Standard Model cross-section and the Standard Model cross-section. Only two of the three possible production modes are considered in this paper, VBF and associated production. In addition, for associated production, only the  $ZH$  mode is considered as the background to the  $W^\pm H$  signal is overwhelming [10].

In this paper, the Monte Carlo samples, for both the VBF and the  $ZH$  channels, the trigger, the event selection, the systematic uncertainties and the results are discussed. We conclude by summarizing the limits on  $\xi^2$  for an invisibly decaying Higgs boson.

This analysis compares signals and backgrounds that have been generated using Standard Model processes. The Higgs boson signal events are simulated to be invisible by changing the properties of the Higgs boson decay chain. In reality an invisibly decaying Higgs boson would be expected to result from a process not contained within the Standard Model, and in this case backgrounds associated with this new physics would be important. However, consideration of “Beyond the Standard Model” backgrounds is beyond the scope of this paper as they would have to be considered in the context of each specific model. This analysis assumes Standard Model backgrounds and serves as a limiting case for the indication of a particle that behaves like a Higgs boson that is not consistent with the Standard Model.

## 2 The Vector Boson Fusion $qqH$ production channel

The vector boson fusion (VBF) channel has the second largest production mode after gluon fusion and has the largest production cross-section for observable invisible Higgs boson decays. The VBF invisible Higgs boson production mode, Figure 1, is characterized by two outgoing jets resulting from the interacting quarks, and large missing transverse energy from the Higgs boson. The topology of the jets is particularly useful in selecting the events as the jets are preferentially separated in pseudo-rapidity ( $\eta$ ) and are correlated in the azimuthal angle  $\phi$ . In addition, the lack of colour flow between the two jets leads to minimal jet activity between the two tagging jets which is potentially useful for selecting events. At high luminosity however, central jet activity resulting from overlapping events may become problematic for cuts based on this event characteristic.

Figure 1: Feynman diagram of the VBF process. The  $V$  represents either a  $Z$  or  $W$  boson.

The study of the VBF channel for this paper includes a mass scan with an estimate of the sensitivity to Higgs boson masses between 110 to 250 GeV. This is based on fully reconstructed signal and background events. In addition to the sensitivity, the trigger acceptance for this channel has been investigated.

### 2.1 Monte Carlo generation for the VBF analysis

Signal and background samples were generated using the standard version of ATLAS software used for this set of papers. The samples were used to determine the sensitivity of ATLAS to an invisible Higgs boson, taking into account the trigger and analysis efficiencies. A number of backgrounds with signatures similar to the signal have been studied and are listed here. In all cases,  $\ell$  represents  $e$  or  $\mu$ .

1. Dijet production from QCD processes form a major background due to the very large cross-section for these processes. Fake missing energy measurements can arise from poorly instrumented regions or inefficiencies in the detector.
2.  $W$ +jet processes with  $W \rightarrow \ell\nu$  mimic the signal when the lepton is outside the detector acceptance. The neutrino provides the missing energy signature.

Higgs boson Mass [GeV ]	Cross-section [pb]	# Events	Generator
110	4.63	10k	JIMMY
130	3.96	30k	JIMMY
130	3.93	10k	PYTHIA6.4
200	2.41	10k	JIMMY
250	1.79	10k	JIMMY

Table 1: Invisible Higgs boson samples generated for this analysis. Leading-order cross-sections for the Higgs boson produced via Vector Boson Fusion were evaluated by the ATLAS Higgs Working group [15].

3. Z+jet processes with  $Z \rightarrow \nu\nu$  constitute an irreducible background.
4. Z+jet with  $Z \rightarrow \ell\ell$  forms a background to the signal when the leptons are not within the acceptance of the detector.

Event generation for the VBF channel has proved challenging given that the predicted  $\eta$  distributions of tagging jets differ greatly according to the event simulation model used. The HERWIG-JIMMY package [11], [12], [13] represents an average response of the available models and has been used to generate data for the Higgs boson mass scan. Signal events have been generated with both HERWIG and PYTHIA [14] at a Higgs boson mass of 130 GeV to estimate the contribution of this effect to the systematic uncertainty. To generate an invisible Higgs boson sample, the Higgs boson is forced to decay into two Z bosons which are subsequently forced to decay into neutrinos. The set of data samples produced for this analysis is summarized in Table 1. The VBF signal Monte-Carlo was produced to leading order. The difference between LO and NLO cross-section is negligible,  $\sim 1\%$ [9], therefore the LO cross-sections were been used for the signal in this note. Table 1 includes the Standard Model VBF Higgs boson production cross-section that were used [9].

For an ideal detector, event selection cuts efficiently remove the QCD dijet background. However, this background is considered because of the large cross-section for the process and the presence of poorly instrumented regions and dead regions generating false missing transverse energy ( $E_T^{miss}$ ) signals. In order to provide enough statistics throughout the full transverse momentum ( $p_T$ ) spectrum, the QCD background was divided into several  $p_T$  ranges to produce several sub-samples, of approximately equal number of events, as shown in Table 2 [16]. The surviving background comes from the high  $p_T$  bins allowing reasonable statistics in the final sample. Thus the binning is used to generate the QCD background within a reasonable amount of computer time and allow for the very high rejection factor for this background in this analysis.

In previous ATLAS studies of the invisible Higgs boson produced via the VBF process, the PYTHIA package has been used to generate both the W+jet and Z+jet backgrounds. However, the PYTHIA implementation for these backgrounds only includes the matrix element term for the  $q\bar{q} \rightarrow gV$  and  $qg \rightarrow qV$  processes. The PYTHIA implementation tends to underestimate the Z+2jets process because it does not include a complete matrix element calculation. In contrast, ALPGEN [17] provides an exact matrix calculation at tree level for up to 3 partons. For this reason, ALPGEN was used to produce both the W+jet and Z+jet backgrounds. Within ALPGEN, there are two different Z+jet implementations, one which only includes QCD matrix element terms and the second which includes the QCD and EW matrix element terms. In the second case, only on-shell bosons are created without  $Z/\gamma^*$  interference, in contrast, the first case does include these effects. By comparing events generated with the two different implementations it was found that the QCD-only process underestimates the background by  $\sim 25\%$ . The effect of a non-zero Z boson width was checked by varying the Z boson mass. This showed that the result was insensitive to

Jet Sample	$\sigma(pb)$	$p_T$ range [GeV ]
J0	$1.76 \times 10^{10}$	8-17
J1	$1.38 \times 10^9$	17-35
J2	$9.33 \times 10^7$	35-70
J3	$5.88 \times 10^6$	70-140
J4	$3.08 \times 10^5$	140-280
J5	$1.25 \times 10^4$	280-560
J6	$3.60 \times 10^2$	560-1120
J7	$5.71 \times 10^0$	1120-2240

Table 2: Cross-section and  $p_T$  range for the QCD dijet background samples generated with PYTHIA. The cross-sections given in the second column are for the specific  $p_T$  range with no other cuts.

the use of on-shell bosons. Therefore, all ALPGEN samples used in this study were generated using the option that included both QCD+EW terms.

For the Z+jet background, three samples were produced for each of the two decay modes,  $Z \rightarrow \nu\nu$  and  $Z \rightarrow \ell\ell$ . Two exclusive samples were produced for the one and two parton final states and one inclusive sample was produced for three or more partons. Default ALPGEN settings were used to generate events except for a cut to remove very low  $E_T^{miss}$  events by setting  $E_T^{miss} > 10$  GeV and a change in acceptance to ensure complete  $\eta$  coverage by opening the phase space setting for both jets and leptons ( $|\eta_j| < 6$  and  $|\eta_\ell| < 6$ ).

In this study, only the leptonic decay of the W boson from the W+jet background was considered. The  $E_T^{miss}$  arises from a combination of the  $E_T^{miss}$  associated with the neutrino and the lepton energy in the case where the lepton escapes detection. The W+jet background was generated in the same manner as for the Z+jet background.

## 2.2 Trigger

The major challenge for triggering candidate events for the VBF invisible Higgs boson analysis is to retain signal events whilst reducing the very large QCD background to an acceptable level. These problems are particularly acute with the first level trigger (L1) which can easily be overwhelmed by the QCD background. A trigger for these signal events is possible using a relatively high  $E_T^{miss}$  cut while selecting one or two jets of moderate transverse energy. For triggers of this type, QCD backgrounds dominate. In order to produce an acceptable rate for the High Level Trigger (HLT), the trigger menu items used to select invisible Higgs boson events should add no more than a few Hz of trigger rate, even at the highest luminosities.

The trigger study of this note is based on the standard full ATLAS simulation of the L1 trigger. The HLT has not been considered, as at the time of the study HLT algorithms for  $E_T^{miss}$  had not been fully implemented and there had been no simulation of forward jets. Jets are classified into central jets  $|\eta| < 3.2$  and forward jets  $3.2 < |\eta| < 5$ .

Data for the trigger study consisted of the sample of VBF Invisible Higgs boson events with a Higgs boson mass of 130 GeV produced using HERWIG and a sample of QCD dijet produced using PYTHIA as described in Section 2.1. The results of this study are shown in Table 3 for  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  luminosity. The acceptances shown in Table 3 give the effect of the trigger on the VBF Higgs boson samples used in the VBF analysis. As such the acceptance is defined as the number of signal events that survive both the trigger and the data selection cuts described in Section 2.3.1, divided by the number of events that survive the selection cuts alone. The trigger rates in Table 3 are the expected raw rates for the specific

Trigger Menu	Acceptance[%] normalized to offline cuts	Rates[Hz] for $\mathcal{L} = 10^{31} \text{ cm}^{-2} \text{ s}^{-1}$
L1_XE60	99	$5.0 \pm 1.3$
L1_XE70	98	$1.5 \pm 0.6$
L1_XE80	96	$0.6 \pm 0.1$
L1_XE100	84	$0.2 \pm 0.1$
L1_XE120	70	$0.1 \pm 0.1$
L1_FJ23+XE70	78	$0.9 \pm 0.6$
L1_J23+L1_XE70	83	$1.4 \pm 0.6$
L1_J23+L1_XE100	73	$0.2 \pm 0.1$
L1_FJ23+L1_XE100	66	$0.0 \pm 0.0$
L1_FJ23+L1_J23+L1_XE70	62	$0.9 \pm 0.6$
L1_FJ23+L1_J23+L1_XE100	55	$0.0 \pm 0.0$

Table 3: Signal acceptance and level one trigger rates for the VBF invisible Higgs boson channel based on full ATLAS simulations and with  $m_H = 130 \text{ GeV}$ . The L1 trigger menu items are  $E_T^{\text{miss}}$  (L1\_XE) central jet (L1\_J) and forward jet (L1\_FJ), see text. The number following the menu object indicates the trigger threshold given in GeV. Both single and combined triggers are shown in this Table. The values are given for a luminosity of  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  and do not account for pile-up effects.

trigger. One expects an overlap with other trigger signatures such that the additional rate produced by these signatures will be less than the calculated raw rates.

The numbers given in Table 3 are the best estimation we currently have of the trigger rates. In reality beam conditions and detector effects could lead to much higher values. It is clear that the trigger strategy will depend on these background effects and on the luminosity. At low luminosities, ( $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ ) it is likely that a simple trigger based on  $E_T^{\text{miss}}$  alone such as  $E_T^{\text{miss}} > 70 \text{ GeV}$  (L1\_XE70) will be sufficient. However if the trigger rate for this item is higher than expected, VBF invisible Higgs boson events could still be triggered using a higher  $E_T^{\text{miss}}$  trigger such as  $E_T^{\text{miss}} > 80 \text{ GeV}$  (L1\_XE80) or  $E_T^{\text{miss}} > 100 \text{ GeV}$  (L1\_XE100) whichever one can be used without pre-scaling. As the luminosity increases or if backgrounds are worse than expected, it will be necessary to use a combined trigger for this channel. The numbers in Table 3 suggest that triggers based on  $E_T^{\text{miss}}$  and either a forward or central jet would be sufficient. However the addition of a single jet to an  $E_T^{\text{miss}}$  trigger provides a relatively small reduction in rate due to correlations that can occur when high energy jets are mis-measured. There is concern that this could be amplified by pile-up effects. Requiring a forward jet plus a central jet plus  $E_T^{\text{miss}}$  is expected to solve these problems albeit with a reduction of signal acceptance. For a luminosity of  $10^{33} \text{ cm}^{-2} \text{ s}^{-1}$ , the most conservative trigger option is a combined trigger with  $E_T^{\text{miss}} > 100 \text{ GeV}$  and a forward and a central jet each with a  $p_T > 23 \text{ GeV}$ . This trigger will have an acceptance rate for the signal of 55% as shown in Table 3. Note that the uncertainties shown in Table 3 are statistical only. A further major uncertainty in trigger rates are pile-up effects which have not been considered here. In practice, adjustments will be required to select the optimum trigger based on the experimental rates observed at the LHC.

Invisibly decaying Higgs boson events produced via vector boson fusion can be selected using a combination of  $E_T^{\text{miss}}$  and jet triggers with a small impact on the overall L1 trigger rate. For low luminosities ( $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ ) it is expected that a  $E_T^{\text{miss}}$  trigger of 70 GeV or greater will be sufficient. For higher luminosities such as  $10^{33} \text{ cm}^{-2} \text{ s}^{-1}$ , a trigger with  $E_T^{\text{miss}} > 100 \text{ GeV}$  and a forward and central jet each with  $p_T > 23 \text{ GeV}$  will be required.

### 2.3 Event selection for the VBF channel

Two separate methods are used to extract the signal: the first method is called the cut-based analysis, the second is the shape analysis. Both analyses are conducted by first applying the selection cuts described in the next sub-section. For the cut-based analysis, the signal is extracted using all the cuts including a cut on  $\phi_{jj}$ , the angle between the two tagged jets in the transverse plane. This is described in Section 2.5. For the shape analysis, this last cut is not applied. Instead, the shape of the  $\phi_{jj}$  distribution is used to extract the fraction of signal events. This is described in Section 2.6. Results are derived separately with these two methods.

The selection cuts described in this section were developed using a signal sample with  $m_H = 130$  GeV.

#### 2.3.1 Selection cuts

The event selection is based on standard ATLAS definitions for jets, leptons and missing transverse energy [18]. A primary characteristic of a signal event is the presence of two jets from the VBF process. Events are selected based on each of the two highest  $p_T$  jets in the event which are referred to as the “tagging jets”. These tagging jets are required to have a  $p_T > 40$  GeV and be in the rapidity range  $|\eta_{j1,2}| < 5$ . Cuts on the product and difference of the pseudorapidity of the two jets are used,  $\eta_{j1} \cdot \eta_{j2} < 0$  and  $\Delta\eta > 4.4$ , respectively. Kinematic distributions of the tagged jets for the signal and background are shown in Figure 2. In the upper two plots of this Figure, it can be seen that signal events and the W+jet and Z+jet backgrounds have very similar  $p_T$  distributions. When the W+jet and Z+jet events are generated with only one parton the  $p_T$  distributions are much softer. When the two parton and three parton components are added the  $p_T$  distribution becomes harder and similar to the signal.

The second major event characteristic used to select events is a large  $E_T^{miss}$  from the invisible decay of the Higgs boson. A cut on this variable significantly reduces the QCD background as no real  $E_T^{miss}$  is expected for QCD events. In this analysis there is a requirement that  $E_T^{miss} > 100$  GeV. The  $E_T^{miss}$  distributions for the signal and backgrounds are shown in Figure 3.

The majority of QCD dijet background events will produce soft jets resulting in the tagging jets having a low invariant mass. This feature can be used to reject QCD events by requiring a minimum invariant mass of 1200 GeV for the tagging jets. The invariant mass distribution of the tagging jets is shown in Figure 3. The QCD dijet background can be further reduced by requiring that the direction of the measured  $E_T^{miss}$  is not correlated with the tagging jets. A missing transverse energy isolation variable,  $I$ , is defined for this purpose as  $I = \min[\phi(E_T^{miss}) - \phi(j_{1,2})]$ . Events with a small value of  $I$  are expected to result from mis-measured jets caused by dead material and cracks in the detector. This is illustrated in Figure 4 which shows that QCD dijet events preferentially have a small value of  $I$ . A selection of  $I < 1$  rad has been used which is compatible with previous analyses. The W+jet and Z+jet backgrounds can be reduced by rejecting events with any identified lepton. For this reason, events with electrons or muons with a  $p_T > 20$  GeV are rejected, as are events containing  $\tau$ -jets with a  $p_T > 30$  GeV. These cuts are based on an earlier ATLAS fast simulation study.

A key aspect of the VBF Higgs boson search is the electroweak nature of the signal, and this can be used to suppress backgrounds by using the fact that the signal has no color flow between the interacting quarks at tree level. Although the W+jet and Z+jet backgrounds include both electroweak and QCD terms, the cross-section is dominated by the QCD contribution. Therefore, unlike the signal, the majority of background events have QCD activity in the central region. The presence of this extra QCD radiation between the two tagging jets provides, in principle, a powerful tool to suppress this background. In practice the difference is diluted both by the underlying event and pile-up. The Underlying Event (UE) arises from interactions of the spectator partons and is not consistently modeled by the available event generators. For example, the ratio of the average jet multiplicity from the UE between HERWIG/PYTHIA is

# HIGGS – SENSITIVITY TO AN INVISIBLY DECAYING HIGGS BOSON

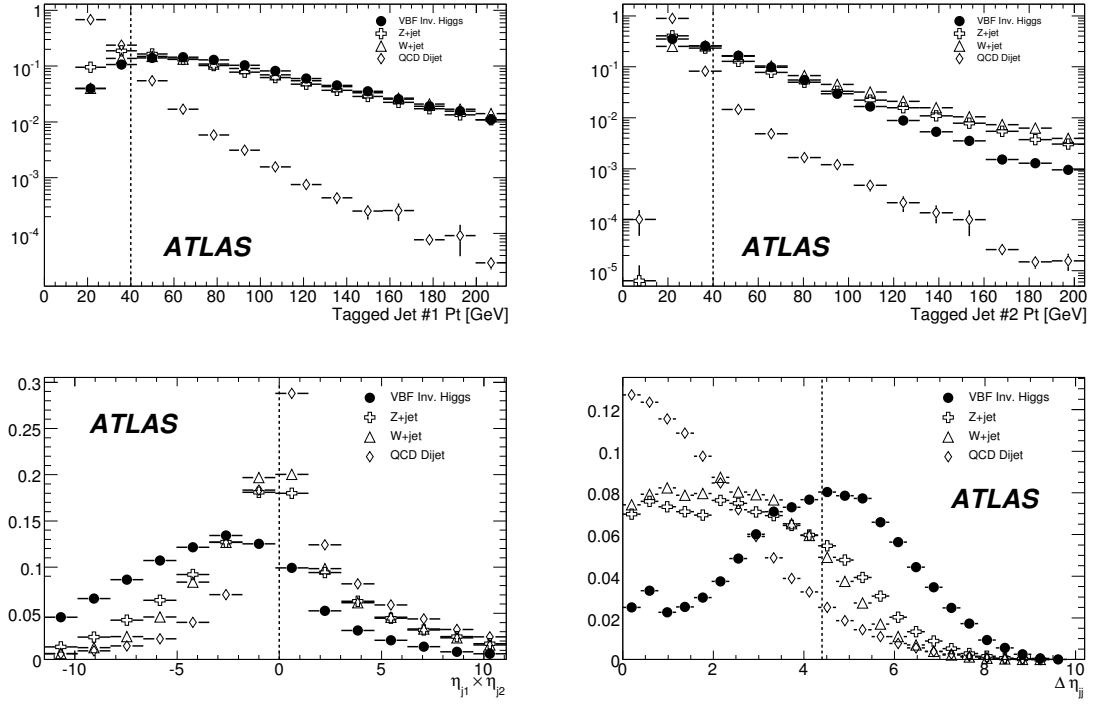

Figure 2: Comparison of tagged jet properties for signal events ( $m_H = 130$  GeV) and the three major backgrounds. The upper left plot shows the  $p_T$  of the leading tagged jet, the upper right plot shows the  $p_T$  of the jet with the second highest  $p_T$ . The lower left plot shows the product of the directions of the two tagged jets in pseudo-rapidity ( $\eta_{j1} \times \eta_{j2}$ ), and the lower right plot shows the difference in  $\eta$  between the two tagged jets ( $\Delta\eta$ ). The enhancement at  $\Delta\eta$  of 0.5 in the VBF signal results from a single high  $p_T$  jet being reconstructed as two jets. The filter cut described in Section 2.1 has been applied to the W+jet and Z+jet Monte-Carlo data, but no trigger cuts have been applied. The distributions are normalized to unity. The vertical dotted lines show the cut values used in the analysis.

Figure 3: The reconstructed invariant mass of the tagging jets (left) and the  $E_T^{miss}$  (right) for the invisible Higgs boson signal ( $m_H = 130$  GeV) and the three main backgrounds. Single events in the high  $E_T^{miss}$  tail of each individual sample (J0, J1 etc) can result in a spike with a large error. The filter cut described in Section 2.1 has been applied to the W+jet and Z+jet Monte-Carlo data, but no trigger cuts have been applied. The distributions are normalized to unity.

Figure 4: The distribution of the reconstructed  $E_T^{miss}$  isolation variable (I) is shown in the right hand plot and the azimuthal angle between the tagging jets ( $\phi_{jj}$ ) is shown in the right hand plot for the invisible Higgs boson signal ( $m_H = 130$  GeV) and the three main backgrounds. The filter cut described in Section 2.1 has been applied to the W+jet and Z+jet Monte-Carlo data, but no trigger cuts have been applied. The distributions are normalized to unity.

between 1.38 and 1.85. Therefore PYTHIA generates events with fewer jets from the UE, but these jets have on average a higher  $p_T$ . If a cut is applied to remove events that have a central jet that exceed a specific  $p_T$  value, the so called Central Jet Veto (CJV) cut, fewer PYTHIA events will survive than HERWIG events. Although there is a clear difference in the topology between the signal and background, the added contribution from the UE has a large effect on the efficiency of this cut. In the same way pile-up, which results from central activity unrelated to the event of interest can also reduce the effectiveness of this CJV cut. The effect of pile-up has not been studied, as suitable data samples were not available. For this analysis, a central jet veto is used requiring that there are no additional jets with  $p_T > 30$  GeV for  $|\eta| < 3.2$ . It should be stressed that this cut is applied after the selection of the two tagging jets which can be located anywhere within the full  $\eta$  range including  $|\eta| < 3.2$ . So this cut does not bias the selection of the tagging jets, nor does it introduce a bias with respect to the trigger which has elements that allow jets to be located within an  $|\eta| < 3.2$ .

Unlike the signal which is uniquely produced via Vector Boson Fusion, the W+jet and Z+jet backgrounds can be produced by the  $q\bar{q} \rightarrow gV$  and  $qg \rightarrow qV$  processes in which the second jet comes from a radiative process. Therefore, the difference in  $\phi$  between the two tagged jets is different for the signal and the radiative background as can be seen in Figure 4. This difference provides additional discriminating power and is used in the analysis presented in Section 2.5 requiring  $\phi_{jj} < 1$  rad. Moreover, the  $\phi_{jj}$  variable motivates the shape analysis presented in Section 2.6.

The selection cuts along with the surviving cross-sections after each cut are shown in Table 4 for a Higgs boson mass  $m_H = 130$  GeV and the three main backgrounds. Table 5 shows the effect of the cuts for the four Higgs boson mass values considered in this study. The cross-sections for W+jet and Z+jet processes were calculated to LO but have been normalized to the results calculated with the generator FEWZ at NNLO which results in a value for the total cross-section which is known to within  $\sim 10\%$ <sup>1</sup> [16].

The first cut applied to the data simulates the effect of the L1 trigger with the most conservative menu option given in Table 3 and discussed in the previous section namely, a  $E_T^{miss} > 100$  GeV, a central jet with  $p_T > 23$  GeV and a forward jet with  $p_T > 23$  GeV. This cut reduces the QCD dijet background rate by approximately 7 orders of magnitude. The effect of the trigger on the W+jet and Z+jet backgrounds is smaller with a reduction of two orders of magnitude, by contrast the signal is reduced by about 50%.

<sup>1</sup>This includes the PDF and QCD scale uncertainties.

Selection Cuts	Higgs boson $m_H = 130$ GeV	W+jet	Z+jet	QCD
Initial $\sigma$ (fb)	$3.93 \times 10^3$	$1.24 \times 10^6$	$4.08 \times 10^5$	$1.91 \times 10^{13}$

Table 4: Cross-section in fb for a Higgs boson ( $m_H = 130$  GeV) and background samples at each step of the selection process. Initial cross-section for W/Z+jet are quoted after VBF filter and NNLO corrections. The first cut is the effect of the L1 trigger simulation with a  $E_T^{miss}$  of 100 GeV, a central jet with  $p_T > 23$  GeV and a forward jet with  $p_T > 23$  GeV (Table 3). The central jet veto is applied to jets other than the two tagging jets and does not bias any of the other cuts. Numbers in parentheses are the efficiencies for each cut.

Higgs boson mass [GeV]	100	130	200	250
Initial $\sigma(fb)$	4630	3930	2410	1780
L1 Trigger	322	271	240	168
+ Tagged jets	166	147	134	93
+ $M_{jj}$	126	111	100	73
+ $E_T^{miss} > 100$ GeV	121	108	98	70
+ Lepton veto	121	107	98	70
+ $I > 1$ rad	108	96	86	63
+ Central jet veto	94	89	79	59
+ $\phi_{jj} < 1$ rad	43	45	39	30

Table 5: Cross-section in fb for each signal mass at each step in the selection cuts. The first cut is the effect of the L1 trigger simulation with a  $E_T^{miss}$  of 100 GeV, a central jet with  $p_T > 23$  GeV and a forward jet with  $p_T > 23$  GeV.

The jet tagging cuts reduces all three backgrounds by a factor of 10. Although a L1  $E_T^{miss}$  is applied a large fraction of events still survive because of the the L1  $E_T^{miss}$  resolution. The other cuts that have a large impact on the QCD rate are the  $E_T^{miss}$  cut and the  $E_T^{miss}$  isolation cut. Together they reduce this background to a negligible level. The effect of these selection cuts on the Z+jet and W+jet backgrounds are less dramatic. The lepton veto reduces the W+jet and Z+jet by  $\sim 36\%$  and  $\sim 3\%$ , respectively. The lepton veto cut removes few events in the Z+jet channel as the  $E_T^{miss}$  cut removes most of the  $Z \rightarrow \ell\ell$  decay mode. The remaining Z+jet events are dominated by the  $Z \rightarrow \nu\nu$  mode. Leptons are only identified for  $|\eta| < 2.5$ , so the lepton veto cut does not remove all the W+jet background events due to this limited  $\eta$  range. Therefore, electrons and  $\tau$ -jet in the forward region ( $|\eta| > 2.5$ ) are mis-identified as jets most of the time. In a similar manner, muons in the forward direction are generally not identified and result in fake  $E_T^{miss}$ .

## 2.4 Systematic uncertainties

Three major types of systematic uncertainties are considered. One arises from the implementation of the Monte Carlo generators, the second from the experimental systematic uncertainties and the third from

Selection Cuts	HERWIG 130 GeV	PYTHIA 130 GeV
Initial $\sigma(fb)$	$3.93 \times 10^3$ (1.000)	$3.93 \times 10^3$ (1.000)
Pre-Cut ( $E_T^{miss} > 80$ GeV)	$1.76 \times 10^3$ (0.448)	$1.78 \times 10^3$ (0.453)
+ Tagged Jets	$4.07 \times 10^2$ (0.231)	$4.10 \times 10^3$ (0.230)
+ $M_{jj}$	$2.45 \times 10^2$ (0.602)	$2.45 \times 10^3$ (0.598)
+ $E_T^{miss} > 100$ GeV	$2.05 \times 10^2$ (0.837)	$2.14 \times 10^3$ (0.873)
+ Lepton Veto	$2.05 \times 10^2$ (1.000)	$2.12 \times 10^2$ (0.991)
+ $I > 1$ rad	$1.84 \times 10^2$ (0.898)	$1.80 \times 10^2$ (0.849)
+ Central Jet Veto	$1.59 \times 10^2$ (0.864)	$1.07 \times 10^1$ (0.594)
+ $\phi_{jj} < 1$ rad	$7.43 \times 10^1$ (0.467)	$4.93 \times 10^1$ (0.461)

Table 6: Comparison between HERWIG and PYTHIA generated samples on the selection cuts for the 130 GeV Higgs boson mass. The cross-section results are quoted in fb and the cut efficiency is given in parenthesis. The major difference occurs in the last two rows of this table.

the theoretical knowledge of the production cross-sections.

Two event generator effects are discussed, the first is the treatment of the Underlying Event (UE) and the second is the effect of using a fixed Z boson mass. To illustrate the effect of the UE, signal events have been generated with two different event generators, HERWIG and PYTHIA that treat the UE in different ways. Table 6 shows the efficiency of each selection cut used in the VBF analyses for the two generators. The difference in cross-sections between the two samples are within  $\sim 2\%$  of each other for cuts up to the  $E_T^{miss}$  isolation cut. However, once the central jet veto is applied, fewer Pythia events survive resulting in a large difference of  $\sim 49\%$ . This is believed to be the result of the difference in the modeling of the UE in the two generators; Pythia tends to produce fewer but harder jets, resulting in more events being removed by the central jet veto cut, see Section 2.3. If the number of background events is underestimated due to a combination of this cut and the choice of generator the sensitivity to the signal will be artificially enhanced. A systematic study of the effect of generator choice on the central jet veto cut would require a large number of data and background samples to be produced with a variety of generators and this is beyond the scope of this paper. It is not clear which generator represents reality best. For consistency both the background and signal samples were generated using HERWIG. When real data becomes available it will be possible to measure the magnitude of central jet activity directly and use this to tune the generators.

The use of ALPGEN requires the use of a fixed Z mass. The effect of the missing off-shell terms from the background samples was checked using the  $Z \rightarrow \nu\nu$  analysis by adding a  $E_T^{miss}$  contribution randomly generated by a Breit-Wigner distribution using the Z mass and width parameters. This study indicated that the effect of using a fixed mass Z boson was negligible.

Two methods are considered in this paper to extract the signal significance. The first, a cut-based analysis, relies on the number of signal and background events after all cuts have been made. The second, a shape analysis relies on the ratio of the number of background events contained in two regions of the  $\phi_{jj}$  variable distribution; namely the number of events for  $\phi_{jj} < 1$  divided by all events. The systematic uncertainties of interest are the ones related to these three quantities; the number of signal and background events and the background shape ratio. They are shown in Table 7.

The event reconstruction variables that result in the largest systematic uncertainties are the jet resolution and the jet energy scale. For the jet energy resolution, the systematic uncertainty was estimated by smearing the momentum of the jets using a Gaussian distribution with a width given by  $\sigma(E) = 0.45\sqrt{E}$  for  $|\eta| < 3.2$  and  $\sigma(E) = 0.63\sqrt{E}$  for  $|\eta| > 3.2$ . Changing the jet energy magnitude also affects the

Systematics	Higgs boson 130 GeV	Background	
		Cut-Based	Shape
Luminosity	3 %		$\sim 0\%$
Jet energy resolution: $\sigma(E) = 0.45\sqrt{E}$ for $ \eta  < 3.2$ $\sigma(E) = 0.63\sqrt{E}$ for $ \eta  > 3.2$	0.8 %	5.3 %	4.5 %
Jets energy scale: +7% for $ \eta  < 3.2$ +15% for $ \eta  > 3.2$	4.0 %	3.2 %	0.2 %
Jets energy scale: -7% for $ \eta  < 3.2$ -15% for $ \eta  > 3.2$	10.0 %	19.5 %	2.8 %
Total	10.5 %	20.4 %	5.3 %

Table 7: Experimental contributions to the systematic uncertainty. The systematic uncertainty on the Jet Energy Scale (JES) is asymmetric. Only the largest (negative) JES systematic uncertainty is included in the total experimental uncertainty shown in the last row of the table.

$E_T^{miss}$ , so for each event,  $E_T^{miss}$  was recalculated for the x- and y-components. The analysis was then repeated to determine the change in the number of signal and background events and the shape ratio. In the same way the effect of changes in the jet energy scale was investigated by shifting the overall scale by  $\pm 7\%$  for  $|\eta| < 3.2$  and  $\pm 15\%$  for  $|\eta| > 3.2$ . Again this affects the  $E_T^{miss}$ , and this change was taken into account. As can be seen in Table 7, there is an asymmetric dependence on the Jet Energy Scale, (JES), so positive and negative deviations are considered separately. Lepton reconstruction was analyzed and found not to contribute to the final systematic uncertainty. The JES uncertainties used here are conservative for  $30 \text{ fb}^{-1}$ , but the impact of this choice on the sensitivity limits presented in this paper is small. Finally, 3% was assigned to the uncertainty in the luminosity. To get the experimental systematic uncertainty for each analysis the terms were added in quadrature giving an overall systematic uncertainty of 20% on the number of background events which applies to the cut-based analysis and an uncertainty of 5.3% on the background shape ratio that applies to the shape analysis.

In addition to the uncertainty in the UE and the reconstruction algorithms, there is a systematic uncertainty which arises from the uncertainty in the absolute cross-section of the backgrounds. The main backgrounds to the invisible Higgs boson channel are Z+jet and W+jet. The total cross-sections for these processes have been corrected to NNLO and are known to  $\sim 10\%$ , (see Section 2.3). However the cuts used to select the VBF process, result in a very restricted phase space which makes it difficult to determine the systematic uncertainty on the cross-section for the final data samples. This means that the systematic uncertainty on the number of background events due to the cross-section is currently unknown, could be very large and is likely to dominate other uncertainties. The shape of the  $\phi_{jj}$  distribution on the other hand is quite well constrained by theory and based on previous studies has a systematic uncertainty of 10% [5]. At NLO it is expected to be 5%. In this analysis a conservative value of 10% is assumed for the uncertainty due to the cross-section which when combined with the much smaller experimental effect leads to an overall systematic uncertainty of 11.3% on the background shape.

## 2.5 Cut-based analysis

This analysis uses the selection cuts summarized in Section 2.3.1. The signal significance is calculated based on the number of signal and background events that remain after all cuts. The limitation of this analysis is that the systematic uncertainty on the background cross-sections described in the previous section could be very large. One way of dealing with this uncertainty is to use experimental data of the Z+jet channel where the Z decays to two leptons. After correction for the detector acceptance, these events can be used to infer the value of the cross-section for the irreducible background in which the Z decays to two neutrinos. A similar analysis can be done for the W+jet background. These so called “data driven” corrections will be the subject of a future publication. In the next section we report on an alternative method which uses the shape of the azimuthal angle distribution between the jets to reduce the dependence of the systematic error on the cross-section. In the current section the sensitivity to an invisible Higgs boson without systematic errors are calculated to provide baseline numbers for the sensitivity to an invisible Higgs boson produced via the VBF process.

The number of signal and background events after the  $\phi_{jj}$  cut is shown in Tables 4 and 5. These numbers can be used to calculate the 95 % CL sensitivity of  $\xi^2$  for the invisible Higgs boson, given the assumed backgrounds. This is done by calculating the number of signal events required to increase the total event count by a factor 1.64 times the uncertainty on the number of background events as shown in Equation 2.

$$1.64\sigma_B = N_S \xi^2 \quad (2)$$

Here  $N_S$  is the number of signal events after the selection cuts and  $\sigma_B = \sqrt{N_B}$ . The results of this analysis gives a  $\xi^2$  for an integrated luminosity of  $30 \text{ fb}^{-1}$  at 95 % C.L. for Higgs mass between 110 GeV and 250 GeV of  $\sim 5 - 8\%$  in the case when systematic uncertainties are not included. An additional 6% statistical uncertainty<sup>2</sup> arises from the limited number of events in the data samples.

## 2.6 Shape analysis

The shape analysis is motivated by a marked difference in the  $\phi_{jj}$  distribution between the signal and the W/Z+jet background as shown in Figure 5, which is taken from reference [5]. This plot shows that the backgrounds peak above a  $\phi_{jj}$  of 1 while the signal is higher at low  $\phi_{jj}$  values. To characterize the shape of the  $\phi_{jj}$  distribution the ratio R has been defined as the number of events with  $\phi_{jj} < 1$  divided by the total number of events as shown in Equation 3. As the proportion of signal in the sample increases the value of R increases.

$$R = \frac{\int_0^1 \frac{d\sigma}{d\phi_{jj}}}{\int_0^\pi \frac{d\sigma}{d\phi_{jj}}} \quad (3)$$

The advantage of the shape analysis described in this section over other analyses is that it does not require a knowledge of the absolute cross-section but rather the ratio of the number of events for ( $\phi_{jj} < 1$ ) to all events. As such, the systematic error associated with the absolute cross-section is reduced to a negligible amount. However, as discussed in Section 2.4, there is a systematic uncertainty associated with the knowledge of the  $\phi_{jj}$  distribution which is known to  $\sim 10\%$  or better. In addition, the systematic uncertainties due to detector effects are much smaller for this ratio than they are for the number of background events, which is the relevant variable for a pure cut-based analysis (Table 7). The overall systematic uncertainty on the ratio R has been calculated to be 11.3%.

Equation 3 can be re-written in the context of this analysis and expanded to provide a background-

---

<sup>2</sup>Based on a binomial error calculation.

Figure 5: The  $\phi_{jj}$  distribution for the signal and background in radians [5]. The solid and dash-dotted lines represent the expected distribution for the Higgs boson signal with Higgs boson masses of  $m_H = 120$  and  $m_H = 300$  GeV respectively. The dotted and dashed lines represent the distributions expected from the backgrounds. The plot shows the distributions after VBF selection cuts have been made. Note that for the  $\phi_{jj}$  plot shown earlier did not have these cuts applied, (Figure 4).

only term, as shown in Equation 4.

$$R = \frac{N_B^1}{N_B^\pi} \left[ 1 + \xi^2 \left( \frac{N_S^1}{N_B^1} - \frac{N_S^\pi}{N_B^\pi} \right) + \dots \right] \quad (4)$$

Here  $N_B^1$  and  $N_S^1$  are the number of events within  $\phi_{jj} < 1$  and  $N_B^\pi$  and  $N_S^\pi$  are the number of events within the entire  $\phi_{jj}$  range. The first term of Equation 4 provides the expected ratio for the background contribution. However, since the ratio between the signal and background are not the same in the presence of a signal, a non-zero value is expected in the second term. The variation from the ‘background only’ ratio dictates the sensitivity to new physics. The ratio  $N_B^1/N_B^\pi$  can be determined using the Standard Model theoretical prediction or by a data driven technique.

The shape analysis applies the selection cuts discussed in Section 2.3.1 but not the  $\phi_{jj}$  cut. Therefore, the results from Table 4 before this last cut are used. The first term of Equation 4 is calculated to be  $0.254 \pm 0.007$ . To determine the 95% C.L. sensitivity limit a variation of  $1.64\sigma_R$  is required, where  $\sigma_R$  is the uncertainty on the ratio  $R$  from Equation 4. Therefore, the first order  $\xi^2$  terms from Equation 4 is set to the required 95% CL sensitivity limit, that is  $1.64\sigma_R$ , as shown in Equation 5.

$$1.64\sigma_R = \xi^2 \left( \frac{N_S^1}{N_B^1} - \frac{N_S^\pi}{N_B^\pi} \right) \left( \frac{N_B^1}{N_B^\pi} \right) \quad (5)$$

Solving for  $\xi^2$  provides the 95 % CL sensitivity limit for the invisible Higgs boson. The results of this analysis are shown in Figure 6. Without systematic errors, the shape analysis gives a value of  $\xi^2$  that ranges from 11 to 19%. This can be compared with the simple cut-based analysis which gave a  $\xi^2$  value that ranged from 5 to 8%. So although the shape analysis method removes the dependence on the absolute cross-section of the backgrounds there is a reduction in the sensitivity to the signal. To include

Figure 6: Sensitivity for an invisible Higgs boson at 95% C.L. via the VBF channel using shape analysis for an integrated luminosity of  $30\text{fb}^{-1}$  with and without systematic uncertainties. The black triangles (circles) are the results from this analysis with (without) systematic uncertainties.

the systematic uncertainties, the uncertainty on the background becomes  $\sigma_R = \sqrt{\sigma_R^2 + \alpha^2 R^2}$ , where  $\alpha$  is the fractional systematic uncertainty given in Table 7. The result obtained that includes systematic uncertainties gives value of  $\xi^2$  of around 60% for  $m_H$  between 100 and 200 GeV. This sensitivity is dominated by the systematic uncertainty that arises from the theoretical knowledge of the shape of the  $\phi_{jj}$  distribution. Using calculations at NLO could reduce this uncertainty by a factor of 2 greatly enhancing the sensitivity of this method of analysis.

## 2.7 Summary for the VBF invisible Higgs boson channel

The study described above has investigated the sensitivity of the ATLAS detector to a Higgs boson particle produced by the VBF process that has an invisible decay mode. It should be stressed that these results do not include pile-up which can reduce the sensitivity. It has been shown that with  $30\text{fb}^{-1}$  of data it is possible to detect this process over a wide range of masses if the Beyond Standard Model cross-section is more than 60% of the Standard Model cross-section for a Higgs mass range of up to 200 GeV and 100% of the Higgs boson decays are invisible. Triggering for this channel is possible using a trigger requiring large  $E_T^{\text{miss}}$  plus a forward and a central jet of moderate  $p_T$ . Triggers of this kind would be useful up to luminosities of at least  $10^{33}\text{cm}^{-2}\text{s}^{-1}$ .

## 3 The associated $ZH$ production channel

The Feynman diagram for associated production in the  $ZH$  channel is shown in Figure 7. The signal of an invisibly decaying Higgs boson in the  $ZH$  channel can be detected when the  $Z$  boson decays into two leptons, which can be used for triggering the event. The presence of an invisibly decaying Higgs boson is detected from the missing transverse energy.

Figure 7: (Left): The Feynman diagram for Higgs boson associated production with a Z boson. (Right): A representation of the decay of a Higgs boson into two invisible neutralinos represented by  $\chi^0$  recoiling against the two leptons coming from the Z decay.

Various backgrounds with signatures similar to the signal have been studied and are listed here. In all cases, unless otherwise specified,  $\ell$  represents  $e$  or  $\mu$ .

1. The  $ZZ \rightarrow \ell\ell\nu\nu$  final state gives the same signature as the signal (irreducible background) and is the main background;
2. The  $t\bar{t} \rightarrow b\ell^+\nu\bar{b}\ell^-\nu$  process mimics the signal when the two  $b$ -jets are not reconstructed, or when a second lepton results from a  $b$  quark decay;
3. The  $W^+W^- \rightarrow \ell\nu\ell\nu$  process mimics the signal but can be greatly reduced by cutting on the  $Z$  mass;
4. The  $ZZ \rightarrow \nu\bar{\nu}\tau\bar{\tau}$  and  $\tau \rightarrow \ell\nu\bar{\nu}$  can also mimic the signal.
5. The  $ZZ \rightarrow \ell\bar{\ell}\tau\bar{\tau}$  and  $\tau \rightarrow \ell\nu\bar{\nu}$  can pass the selection criteria if some particles are missed;
6. The  $ZW \rightarrow \ell\ell\ell\nu$  decay mode also simulates the signal when one lepton is not detected;
7. The  $Z$  plus jets background, with  $Z \rightarrow \ell\bar{\ell}$  (Drell-Yan process) final state can be mistaken for the signal when poor jet reconstruction leads to missing transverse energy.

### 3.1 Monte Carlo generation for the ZH channel

The signal and the background events have been generated using different particle generators chosen according to which process they simulate best. The events are fully simulated then reconstructed using ATHENA. The diboson production cross-sections are taken from Ref. [16]. All events were passed through a filter immediately after generation. The two filters used are described in detail in Section 3.2.2. Only the few samples generated with the simpler lepton filter will be mentioned here. All other samples were generated with the filter containing  $m_Z$  and  $E_T^{miss}$  cuts.

Details on the generated events and pre-defined parameters are given below. All generators use the CTEQ6M structure functions to generate the processes.

- Seven signal samples were generated using PYTHIA, with  $m_H = 110, 120, 130, 140, 150, 200$  and  $250$  GeV. Only the samples with  $m_H = 130$  and  $140$  GeV used the lepton filter. To generate the invisibility of the Higgs boson, the  $H$  is produced as a stable particle, which goes undetected.
- $ZZ \rightarrow \ell^+\ell^-\nu\bar{\nu}$  is generated using PYTHIA. This is the main and irreducible background. One  $Z$  decays to a lepton pair while the other is allowed to decay to any flavor of neutrino pairs.

- $t\bar{t}$  is produced with the MC@NLO generator with all top quark decay modes allowed. The filter described in detail in Section 3.2.2 retains mostly  $t\bar{t} \rightarrow b\ell^+\nu\bar{b}\ell^-\bar{\nu}$  events with  $\ell = e$  or  $\mu$  only. Hadronic top quark decays with a subsequent  $b \rightarrow c\ell\nu$  decay are also included.
- $W^+W^- \rightarrow \ell^+\nu\ell^-\nu$  is generated with MC@NLO.
- $ZZ \rightarrow \tau^+\tau^-\nu\nu$  and  $ZZ \rightarrow \ell\ell\tau^+\tau^-$  events are generated with PYTHIA. The  $\tau$  was allowed to decay hadronically and leptonically in both samples.
- $ZW^\pm \rightarrow \ell^+\ell^-\ell^\pm\nu$  samples are produced with the MC@NLO generator. Since the cross-sections for  $ZW^+$  and  $ZW^-$  production are different, two different datasets were generated. The ZW samples were not filtered since MC@NLO does not include the Z width at generation, leading to problems when trying to apply a cut on the Z mass at the generator level. For these datasets, we use samples generated with the lepton filter which selected events containing at least two leptons. These events need to be reweighted after full reconstruction to account for the distorted Z mass distribution.
- $Z \rightarrow \ell^+\ell^- + jet$  events are produced using the SHERPA generator.

### 3.2 Event selection for ZH channel

The event selection is made in three stages:

1. For simulated samples, a filter is applied immediately after the event Monte Carlo generation to avoid unnecessary simulation of a large fraction of the background which would otherwise be readily rejected at the preselection level. The event filter cuts are loose preselection cuts applied on true Monte Carlo quantities.
2. The preselection cuts use fully reconstructed variables and aim at rejecting most backgrounds, retaining only the most likely events to be used at the final selection level.
3. The final selection uses a multivariate analysis (Boosted Decision Tree) to refine the selection cuts while retaining a high signal efficiency.

#### 3.2.1 Analysis framework for the ZH channel

The standard ATLAS selection criteria are used to identify these objects [18].

#### 3.2.2 Filter for the ZH channel

The filter decision is based on true Monte Carlo quantities. The filter must not reject events that would have passed the preselection cuts to avoid introducing biases, and must have a large rejection efficiency against background. To do so, the filter uses cuts looser than, but similar to, the preselection cuts, namely:

- The events must contain at least two leptons with  $p_T > 4.5$  GeV of same flavor but opposite charge within  $\eta < 2.7$ .
- The reconstructed mass of these two leptons must be within  $\pm 25$  GeV of the Z mass.
- The events must satisfy  $E_T^{miss} > 50$  GeV. The  $E_T^{miss}$  is computed from a vectorial sum over all invisible, stable particles such as Higgs bosons and neutrinos, and all lost particles falling outside the calorimeter fiducial region of  $p_T > 5.0$  GeV and  $\eta > 5.0$ .

Table 9: Monte Carlo estimates of the cross-section (fb) for the signal with seven different Higgs mass hypotheses following successive preselection cuts described in Section 3.2.4 for the ZH channel analysis. The number of generated events refers to filtered events. Two samples were generated using a simpler filter that retained events containing at least two leptons, ( $m_H = 130$  and 140 GeV) whereas all other samples used a filter that required finding two leptons forming a Z boson and large  $E_T^{miss}$ , as described in Section 3.2.2. The efficiency for this filter increases with the Higgs mass hypothesis.

A simpler lepton filter with only the first selection cut was used for the  $ZW \rightarrow \ell\ell\nu$  samples, for two signal samples with Higgs mass hypothesis  $m_H = 130$  and 140 GeV, and for the  $ZZ \rightarrow \ell\ell\ell\ell$  sample used for a normalization study.

The filter reduces the total CPU time needed for full reconstruction by more than a factor of 1000. The results are summarized for a signal with a Higgs boson mass hypothesis of 130 GeV and the background samples in Table 8. In Table 9, the effect of the filter, trigger and preselection cuts are shown for the signal at other Higgs boson masses.

### 3.2.3 Trigger for ZH channel

An invisibly decaying Higgs boson in the  $ZH$  channel can be detected when the  $Z$  decays into two leptons. We trigger on such events using the full simulation of the trigger and by requiring either one or

two isolated, high  $p_T$  leptons satisfying any of the following trigger signatures:

- single electron trigger: one isolated lepton with  $p_T > 22$  GeV.
- single muon trigger: one muon with  $p_T > 20$  GeV.
- di-electron trigger: two isolated electrons with  $p_T > 15$  GeV.
- missing transverse energy trigger:  $E_T^{miss} > 100$  GeV.

The di-muon trigger with a lower  $p_T$  momentum cut was not implemented in this analysis but will be used in the future. The overall trigger efficiency of 92.8% compares well with what is retained when applying cuts on fully reconstructed variables, selecting events containing either one electron with  $p_T > 25$  GeV, two electrons with  $p_T > 15$  GeV or one muon with  $p_T > 20$  GeV. The effect of the trigger on all samples studied is given in Table 8.

### 3.2.4 Event preselection

A first preselection is applied to reject most backgrounds, in particular the  $t\bar{t}$  and (Z+jet) backgrounds. The following cuts are applied:

- the event must satisfy one of the trigger signatures described in the previous section;
- large missing transverse energy, i.e.  $E_T^{miss} > 90$  GeV.
- the event must contain exactly two leptons of the same flavor but opposite charge with  $p_T > 15$  GeV;
- an anti-b-tag is applied to further suppress the  $t\bar{t}$  background.
- a loose cut on the invariant mass of the two leptons, namely  $|m_{\ell\ell} - m_Z| < 20$  GeV, is applied to reject some  $t\bar{t}$  background without reducing the signal efficiency.

The  $\sigma \cdot BR$  for the signal and the background processes listed in Section 3 are shown in Table 8. The effects of the filter and preselection cuts are also shown in this table.

### 3.2.5 Final event selection

In order to improve the sensitivity of this channel, the most discriminative variables are used to form a multivariate analysis (Boosted Decision Tree or BDT). Sixteen different variables are used as inputs to the BDT, namely:

- the missing transverse energy  $E_T^{miss}$ ,
- the transverse mass  $m_T = \sqrt{2p_T^{\ell\ell} \cdot E_T^{miss}(1 - \cos\Delta\phi)}$  where  $\Delta\phi$  is the azimuthal angle between the dilepton system and  $\vec{p}_T^{miss}$ ,
- the cosine of the angle between  $\vec{p}_T^{miss}$  and the most energetic lepton,
- the reconstructed Z mass,
- the transverse momentum of each lepton,
- the cosine of the angle between the two leptons in the transverse plane and in 3-dimensions,

- the cosine of the angle between  $\vec{p}_T^{miss}$  and  $\vec{p}_T^Z$ ,
- the cosine of the angle between the most energetic jet and  $\vec{p}_T^{miss}$ ,
- the energy found in a cone  $\Delta R = 0.1$  rad around each lepton; the lepton isolation variable is particularly useful for muons where very little energy is found around isolated muons but not so much for electrons where the energy deposit is much wider,
- the energy of each of the three most energetic jets, and
- the total number of jets.

These variables are shown in Figures 8 to 11 for the signal and the background after applying the preselection cuts listed in Section 3.2.4. Each distribution has been normalized to unity. The various backgrounds have been regrouped: the irreducible background,  $ZZ \rightarrow \ell\ell\nu\nu$ , the non-resonant background:  $t\bar{t}$  and  $WW$ , and finally all other backgrounds containing at least one Z boson:  $ZZ \rightarrow \ell\ell\tau\tau$ ,  $ZZ \rightarrow \tau\tau\nu\nu$ ,  $ZW$  and  $(Z + jet)$ .

Each of the main backgrounds after the preselection cuts, namely  $t\bar{t} \rightarrow b\ell\nu b\ell\nu$ ,  $WW \rightarrow \ell\nu\ell\nu$ ,  $ZZ \rightarrow \ell\ell\tau\tau$ ,  $ZW \rightarrow \ell\ell\nu\nu$  and  $(Z+jet)$  are compared to the signal to train a Boosted Decision Tree (BDT) [19]. Each one of these backgrounds is trained separately. Nothing is gained from training a BDT against the irreducible background,  $ZZ \rightarrow \ell\ell\nu\nu$ , so this background is not used. An ensemble (forest) of decision trees is successively generated from the training sample, where each new tree is trained by giving increased weights to the events that have been misclassified in the previous tree. The classifier response is obtained as the sum of the classification results for each tree, weighted by the purity obtained for all training events in that tree. The large number of decision trees in the forest increases the performance of the classifier and stabilizes the response with respect to statistical fluctuations in the training sample.

For each background type, a set of weights is established. Half the Monte Carlo events contained in each file is used for the training and the other half for the analysis. The file containing the signal and all the backgrounds, including the less important ones, is then analyzed using these weights. Each event is assigned a weight corresponding to the likelihood of being identified as signal or background. The BDT weight distributions are shown in Figure 12. Each plot shows the output variable distribution for Boosted Decision Trees trained against different backgrounds, namely, from top plot to bottom plot, the  $t\bar{t} \rightarrow b\ell\nu b\ell\nu$ ,  $WW \rightarrow \ell\nu\ell\nu$ ,  $ZZ \rightarrow \ell\ell\tau\tau$ ,  $ZW \rightarrow \ell\ell\nu\nu$  and  $Z+jet$ . The  $ZZ \rightarrow \tau\tau\nu\nu$  background is not used to train a specific BDT since too few events survive the preselection cuts. The cuts on the five BDT outputs are adjusted to minimize the value of  $\xi^2$ , defined in Equation 2.

The same procedure is repeated using different Higgs boson mass hypotheses ranging from  $m_H = 110$  GeV to  $m_H = 250$  GeV, optimizing the cuts each time. The numbers of events surviving all Boosted Decision Trees cuts for each Monte Carlo sample and these seven Higgs boson mass hypotheses are given in Table 11. The BDT inputs variables are also ranked during each training against a particular background. Each time, the input variables are assigned a weight proportional to their importance in separating power. The sum of these weights are given in Table 10, showing which variables offer the best separation power. The order of importance varies for each of the trees but all variables are useful in at least one tree. The Z mass is the overall most discriminative variable, mostly due to its very high ranking in the BDT trained against  $t\bar{t}$  and  $WW$  backgrounds.

### 3.3 Systematic uncertainties

#### 3.3.1 Background cross-section

Since this is a counting experiment, one is looking for events in excess of what is expected by the Standard Model. However, exactly what is expected from Standard Model backgrounds is not well

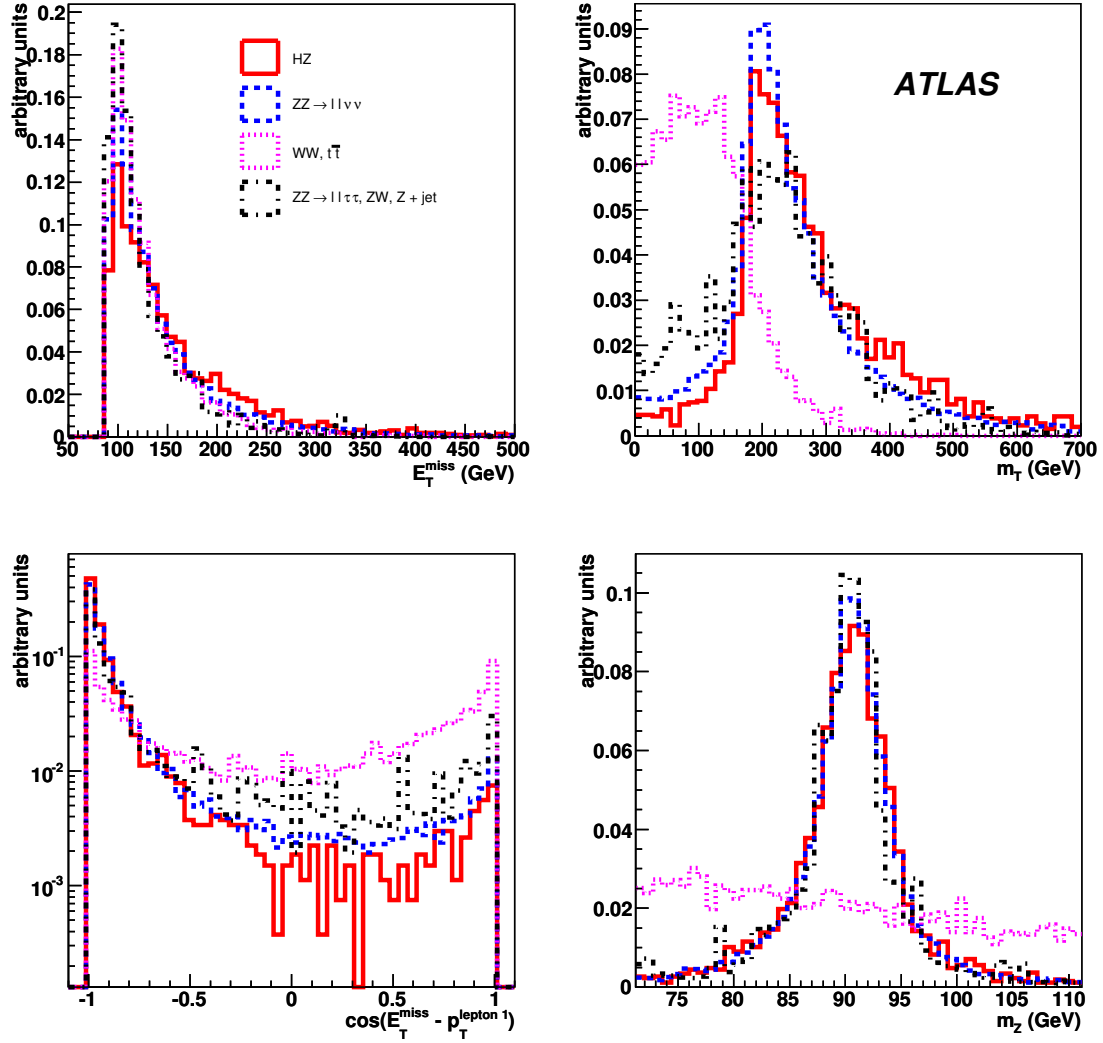

Figure 8: Input variables used by the Boosted Decision Tree for the signal with  $m_H = 130$  GeV and the main backgrounds. Top left: Missing  $E_T$ . Top right: transverse mass, defined as the reconstructed mass in the transverse plane, namely  $m_T^2 = E_T^2 - p_T^2$ . Bottom left: cosine of the angle between the missing  $E_T$  and highest momentum lepton in the transverse plane. Bottom right: reconstructed Z mass. Each plot has been normalized to unity. The combined samples had first been scaled to the same luminosity.

Figure 9: Input variables used by the Boosted Decision Tree for the signal with  $m_H = 130$  GeV and the main backgrounds. Top left: Transverse momentum of the most energetic lepton. Top right: Transverse momentum of the second lepton. Bottom left: Cosine of the angle between the two leptons in the transverse plane and, Bottom right: in 3-dimensions. Each plot has been normalized to unity. The combined samples had first been scaled to the same luminosity.

Figure 10: Input variables used by the Boosted Decision Tree for the signal with  $m_H = 130$  GeV and the main backgrounds. Top left: The cosine of the angle between the direction of missing  $E_T$  and the reconstructed Z transverse momentum. Top right: The cosine of the angle between the most energetic jet and the direction of missing  $E_T$ . Bottom left: The energy contained in a cone of 0.10 rad around the most energetic lepton. Bottom right: The energy contained in a cone of 0.10 rad around the second lepton. Each plot has been normalized to unity. The combined samples had first been scaled to the same luminosity.

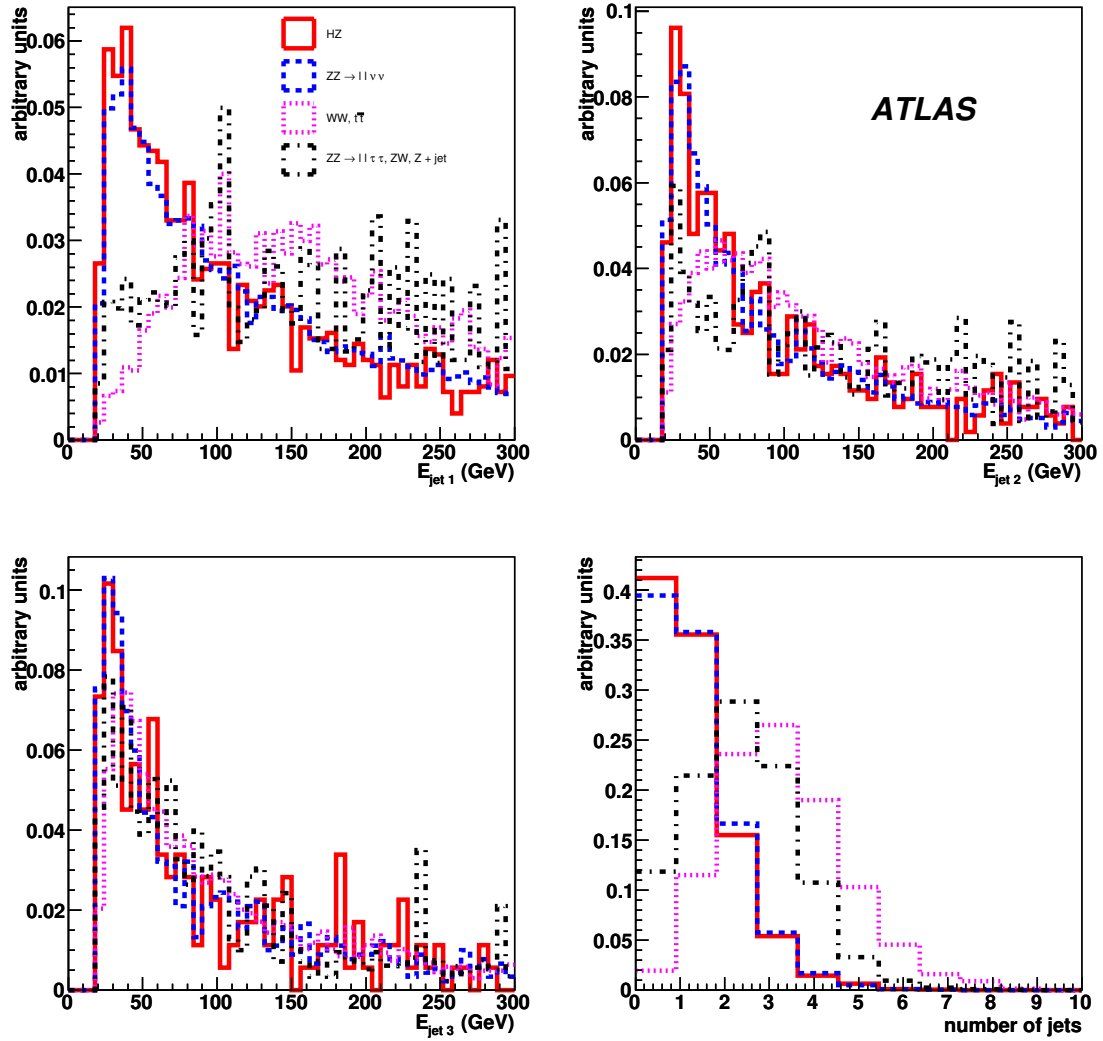

Figure 11: Input variables used by the Boosted Decision Tree for the signal with  $m_H = 130$  GeV and the main backgrounds. Top left: The energy distribution for the most energetic jet; Top right: for the second and, Bottom left: third most energetic jets. Bottom right: the number of jets in the event. Each plot has been normalized to unity. The combined samples had first been scaled to the same luminosity.

Figure 12: The Boosted Decision Tree (BDT) output variables obtained after comparing half the signal events to five different backgrounds separately, namely, from top to bottom:  $t\bar{t} \rightarrow b\ell\nu b\ell\nu$ ,  $WW \rightarrow \ell\nu\ell\nu$ ,  $ZZ \rightarrow \ell\ell\tau\tau$ ,  $ZW \rightarrow \ell\ell\nu\nu$  and  $Z \rightarrow \ell\ell + \text{jets}$ . The BDT assigns values close to +1 for a signal-like event and -1 for background-like events. The distributions are shown for the signal and all types of background when using the other half of the events for the analysis. The Boosted Decision Trees trained against the ZW background offers the best separation power. The  $\xi^2$  decreases further once additional cuts on the other BDT output variables are applied, namely the WW BDT output, then the  $ZZ \rightarrow \ell\ell\tau\tau$  BDT output, the (Z+jet) BDT output and finally the  $t\bar{t}$  BDT output. All BDT output cut values are indicated by a vertical dashed line. Nothing is gained from training a BDT against the irreducible background,  $ZZ \rightarrow \ell\ell\nu\nu$  for all Higgs boson mass hypotheses, so it is not used.

input variable to BDT	sum of weights
Z mass	0.57
$\cos \ell \ell$ (in 2D)	0.46
$\cos \ell \ell$ (in 3D)	0.42
$\cos(E_T^{miss} - \vec{p}_Z)$	0.41

$\cos E_T^{miss} - p_T^{lepton\#1}$	0.31
$E_T^{miss}$	0.28
$p_T^{lepton\#1}$	0.27
$E_{jet\#1}$	0.26
$E_{jet\#2}$	0.23
$p_T^{lepton\#2}$	0.21
energy in a cone around lepton # 1	0.17
energy in a cone around lepton # 2	0.16
$E_{jet\#3}$	0.13

Table 10: Order of importance for the 16 input variables used to train the separate Boosted Decision Trees used for the analysis at  $m_H = 130$  GeV. The second column gives the sum of the weights given to each input variable by the five separate BDT used for the analysis. These weights are not used for the analysis per se but give an idea of the relative importance of each input variable. In particular, the first four variables are used to mostly reject the non-resonant background.

Table 11: Monte Carlo estimates of the cross-sections in fb surviving the final Boosted Decision Tree selection cuts for each background process and seven mass hypotheses for the ZH channel. The corresponding numbers of events for  $30 \text{ fb}^{-1}$  of total integrated luminosity are also given. The final cuts on the Boosted Decision Tree output variables were set separately for each BDT output variable and for each mass hypothesis, each time optimizing the sensitivity  $\xi^2$ .

known, given the theoretical uncertainties on the Standard Model production cross-sections and this leads to the main source of systematic uncertainty. The current best estimates for each of these cross-sections from the next-to-leading order calculation is about 6% for  $ZZ$  and 5% for  $ZW$  [20]. The uncertainty on the  $(Z+\text{jet})$  cross-section has no impact on the final results since this background is negligible. Several control samples can be used to constrain the  $ZZ$  and  $ZW$  cross-sections. For  $ZZ$ , one can use the four lepton final state (even including  $\tau$ ) but this will require a large data sample (of the order of at least  $30 \text{ fb}^{-1}$ ) to reduce the statistical uncertainty. For the  $ZW$  cross-section, one can use a  $ZW$  control sample with events containing three identified leptons. Both these cross-sections will be measured in ATLAS data. Uncertainties associated with kinematic distributions have not been taken into account at this point. A combined theoretical uncertainty of 5.8% obtained from a weighted average is assigned to the background production cross-section.

One could in principle use  $ZZ \rightarrow \ell\ell\ell\ell$  events from data to calibrate the number of events coming from  $ZZ \rightarrow \ell\ell\nu\nu$  decays. Such an approach was proposed in [21] where one would first select a pure sample of  $ZZ \rightarrow \ell\ell\ell\ell$  events by finding two  $Z$  bosons, then declaring one  $Z$  to decay invisibly. This would work in the absence of other backgrounds but it is not possible to completely eliminate the  $ZW \rightarrow \ell\ell\nu\nu$  background. More importantly, such a technique has a very low efficiency: about 1.8% of all  $ZZ \rightarrow \ell\ell\ell\ell$  survive the preselection cuts, with  $\ell$  here being  $e, \mu$  or  $\tau$ . Only a dozen of events would survive all of the BDT selection cuts for  $30 \text{ fb}^{-1}$  of data. Hence, it is deemed impossible to calibrate quantitatively the  $ZZ \rightarrow \ell\ell\ell\ell$  cross-section using this technique. However, one could still check the effect of the preselection cuts on  $ZZ \rightarrow \ell\ell\ell\ell$  events with two leptons declared invisible as described above to ensure that the main and irreducible background,  $ZZ \rightarrow \ell\ell\nu\nu$ , behaves as expected under these cuts. About 85  $ZZ \rightarrow \ell\ell\ell\ell$  events are expected to pass the preselection cuts, as opposed to 163  $ZZ \rightarrow \ell\ell\nu\nu$  events for  $30 \text{ fb}^{-1}$  of integrated luminosity. After the preselection cuts, the  $ZZ \rightarrow \ell\ell\nu\nu$  background corresponds to about 36% of the total number of selected events in the absence of non Standard Model contributions, as seen from Table 8. This method would provide a normalization of the cross-section using data at about 11% uncertainty level.

### 3.3.2 Effect related to the training of the Boosted Decision Tree

Since half the events are used for training the BDT, and the other half for testing, this arbitrary choice has a slight effect on the outcome. For the central value of this analysis, we used every other event for the training. To estimate the effect of this choice, the analysis was redone using the first half of the events for training, and the second half for testing. Since we are only using Monte Carlo events, this second choice does not introduce additional time-dependent effects that one would expect with real data. The difference in the results, namely +0.2% signal events and +0.7% background events, is ascribed as a contribution to the systematic uncertainty.

### 3.3.3 Lepton momentum resolution effect and energy scale effect

Different tests are done to assess the contributions to the systematic uncertainty from the lepton momentum resolution and the uncertainty on the lepton energy scale. Each time, new modified input variables are used to retrain the BDT and assess the overall effect by comparing the new number of selected signal and background events to the original numbers of events selected. All contributions to the systematic uncertainty are summarized in Table 12.

The tests performed are:

- The lepton momenta are smeared using a Gaussian distribution. A constant sigma of 0.73% is used for electrons. For muons, the sigma is calculated using the following formula:  $\sigma(p_T) = [(0.011 \cdot p_T)^2 + (0.00017 \cdot p_T^2)^2]^{1/2} / p_T$  with  $p_T$  in GeV. The smearing is applied to one type of leptons at a time.

	signal	background
electron reconstruction efficiency	$\pm 0.2\%$	$\pm 0.2\%$
electron $p_T$ resolution ( $\pm 0.73\%$ )	$+0.5\%$	$+1.7\%$
electron energy scale ( $\pm 0.5\%$ )	$+1.1\%$	$+2.1\%$
sub-total for electrons (43% of events)	$+1.2\% - 0.2\%$	$+2.7\% - 0.2\%$
muon reconstruction efficiency	$\pm 1.0\%$	$\pm 1.0\%$
muon $p_T$ resolution (see formula in text)	$+1.1\%$	$+1.9\%$
muon energy scale ( $\pm 1\%$ )	$+1.0\%$	$+2.2\%$
sub-total for muons (57% of events)	$+1.8\% - 1.0\%$	$+3.1\% - 1.0\%$
combined contributions for leptons	$+1.5\% - 0.7\%$	$+2.9\% - 0.7\%$
jet energy scale ( $\pm 7\%$ or $\pm 15\%$ )	$+0.8\%$	$+0.2\% - 2.2\%$
jet energy resolution effect on $E_T^{miss}$	$-2.2\%$	$-0.4\%$
luminosity	-	$\pm 3.0\%$
cross-section	-	$\pm 5.8\%$
filter effects	$\pm 1.4\%$	$\pm 1.4\%$
Boosted Decision Tree training effects	$\pm 0.2\%$	$\pm 0.7\%$
total	$+2.2\% - 2.6\%$	$+7.3\% - 7.1\%$

Table 12: Contributions to the systematic uncertainties. The Higgs boson mass was set to 130 GeV to assess these uncertainties. The final background uncertainty is rounded-off to  $\pm 7.2\%$ .

- For each type of lepton, a multiplicative scaling factor is applied to simulate an energy scale uncertainty of  $\pm 0.5\%$  for electrons and  $\pm 1.0\%$  for muons.

### 3.3.4 Jet momentum resolution effect and energy scale effect

Three different modifications are done in turn to the jet energy to evaluate the contributions from the jet energy scale and jet energy resolution to the missing energy evaluation. After each modification, the missing  $E_T$  is recalculated. Each contribution is shown in Table 12. The three modifications made to the jet energy are:

- Jet energy scale: the jet energy is increased by  $\pm 7\%$  for jets within  $\eta \leq 3.2$  and  $\pm 15\%$  for jets within  $\eta > 3.2$ .
- Jet energy resolution: the jet energy is smeared using a Gaussian by  $0.45 \cdot \sqrt{E}$  for jets within  $\eta \leq 3.2$  and  $0.63 \cdot \sqrt{E}$  for  $\eta > 3.2$ .

## 3.4 Results for the ZH channel

The sensitivity with  $30 \text{ fb}^{-1}$  of data is evaluated in terms of  $\xi^2$  with  $\xi^2 = 1.64 \sigma_B / N_S$  for a 95% CL as for the VBF analysis where  $\sigma_B$  is the combined statistical and systematic uncertainty as detailed in Section 2.5. The values of  $\xi^2$  are summarized in Table 13.

### 3.5 Cross-checks with a cut-based analysis

To ensure that the Boosted Decision Tree performed as expected, we duplicated a previous ATLAS analysis performed using a cuts-based approach [21]. The same cuts as were applied to our current

$m_H$	# signal	# background	$\sigma_B$	$\xi^2$
110 GeV	39.2	115.9	13.6	56.7%
120 GeV	82.5	449.4	38.3	76.2%
130 GeV	26.8	98.6	12.2	74.4%
140 GeV	39.5	217.0	21.3	88.5%
150 GeV	36.5	199.4	20.0	89.9%
200 GeV	18.5	164.4	17.3	153.4%
250 GeV	9.3	83.8	10.9	191.6%

Table 13: The sensitivity with  $30 \text{ fb}^{-1}$  at 95% confidence level calculated in terms of  $\xi^2$  for seven different mass hypotheses for the ZH channel.

Monte Carlo samples after the filter and trigger cuts of this analysis, and using the signal generated with  $m_H = 130 \text{ GeV}$ . These cuts are:

1. Filter cuts as in this analysis
2. Trigger cuts as in this analysis
3. Lepton cuts: select events containing no more than two leptons with  $p_T > 7 \text{ GeV}$ . Electrons must have  $p_T > 15 \text{ GeV}$  within  $|\eta| < 2.5$  and muons are selected if  $p_T > 10 \text{ GeV}$  and  $|\eta| < 2.4$ . Two leptons of the same flavor but opposite charge are required.
4. Z mass: the reconstructed Z mass must be within 10 GeV from the pole mass.
5.  $E_T^{\text{miss}} > 100 \text{ GeV}$ .
6. Jet veto: all events containing a jet having  $p_T > 30 \text{ GeV}$  within  $|\eta| < 4.9$  are rejected.
7. b-jet veto: all events containing a b-tagged jet having at  $p_T > 15 \text{ GeV}$  within  $|\eta| < 4.9$  are rejected.
8. Transverse mass:  $m_T > 200 \text{ GeV}$ .

The two analyses can be compared after the MET cut. The sensitivity with  $30 \text{ fb}^{-1}$  at 95% confidence level calculated in terms of  $\xi^2$  for this cut-based analysis is 87.9% for  $m_H = 130 \text{ GeV}$ . This compares well with what was obtained with the BDT technique ( $\xi^2 = 74.4\%$  for the same mass value with the BDT approach). The difference in sensitivity increases further for higher Higgs mass hypotheses. The results are given in Table 14.

## 4 Comparison of results and summary

The sensitivity of ATLAS to an invisibly decaying Higgs boson produced via the VBF and ZH channel has been examined. A comparison between the sensitivities of the two channels can be seen in Figure 13. This plot shows that the channels have a similar sensitivity for low Higgs boson masses. It is possible to look at combined statistics for the ZH analysis and the VBF shape analyses although the analysis techniques are different. Clearly the improvement in sensitivity by combining statistics is not large. Of far greater significance in the analysis of real ATLAS data would be the observation of a significant excess of events in two different and distinct channels. An observation of this kind would give credibility to the hypothesis that a particle is being generated that behaves like a Higgs boson and decays invisibly.

channel	$ZH$ $\ell\bar{\ell}$ inv.	$ZZ$ $\ell\bar{\ell}\nu\nu$	$t\bar{t}$	$WW$ $\ell\nu\ell\nu$	$ZZ$ $\tau\tau\nu\nu$	$ZZ$ $\ell\ell\tau\tau$	$ZW$ $\ell\ell\nu$	$Z$ +jet $\ell\ell$ +jet
$\sigma$ *BR in fb	46.2	728.0	833000.0	5245.6	364.0	123.0	820.0	3105062.8
after filter	34.9	212.6	9412.9	236.5	18.8	87.8	820.0	478.4
after trigger	32.5	198.5	8620.6	217.1	14.2	77.8	735.3	460.6
$p_T$ lepton +ID + charge cut	23.8	148.1	4451.2	158.4	2.7	37.6	177.5	221.6
after $m_Z \pm 10$ GeV cut	20.7	133.0	1654.7	51.1	0.0	28.8	125.4	192.9
after $E_T^{miss} > 100$ cut	7.4	44.9	460.7	7.3	0.0	0.8	13.7	27.9
no jet with $p_T > 30$ GeV	4.2	23.7	5.8	0.8	0.0	0.3	4.2	0.1
b-tag cut for jet with $p_T > 15$ GeV	4.2	23.6	4.8	0.8	0.0	0.3	4.1	0.1
after $m_T > 200$ GeV cut	3.9	21.3	0.5	0.4	0.0	0.3	3.4	0.1

Table 14: Monte Carlo estimates of the cross-sections in fb after applying simple cuts for each background process and one mass hypothesis of  $m_H = 130$  GeV for the  $ZH$  channel. The corresponding  $\xi^2$  would be 87.9%.

Figure 13: Sensitivity to an invisible Higgs boson with ATLAS for both the VBF and  $ZH$  channels with  $30 \text{ fb}^{-1}$  of data assuming only Standard Model backgrounds. The open crosses show the sensitivity for the  $ZH$  analysis and the solid triangles show the sensitivity for the VBF shape analysis for 95 % CL. Both these results include systematic uncertainties.

In summary, a study using fully simulated ATLAS data has shown that the ATLAS experiment will be sensitive to an invisibly decaying Higgs boson in both the VBF and  $ZH$  production channels assuming only Standard Model backgrounds. It is clear that the analysis will require a good understanding of the experimental systematic uncertainties. If the decay of a Higgs boson was entirely in the invisible mode, this analysis has shown that with  $30 \text{ fb}^{-1}$  of data, ATLAS will be sensitive to a situation in which the beyond the Standard Model cross-section is of the order of 80% the Standard Model Higgs boson cross-sections for a Higgs Boson mass of less than 150 GeV. The VBF analysis has a sensitivity of better than 90% up to a Higgs Boson mass of 250 GeV.

# Charged Higgs Boson Searches

## Abstract

The discovery of a charged Higgs boson would be tangible proof of physics beyond the Standard Model. This note presents the ATLAS potential for discovering a charged Higgs boson, utilizing five different final states of the signal arising from the three dominating fermionic decay modes of the charged Higgs boson. The search covers the region below the top quark mass, taking into account the present experimental constraints, the transition region with a charged Higgs boson mass of the order of the top quark mass, and the high-mass region with a charged Higgs boson mass up to 600 GeV. All studies are performed with a realistic simulation of the detector response including all three trigger levels and taking into account all dominant systematic uncertainties. Results are given in terms of discovery and exclusion contours for each channel individually and for all channels combined, showing that the ATLAS experiment is capable of detecting the charged Higgs boson in a significant fraction of the  $(\tan\beta, m_{H^\pm})$  parameter space with its first  $10 \text{ fb}^{-1}$  of data. The so-called intermediate  $\tan\beta$  region (around  $\tan\beta = 7$ ) is experimentally hard to reach but exclusion sensitivity is given in this area.

## 1 Introduction

Charged Higgs bosons ( $H^\pm$ )<sup>1</sup> are naturally predicted in many non-minimal Higgs scenarios, such as Two Higgs Doublet Models (2HDM), and models with Higgs triplets including Little Higgs models. Their discovery would be a definite signal for the existence of New Physics beyond the Standard Model, possibly the first experimental evidence for the Minimal Supersymmetric Standard Model (MSSM) if it is realised in nature, and the supersymmetry mass scale is high enough that sparticles escape discovery. The following analyses will only consider the 2HDM, in particular the so-called type II-2HDM, which is the Higgs sector of the MSSM.

The search strategies for charged Higgs bosons depend on their hypothesized mass, which dictates both the production rate and the available decay modes. Below the top quark mass, the main production mode is through top quark decays,  $t \rightarrow H^+ b$ , and in this range the  $H^+ \rightarrow \tau \nu$  decay mode is dominant. Above the top quark threshold, production mainly takes place through  $gb$  fusion ( $gb \rightarrow tH^+$ ), and for such high charged Higgs boson masses the decay into a top quark and a  $b$  quark dominates,  $H^+ \rightarrow tb$ . A more detailed discussion of the different signal final states used for this study including backgrounds, cross-sections and branching ratios can be found in Reference [1].

Charged Higgs boson searches involve several higher level reconstructed physics objects such as electrons, muons, jets, jets tagged as  $b$  jets and finally jets identified as  $\tau$  jets. These objects are reconstructed by dedicated ATLAS algorithms and details about their performance can be found in References [2–6]. In the following, only efficiencies will be quoted for the different objects.

The note is organized as follows: Section 2 summarizes the trigger menus used for the signatures under investigation. The analysis sections are divided into light (Section 3) and heavy (Section 4)  $H^+$  studies, which are in turn divided according to the signal final state: First,  $t\bar{t} \rightarrow bH^+bW \rightarrow b\tau(had)\nu bqq$  is discussed in Section 3.1, then  $t\bar{t} \rightarrow bH^+bW \rightarrow b\tau(lep)\nu bqq$  in Section 3.2. Section 3.3 addresses  $t\bar{t} \rightarrow bH^+bW \rightarrow b\tau(had)\nu b\ell\nu$ . Two studies for heavy  $H^+$  are described, namely for  $gg/gb \rightarrow t[b]H^+ \rightarrow bqq[b]\tau(had)\nu$  (Section 4.1) and  $gg/gb \rightarrow t[b]H^+ \rightarrow t[b]tb \rightarrow bW[b]bWb \rightarrow b\ell\nu[b]bqqb$  (Section 4.2). In Section 5, systematic uncertainties and their impact are discussed, followed by a description of the

---

<sup>1</sup>In the following, the charged Higgs boson will be denoted  $H^+$ , but  $H^-$  is always implicitly included.

data-driven  $t\bar{t}$  control sample method which is needed for the extraction of the background shape and normalization in all  $H^+$  studies. Section 6 provides combined results from the different search topologies. The charged Higgs boson results are summarized in Section 7.

## 2 Trigger

The production and decay modes of the charged Higgs boson studied here lead to final states containing the following: two to four  $b$  jets, light jets from hadronic decays of  $W$  bosons, one or more neutrinos from  $W$  or  $H^+$  decays, and for most channels a tau lepton decaying either hadronically or into an electron or muon plus neutrinos. These event characteristics suggest the following ATLAS Trigger [7] menus, one for an instantaneous luminosity of  $L = 10^{31} \text{cm}^{-2} \text{s}^{-1}$ , and two alternatives for  $L = 10^{33} \text{cm}^{-2} \text{s}^{-1}$ , based on these trigger signatures:

- $L = 10^{31} \text{cm}^{-2} \text{s}^{-1}$ : xE70, e22i, mu20, xE30\_L1\_TAU13, xE20\_3j20\_L1\_TAU13
- $L = 10^{33} \text{cm}^{-2} \text{s}^{-1}$ : xE80, e55, mu40, xE50\_L1\_TAU30, xE40\_3j20\_L1\_TAU30 or  
xE80, e22i\_xE30, mu20\_xE30, xE50\_L1\_TAU30, xE40\_3j20\_L1\_TAU30

where xE represents a missing transverse energy trigger selection, and e, mu, tau and j correspond to electron, muon, tau, and jet triggers, respectively. A number before each symbol indicates the required trigger multiplicity, as in 3j for three jets. Values after these symbols are the approximate trigger thresholds in transverse momentum, and a final i means that isolation requirements are applied. L1\_ indicates that the stated threshold for the following trigger selection is applied at the first trigger level while the high level trigger selection is softer. Combined triggers are indicated by the juxtaposition of two or more selections. Each analysis uses a subset of items of the two  $10^{33}$  menus.

The menus were chosen based on a careful study of the signal event characteristics and the most realistic trigger signature rates available. The chosen signatures meet the requirements of the trigger bandwidth budget [7] at all trigger levels. For each of the channels studied in the following sections, the trigger efficiencies will be evaluated.

## 3 Light Charged Higgs Boson Searches

In this section, charged Higgs boson searches in the three light  $H^+$  channels ( $m_{H^+} < m_t$ ) selected for investigation are presented:

- $t\bar{t} \rightarrow bH^+bW \rightarrow b\tau(had)vbqq$
- $t\bar{t} \rightarrow bH^+bW \rightarrow b\tau(lep)vbqq$
- $t\bar{t} \rightarrow bH^+bW \rightarrow b\tau(had)vb\ell\nu$

where for a tau lepton,  $\tau(had)$  indicates its hadronic decay and  $\tau(lep)$  its decay to an electron or muon plus neutrinos. If the charged Higgs boson is light, then  $\text{BR}(t \rightarrow bW)$  might not be close to unity, as it is in the Standard Model prediction. This means that the expected background from Standard Model  $t\bar{t}$  decays (the dominant background to all  $H^+$  searches) is reduced. Since the number of events after the event selection is  $N_{t\bar{t}}^{\text{SM}}$  for the background-only hypothesis, and  $N_{H^+} + N_{t\bar{t}}^{\text{MSSM}}$  in the signal+background case, the number of observable excess events is thus not simply the number of  $H^+$  events ( $N_{H^+}$ ) — it is decreased by the difference in the SM and the MSSM  $t\bar{t}$  prediction:  $N_{\text{excess}} = N_{H^+} - (N_{t\bar{t}}^{\text{SM}} - N_{t\bar{t}}^{\text{MSSM}})$ . This is taken into account consistently.

All plots, tables and results in this section are based on the trigger menu for an instantaneous luminosity of  $L=10^{33} \text{cm}^{-2} \text{s}^{-1}$  presented in Section 2, on the signal cross-sections for the  $m_h$ -max MSSM scenario (see Reference [1]) and the background cross-sections given in Reference [8].

### 3.1 $t\bar{t} \rightarrow bH^+bW \rightarrow b\tau(had)vbqq$

The channel in which both the  $\tau$  and the  $W$  boson decay hadronically has a relatively high cross-section, making it a priori one of the most promising in searches for  $H^+$  lighter than the top quark. On the other hand, the absence of leptons, as well as the high hadronic activity, is a challenge, particularly for the trigger. The events are characterised by a  $\tau$  jet, four other jets, two of which are initiated by  $b$  quarks, and missing energy. The main expected backgrounds for this channel are  $t\bar{t}$  events where one top quark decays hadronically and the other to a hadronically decaying  $\tau$ . For this study all  $t\bar{t}$  decay modes have been considered as background, as well as single top,  $W$ +jets and QCD dijet events. For ATLAS, this channel has previously only been studied using fast simulation [9].

#### 3.1.1 Preselection

**Trigger** Either the xE50\_L1\_TAU30 or the xE40\_3j20\_L1\_TAU30 trigger signature (see Section 2) is required for this study.

**Cuts I** Following the trigger, a set of cuts was used to preselect the signal and suppress the background. This first cut set relates primarily to the multiplicity of the offline analysis objects (which are different from the trigger objects, leading in some cases to lower optimum cut values for the offline objects). These are given in Table 3.1.1.

**Cuts II** After the first set of cuts, the  $W$  is reconstructed from the pair of light jets with invariant mass  $m_{jj}$  closest to the nominal  $W$  mass,  $m_W$ . The parent top quark is then found by pairing the reconstructed  $W$  with the  $b$  quark which leads to an apparent top quark mass  $m_{j\bar{b}}$  closest to the nominal value  $m_t$ . Cuts are made both on the  $W$  and the top quark reconstructed masses. The top quark on the  $H^+$  side cannot be fully reconstructed due to the presence of the neutrino, but information on its azimuthal angle,  $\phi$ , and transverse momentum,  $p_T$ , can still be extracted.

At this stage a large number of background events still remains, mainly from Standard Model  $t\bar{t}$  as well as from QCD and single-top production. In order to discriminate against the latter two, two cuts (items 8 and 9 in Table 3.1.1) are applied aiming to enhance the topology of  $t\bar{t}$  decays.

Table 1:  $t\bar{t} \rightarrow bH^+bW \rightarrow b\tau(had)vbqq$ : Applied precuts. A  $b$ -tagging cut is applied to all jets, yielding  $b$  jet reconstruction efficiency of about 70%. For  $\tau$  jets, a cut on the  $\tau$ -tagging variable is applied such that a reconstruction efficiency of about 32% is obtained for a pseudorapidity  $|\eta| < 1.5$ , and a tighter cut (due to the high QCD jet fake-rate for large  $\eta$ ) for  $|\eta| > 1.5$  leads to an efficiency of about 20% in this region. The  $E_T^{miss}$  cut is increased to 50 GeV if only the signature xE50\_L1\_TAU30 has triggered the event.

Cuts I	Cuts II
1. exactly 1 $\tau$ -tagged jet with $p_T > 35$ GeV	6. $ m_W^{rec} - m_W  < 30$ GeV
2. exactly 2 $b$ -tagged jets with $p_T > 15$ GeV	7. $ m_t^{rec} - m_t  < 40$ GeV
3. at least 2 non-tagged jets with $p_T > 15$ GeV	8. $\Delta\phi(p_T^{\text{hardest top}}, p_T^{\text{softest top}}) > 2.5$
4. veto on isolated leptons with $p_T > 5$ GeV	9. $p_T^{\text{hardest top}} / p_T^{\text{softest top}} < 2$
5. $E_T^{miss} > 40/50$ GeV	

Figure 1:  $t\bar{t} \rightarrow bH^+bW \rightarrow b\tau(had)\nu bqq$ : Likelihood distribution (a) and transverse mass (b) for an  $H^+$  mass of 130 GeV and the corresponding background, stacked and normalized to the cross-section with  $\tan\beta = 20$ . The hatched area shows what would be expected from a Standard Model only scenario. A cut at 0.6 is made on the likelihood and at 65 GeV on the transverse mass.

### 3.1.2 Likelihood Discriminant

Following these cuts, the remaining background is dominated by  $t\bar{t}$  events, particularly those in which one  $W$  decays hadronically and the other to a  $\tau$  and a neutrino, and all reducible backgrounds are effectively suppressed. In order to discriminate between this background and the signal, a Likelihood Discriminant method has been implemented. The variables used (listed in Table 2) have been selected to reflect the two characteristics which distinguish the signal from the background: the heavier mass of the  $H^+$  compared to the  $W$ , with its effects on the kinematics of the event; and the difference in  $\tau$  polarization depending on the parent. This difference, exploited in variable I, will cause the leading track within the  $\tau$  jet to be harder [10]. Also selected combinations of variables have been included, as correlations are not included in the definition of the likelihood used. Likelihood discriminants are constructed for the five different studied  $H^+$  mass points (90, 110, 120, 130 and 150 GeV). Figure 1a shows the resulting likelihood distribution for an  $H^+$  mass of 130 GeV and the background.

Table 2:  $t\bar{t} \rightarrow bH^+bW \rightarrow b\tau(had)\nu bqq$ : Variables used for the Likelihood Discriminant.  $\tau$  denotes the  $\tau$  jet in the event,  $b_{H^+}$  is the  $b$  jet coming from the same top as the presumed  $H^+$ , and  $M(\tau, b_{H^+})$  is the invariant mass of the  $\tau$  jet and the  $b_{H^+}$  jet.  $\Delta R = \sqrt{(\Delta\phi)^2 + (\Delta\eta)^2}$  represents a distance.

I.	$p_T^{\text{leading } \tau \text{ track}}/p_T^\tau$	V.	$p_T^\tau/p_T^{b_{H^+}}$
II.	$1 - \cos(\Delta\phi(\tau, p_T^{\text{miss}}))$	VI.	$M(\tau, b_{H^+})$
III.	$1 - \cos(\Delta\phi(H^+, b_{H^+}))$	VII.	$\Delta R(\tau, b_{H^+})$
IV.	$M(\tau, b_{H^+}) \cdot \Delta R(\tau, b_{H^+})$		

A cut is applied on the obtained likelihood, requiring a value higher than 0.6 for an event to be retained (0.8 for a charged Higgs boson mass  $m_{H^+} = 150$  GeV, due to the better signal-background separation). The transverse mass of the  $H^+$  is then calculated for the retained events (shown in Fig. 1b). A final cut is then applied to this reconstructed transverse mass of the  $H^+$  candidate (at 50 GeV for  $m_{H^+} = 90$  GeV, at 60 GeV for  $m_{H^+} = 110$  and 120 GeV, at 65 GeV for  $m_{H^+} = 130$  GeV and at 75 GeV for  $m_{H^+} = 150$  GeV). These cut values have been selected to optimize the significance considering both systematic and statistical uncertainties.

## 3.1.3 Results

Table 3:  $t\bar{t} \rightarrow bH^+bW \rightarrow b\tau(had)vbqq$ : Selection cut flow. For each sample, the cross-sections after cuts are given in fb and for  $\tan\beta = 20$  in the first line and the relative cut efficiencies in the second line (in italics). Standard Model cross-sections are given for all the backgrounds. There are insufficient Monte Carlo statistics for the QCD events – see discussion in the text for a cross-section estimate.

Table 3 shows the selection cut flow for the five different signal mass points and all backgrounds studied in this note. The expected cross-section after the trigger and after the first and second set of cuts is presented, as well as the relative efficiency of each step.

It is difficult to draw conclusions about the suppression of the QCD background, due to its very high cross-section at the LHC. This leads to large statistical uncertainties since no simulated event survives the entire analysis chain. In fact already the expected cross-section after Cuts I (see Table 3) is governed by large statistical uncertainties. A very conservative upper limit for the expected number of QCD events can be obtained by assuming that the expected efficiency of QCD events is limited from above by the efficiency of the hadronic  $t\bar{t}$  events for all cuts for which the number of simulated QCD events is not sufficient to draw definitive conclusions<sup>2</sup>. This assumption is very conservative since the second set of cuts have been specifically designed to identify the  $t\bar{t}$  topology in order to reject QCD. Nevertheless, using this assumption, the cross-section of surviving QCD events is limited by 55 fb after the likelihood cut (for  $m_{H^+} = 130$  GeV), while after the cut on the transverse mass this estimate is down to 50 fb. Given the conservative nature of this estimate, the assumption that the background from QCD events is negligible compared to the one from  $t\bar{t}$  events is justified.

Table 4 shows the final expected cross-section following the cut on the likelihood discriminant and the further cut on the transverse mass of the  $H^+$  candidate. The shape of the likelihood discriminant

<sup>2</sup>After Cuts II, even more conservatively, this limit is taken from the efficiency for the  $t\bar{t} \geq 1$   $e/\mu/\tau$  events, due to the limited number of surviving hadronic  $t\bar{t}$  events at this point.

Table 4:  $t\bar{t} \rightarrow bH^+bW \rightarrow b\tau(had)\nu bqq$ : Final event selection results. The cross-sections after all cuts are given in fb and for  $\tan\beta = 20$  as well as the relative cut efficiencies. Standard Model cross-sections are given for  $t\bar{t}$ . Backgrounds not tabulated have been found to be negligible.

Channel	Cut	Signal		$t\bar{t} \geq 1$ $e/\mu/\tau$	
		[fb]	[/]	[fb]	[/]

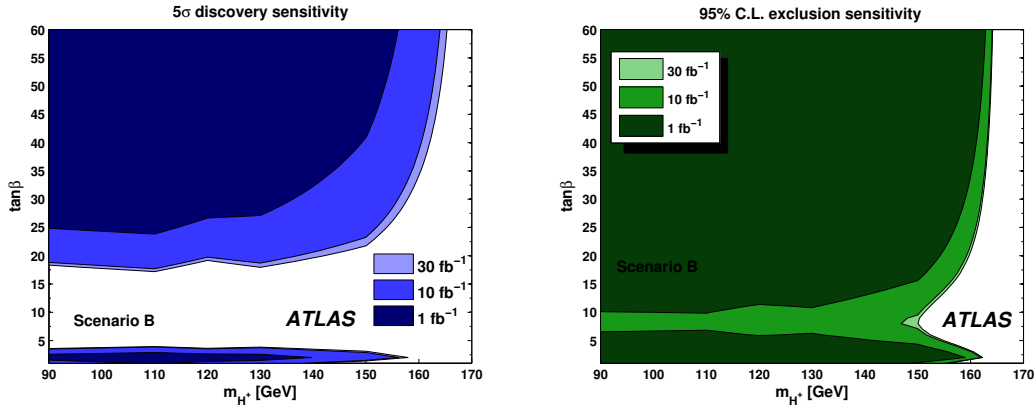

Figure 2:  $t\bar{t} \rightarrow bH^+bW \rightarrow b\tau(had)\nu bqq$ : Discovery (left) and exclusion contour (right) for Scenario B ( $m_h$ -max) [1]. Systematic and statistical uncertainties are included. The systematic uncertainty is assumed to be 10% for the background, and 24% for the signal (see Sections 5.2 and 5.1). The lines indicate a 5 $\sigma$  significance for the discovery and a 95% CL for the exclusion contour.

depends on the mass point for which the analysis is performed, i.e. one will need to run a separate analysis using a different likelihood discriminant for each mass point. Therefore the background rejection will naturally depend on the mass point for which it is evaluated.

The shape-based Profile Likelihood method (see Section 6) is applied on the entire transverse mass histogram for each masspoint, in order to extract the significance of the signal hypothesis. Fig. 2 shows the discovery contour in the  $(\tan\beta, m_{H^+})$  plane for an integrated luminosity of  $\mathcal{L} = 10 \text{ fb}^{-1}$  as well as the exclusion reach for  $\mathcal{L} = 1 \text{ fb}^{-1}$ .

### 3.2 $t\bar{t} \rightarrow bH^+bW \rightarrow b\tau(lep)\nu bqq$

The events of the leptonic  $\tau$  channel are characterized by a single isolated lepton, and large missing energy due to three neutrinos in the final state. A full reconstruction of the event is therefore impossible. Instead, kinematic properties of the event are used to discriminate between the signal and the main

background, which is the Standard Model semi-leptonic  $t\bar{t}$  process.

The branching ratio to  $\tau$  leptons of a light charged Higgs boson is expected to be almost 100%, while the Standard Model  $W$  decay is universal with respect to lepton flavor. This means that the most prominent signature of the signal is an excess of kinematically  $\tau$ -like events.

Furthermore, it is possible to construct a quantity that is bound by the charged Higgs boson mass (in analogy to the transverse mass in a  $W$  decay). This ‘charged Higgs boson transverse mass’ can be used to provide further discrimination power against the background, as well as a direct indication for the charged Higgs boson mass.

### 3.2.1 Preselection

**Trigger** The trigger requirement is based on either an isolated lepton or missing transverse energy (x $E$ ). Events are required to pass one of the following three trigger signatures (see Section 2): e22i\_xE30, mu20\_xE30, or xE80.

**Offline** Events that have passed the trigger are selected based on the following cuts:

- Exactly one isolated lepton with  $p_T > 5$  GeV. If the event has not been triggered by the xE80 signature then the requirement is raised to 20 GeV or 25 GeV (for the e25i\_xE30 and mu20i\_xE30 requirement, respectively).
- Missing transverse energy  $E_T^{miss} > 120$  GeV
- At least 4 jets with  $p_T > 40$  GeV and  $|\eta| < 2.5$
- Exactly two out of the four leading jets are tagged as  $b$  jets

Events surviving these selection cuts are expected to be dominantly  $t\bar{t}$  events.

### 3.2.2 Method for final state reconstruction

First, the hadronic  $W$  is reconstructed from the light (non  $b$ -tagged) jets. All possible pairs of light jets are considered and the one which gives an invariant mass closest to  $m_W$  is selected.

The assignment of the two  $b$  jets to the hadronic & leptonic sides is done using the angular correlation between the  $b$  jets and their associated particles, i.e. the lepton and the reconstructed  $W$ . The charge correlation between the lepton and its associated  $b$  jet is also used. The charge of the  $b$  jet is defined in the following way:

$$Q_{jet} = \frac{\sum (p_L^i)^\alpha q^i}{\sum (p_L^i)^\alpha} \quad (1)$$

where the sum is over tracks  $i$  belonging to the jet,  $q^i$  is the charge associated to the track, and  $p_L^i$  is the longitudinal component of the track momentum with respect to the jet direction. The parameter  $\alpha$  is optimized to give maximal separation between  $b$  and  $\bar{b}$  jets. The value obtained from optimization with MC data is  $\alpha = 0.5$ .

A likelihood ratio combining the angular and charge correlations is used. This likelihood ratio is defined between two hypotheses corresponding to the two possibilities of assigning the  $b$  jets. The hypothesis which achieves the higher likelihood ratio score is adopted. This algorithm selects the correct  $b$  jets assignment for about 70% of the events, when no cut is applied to the likelihood score of the selected hypothesis. Higher purity can be achieved at the cost of lower efficiency by placing such a cut, but this is not done for this analysis.

Figure 3:  $t\bar{t} \rightarrow bH^+bW \rightarrow b\tau(\text{lep})\nu bqq$ : (a)  $\cos \psi$  distribution, (b) W transverse mass distribution, for signal and background, after selection cuts, for charged Higgs boson masses of 90 and 150 GeV.

Once the  $b$  jets are assigned, the reconstructed top quark mass  $m_{top}^{rec}$  on the hadronic side of the event can be evaluated, and only those events which satisfy  $100 \text{ GeV} < m_{top}^{rec} < 300 \text{ GeV}$  are retained for further analysis.

### 3.2.3 Further reduction of $t\bar{t}$ background

In order to reduce the number of background events in which the lepton comes directly from a  $W$  decay, the decay angle  $\cos \psi$  is used

$$\cos \psi = \frac{2m_{\ell b}^2}{m_{top}^2 - m_W^2} - 1. \quad (2)$$

In such events,  $\psi$  is the angle between the lepton and top quark directions in the  $W$  rest frame (In the limit that the  $b$  quark is massless). The top quark, due to its large mass, couples mostly to the longitudinal polarization component of the  $W$  boson. As a result the  $\cos \psi$  distribution would have a large ( $\approx 70\%$ ) contribution that is symmetric around  $\cos \psi = 0$  [11–13]. However, both the left-handed component of the  $W$  boson and the indirect leptons coming from  $\tau$  decays contribute to the lower  $\cos \psi$  region, and this region is further enhanced by the selection cuts that favor events with large missing energy and therefore leptonic  $\tau$  decays. The signal contribution is similar to that of the indirect leptons, and the less energetic  $b$  jets, due to the higher  $H^+$  mass, push  $\cos \psi$  to even lower values. This can be seen in Fig. 3 (a). As a further selection cut, events are required to have  $\cos \psi < -0.8$ .

The transverse mass of the  $W$  (in the hypothesis of a leptonic  $W$  decay),  $m_T^W$ , calculated using the missing transverse momentum and the lepton transverse momentum, provides further discrimination against the  $t\bar{t}$  background with a direct lepton from a  $W$ . The separation is most distinct for low charged Higgs boson masses and is shown for two different  $H^+$  masses in Fig. 3 (b).

**Charged Higgs Boson Transverse Mass** A generalized transverse mass for the charged Higgs boson (in the hypothesis of a  $H^+ \rightarrow \tau\nu$  decay) in this channel can be defined. The derivation and properties of this variable are described in Reference [14].

$$(m_T^{H^+})^2 = (\sqrt{m_{top}^2 + (\vec{p}_T^{lep} + \vec{p}_T^b + \vec{p}_T^{miss})^2 - p_T^b})^2 - (\vec{p}_T^{miss} + \vec{p}_T^{lep})^2 \quad (3)$$

This transverse mass satisfies  $m_{H^+} < m_T^{H^+} < m_{top}$ . Figure 4 shows the distributions of  $m_T^{H^+}$  for several charged Higgs boson masses.

Figure 4:  $t\bar{t} \rightarrow bH^+bW \rightarrow b\tau(\text{lep})\nu bqq$ :  $m_T^{H^+}$  distribution, after selection cuts, for  $m_{H^+} = 90, 120$ , and  $150$  GeV. The dotted line represents the nominal simulated mass.

### 3.2.4 Results

The cross-sections of signal and background events surviving selection cuts are shown in Table 5.

Table 5:  $t\bar{t} \rightarrow bH^+bW \rightarrow b\tau(\text{lep})\nu bqq$ : Selection cut flow. For each sample, the cross-sections after cuts (in fb) are given in the first line and the relative cut efficiencies in the second line (in italics). The signal cross-sections correspond to  $\tan\beta = 20$ .

Figure 5 (a) shows the  $m_T^W$  differential cross-section for  $\tan\beta = 20$ . Figure 5 (b) shows the corresponding distributions for  $m_T^{H^+}$ .

The statistical significance of the signal is calculated from both the  $W$  transverse mass and the  $H^+$  transverse mass distributions, after event reconstruction and all selection cuts. The final significance is taken as the maximum of these two. In Fig. 6, the  $5\sigma$  discovery contour is plotted in the  $(m_{H^\pm}, \tan\beta)$  plane.

Figure 5:  $t\bar{t} \rightarrow bH^+bW \rightarrow b\tau(\text{lep})\nu bqq$ : Transverse mass differential cross-section for signal and background, for  $\tan\beta = 20$ , and for the hypothesis of (a)  $W$ , and (b)  $H^+$ .

Figure 6:  $t\bar{t} \rightarrow bH^+bW \rightarrow b\tau(\text{lep})\nu bqq$ : Discovery (left) and exclusion contour (right) for Scenario B ( $m_h$ -max) [1]. Systematic and statistical uncertainties are included. The systematic uncertainty is assumed to be 10% for the background, and 35% for the signal (see Sections 5.2 and 5.1). The lines indicate a  $5\sigma$  significance for the discovery and a 95% CL for the exclusion contour.

### 3.3 $t\bar{t} \rightarrow bH^+bW \rightarrow b\tau(\text{had})\nu b\ell\nu$

In this channel a light charged Higgs boson is produced in  $t\bar{t}$  decay. The  $W$  boson from one top quark decays into leptons, while the  $\tau$  lepton originating from the  $H^+$  decay results in a jet. At least three neutrinos are present in the event and thus the reconstruction of the complete event is impossible. Due to the high branching ratio of this charged Higgs boson decay ( $\text{BR}(H^+ \rightarrow \tau\nu) \approx 100\%$  for low  $m_{H^+}$ ), the signal can be observed as an excess of tau leptons in the final state over the main background of Standard Model  $t\bar{t}$  production.

Due to the production mechanism, the Standard Model  $t\bar{t}$  events will be the most important background to this channel. However, significant contributions from other backgrounds are still possible, and thus important to study: In the inclusive process  $pp \rightarrow W + \text{jets}$ , the final state is similar to the signal signature if one of the jets is mis-tagged as a  $\tau$  jet or a lepton and the  $W$  boson decays to the appropriate other object. Furthermore, the backgrounds constituted by single top quark events are considered. Single

top quarks can be produced with an associated  $W$  boson or  $b$  jet, and thus produce final states similar to the signal. Their contribution to the total background is however expected to be small due to the smaller cross-sections. Finally, the overwhelming background of QCD dijet is expected to be completely suppressed by demanding a high quantity of missing transverse energy and an isolated lepton.

### 3.3.1 Event Selection

**Trigger:** Events are required to pass one of the following three trigger items (see Section 2):  $e22i\_xE30$ ,  $\mu20\_xE30$ , or  $xE40\_3j20\_L1\_TAU30$ .

**Selection:** To select signal events and suppress the Standard Model  $t\bar{t}$  background several small differences between the processes are exploited. The following cuts are applied:

1.  $N_{e,\mu} \geq 1$ : At least one isolated lepton with  $p_T > 10$  GeV; muons with  $|\eta| < 2.7$  and electrons with  $|\eta| < 2.5$  are considered.
2.  $N_{\text{jets}} = N_{\text{light jets}} + N_{b \text{ jets}} + N_{\tau \text{ jets}} \geq 3$ : At least three jets with  $p_T > 20$  GeV.
3.  $N_{\tau \text{ jet}} \geq 1$ : At least one of the jets is required to be  $\tau$ -tagged. A  $\tau$  jet quality cut is applied, leading to a  $\tau$  jet reconstruction efficiency of about 30%.
4.  $N_{b \text{ jet}} \geq 1$ : At least one  $b$  jet with  $p_T > 20$  GeV is required, and a  $b$  jet quality cut is applied, leading to a  $b$  jet efficiency of about 60%.
5.  $p_T^\tau > 40$  GeV
6.  $p_T^e > 25$  GeV or  $p_T^\mu > 20$  GeV: This cut is only applied if the event was triggered by the appropriate lepton signature. If both lepton trigger requirements are met then only the cut on  $p_T^e$  is applied.
7.  $q_\tau + q_l = 0$ : The  $\tau$  jet and the lepton are required to have opposite charge.
8.  $E_T^{\text{miss}} > 175$  GeV

Figure 7 (a) shows the jet multiplicity of the signal and the main  $t\bar{t}$  background. While there are more jets for the  $t\bar{t}$  background than the signal a cut on jet multiplicity suppresses other backgrounds. Figure 7 (b) displays the  $\tau$  transverse momentum ( $p_T^\tau$ ). Cut 6 is only applied, if the event was triggered by a lepton signature. For such events, a  $p_T$  cut is applied to the reconstructed lepton according to the trigger threshold.

### 3.3.2 Results

In Table 6 the cross-sections for signal and background after each cut are shown. The first two cuts select events which include a lepton and three jets, assumed to be the two  $b$  jets and a  $\tau$  jet. These cuts are motivated by the final state under study, but do not reduce the most important leptonic  $t\bar{t}$  background. Requiring one jet to be a  $\tau$  jet removes more than 95% of the  $t\bar{t}$  background while at least one quarter of the signal remains, depending on the charged Higgs boson mass. Only one jet is required to be  $b$ -tagged, which is motivated by the fact that  $m_{H^+} > m_W$  and thus the  $b$  quark produced in  $t \rightarrow bH^+$  is in average softer (the most probable value for  $p_T^b$  is about 55 GeV for  $t \rightarrow bW$ , and between 15 GeV for  $m_{H^+} = 150$  GeV and 45 GeV for  $m_{H^+} = 90$  GeV for  $t \rightarrow bH^+$ ). The  $b$ -tagging efficiency decreases quickly for low  $p_T^b$  [5] and thus the number of reconstructed  $b$  jets decreases with increasing  $m_{H^+}$ .

Due to the mass difference mentioned above and the  $\tau$  polarizations being different depending on whether the  $\tau$  jet originated from an  $H^+$  or  $W$ , the  $\tau$ -jet is expected to be harder for the signal than the background, motivating a cut on  $p_T^\tau$ . A harder  $\tau$  jet in turn leads to more missing energy, thus making

Figure 7:  $t\bar{t} \rightarrow bH^+bW \rightarrow b\tau(had)\nu b\ell\nu$ : (a) Multiplicity of jets and (b)  $\tau$  jet transverse momentum ( $p_T^\tau$ ).

Figure 8:  $t\bar{t} \rightarrow bH^+bW \rightarrow b\tau(had)\nu b\ell\nu$ :  $E_T^{miss}$  differential cross-section after all cuts for  $\tan\beta = 20$ . The signal contributions for the different mass hypothesis are individually stacked on top of the background distribution.

the  $E_T^{miss}$  an attractive variable to cut on. A high value is required for  $E_T^{miss}$ . This is mainly needed to optimize the significance with respect to the systematic error. Multidimensional optimization attempts have shown that above respective thresholds, the significance is not very sensitive to changes in the values of other continuous selection cuts (such as  $p_T^\tau$ ).

The normalized number of events as a function of the missing transverse energy is shown in Fig. 8. A clear excess is observable for low charged Higgs boson masses, while close to the top quark mass there is only sensitivity for very high values of  $\tan\beta$ . Figure 9 shows the final discovery and exclusion contours for the channel under investigation. A significant region of the parameter space above  $\tan\beta = 30$  is covered by this decay mode, while the sensitivity for low and intermediate  $\tan\beta$  is limited.

## 4 Heavy Charged Higgs Boson Searches

In this chapter, charged Higgs boson searches in the two heavy  $H^+$  ( $m_{H^+} \gtrsim m_t$ ) channels selected for investigation are presented:

- $gg/gb \rightarrow t[b]H^+ \rightarrow bq\bar{q}[b]\tau(had)\nu$
- $gg/gb \rightarrow t[b]H^+ \rightarrow t[b]tb \rightarrow bW[b]bWb \rightarrow b\ell\nu[b]bqqb$

The notation  $[b]$  implies the additional  $b$  given in the production mode  $gg \rightarrow tbH^+$ , which is not produced in the mode  $gb \rightarrow tH^+$ . All plots, tables and results in this section are based on the trigger menu for an

Table 6:  $t\bar{t} \rightarrow bH^+bW \rightarrow b\tau(had)\nu b\ell\nu$ : Event selection cut flow. For each sample, the cross-sections after cuts are given in fb and for  $\tan\beta = 20$  in the first line and the relative cut efficiencies in the second line (in italics).

Figure 9:  $t\bar{t} \rightarrow bH^+bW \rightarrow b\tau(had)\nu b\ell\nu$ : Discovery (left) and exclusion contour (right) for Scenario B ( $m_h$ -max) [1]. Systematic and statistical uncertainties are included. The systematic uncertainty is assumed to be 10% for the background, and 41% for the signal (see Sections 5.2 and 5.1). The lines indicate a  $5\sigma$  significance for the discovery and a 95% CL for the exclusion contour.

Figure 10:  $gg/gb \rightarrow t[b]H^+ \rightarrow bqq[b]\tau(had)\nu$ : Probability density functions for  $t\bar{t}$  and two signal mass points. The plots show, from the upper left to the lower right,  $\log(p_T^\tau)$ ,  $\log(E_T^{miss})$ , and  $1 - \cos(\Delta\phi)$ .

instantaneous luminosity of  $L=10^{33}\text{cm}^{-2}\text{s}^{-1}$  presented in Section 2, on the signal cross-sections for the  $m_h$ -max MSSM scenario (see Reference [1]) and the background cross-sections given in Reference [8].

#### 4.1 $gg/gb \rightarrow t[b]H^+ \rightarrow bqq[b]\tau(had)\nu$

The following section describes the event selection for the  $H^+ \rightarrow \tau\nu$  channel for the case  $m_{H^+} \gtrsim m_t$ . The signal final state is characterised by a hard  $\tau$  jet, large missing transverse momentum (due to the neutrino), one or two  $b$  jets, two light jets, a  $W$  boson and a top quark (the mass of which can be reconstructed) and has previously been investigated in Reference [15].

The main background to this signal channel are  $t\bar{t}$  decays, in particular when one of the top quarks decays to a  $\tau$  jet,  $t \rightarrow b\tau(had)\nu$ , and the other one hadronically,  $t \rightarrow bqq$ . However, other  $t\bar{t}$  modes can also contribute when some of the objects in the event are not correctly reconstructed, e.g. a light jet as a  $\tau$  jet. Other backgrounds to be considered are single top,  $W$ +jets and QCD multi-jet events. A parametrized detector simulation has been used to evaluate the leptonic ( $e, \mu, \tau$ )  $t\bar{t}$  background. The parametrization has been adjusted (using a smaller full detector simulation  $t\bar{t}$  sample) such that the distributions of all the quantities in the events agree with the full detector simulation.

##### 4.1.1 Preselection

**Trigger:** The trigger selection employs items of the  $H^+$  trigger menu (see Section 2). Events are required to pass at least one of the two following trigger item combinations: `xE40_3j20_L1_TAU30` or `xE50_L1_TAU30`.

**$\tau$  jet reconstruction:** Only  $\tau$  jet candidates with transverse momenta greater than 15 GeV with a pseudorapidity outside of the crack region  $1.4 < \eta < 1.6$  are considered, and a high cut on the  $\tau$  quality variable is placed yielding a  $\tau$  reconstruction efficiency of about 20% and leading to a high rejection of parton jets. Exactly one  $\tau$  jet is required in the event, followed by a cut of  $p_T^\tau > 50$  GeV in order to reduce the QCD background at an early stage.

**Jet reconstruction:** At least three more jets with  $p_T > 15$  GeV are required, and exactly one of them has to be  $b$ -tagged. For this purpose, a  $b$ -tagging cut is applied to all jets with a  $b$ -tagging efficiency of about 70%.

**Missing Transverse Energy:** A soft cut of 40 GeV on the transverse missing energy  $E_T^{miss}$  is applied to remove most of the QCD background already in the preselection, while it affects the  $t\bar{t}$  background only slightly (about 30% of the  $t\bar{t}$  events with leptons are removed).

Figure 11:  $gg/gb \rightarrow t[b]H^+ \rightarrow bqq[b]\tau(had)\nu$ : Likelihood distributions. The areas are normalized to unity. The background likelihood for 170 GeV does not peak at 0 because of the trigger selection (and to a smaller degree the less stringent preselection cuts for the PDF determination) which already removes most of the events in the first bins.

**W boson and top quark reconstruction:** For further discrimination of all backgrounds without hadronically decaying top quarks, an attempt is made to reconstruct a W boson and a top quark. For all combinations of the  $b$  jet with two other jets, the minimum value of

$$\chi^2 = \frac{(m_{jj} - m_W)^2}{\sigma_{m_W}^2} + \frac{(m_{b(jj)^r} - m_t)^2}{\sigma_{m_t}^2} \quad (4)$$

is calculated for each event ( $m_W$  and  $m_t$  are the nominal W and  $t$  masses,  $(jj)^r$  are the two jets used in the W reconstruction, rescaled to the W mass, and  $\sigma_{m_W}$  and  $\sigma_{m_t}$  represent the resolution of the W and  $t$  mass reconstruction, 10 GeV and 15 GeV). The resulting  $\chi^2$  values are required to be smaller than 3.

**Lepton veto:** To eliminate events with leptons (in particular leptonic  $t\bar{t}$  modes), events with at least one isolated lepton ( $e, \mu$ ) with  $p_T^\ell > 7$  GeV are rejected.

The preselection aims at suppressing the reducible background such that only  $t\bar{t}$  events involving one hadronic and one semileptonic top quark decay survive.  $W$ +jets events are successfully removed by requiring a  $b$ -tagged jet and a reconstructed top quark in the events, single top events by requiring a hard  $\tau$  jet and high  $E_T^{\text{miss}}$  together with a reconstructed hadronically decaying top quark, and QCD events by requiring high  $E_T^{\text{miss}}$  (and additionally by requiring  $b$ - and  $\tau$ -tags and a reconstructed top quark).

#### 4.1.2 Likelihood for further reduction of the $t\bar{t}$ background

After the preselection cuts, the background is dominated by  $t\bar{t}$  events with one  $W$  decaying hadronically, and the other one to a hadronically decaying  $\tau$  lepton and a neutrino (75% of the remaining background). An uncorrelated likelihood approach has been chosen to reduce this background, employing the following discriminant variables: (i)  $p_T^\tau$ , (ii)  $E_T^{\text{miss}}$ , (iii)  $\Delta\phi$  (azimuthal angle between the  $\tau$  jet and the missing momentum), (iv)  $H_T$  (scalar sum of the  $p_T$  of all jets in the event (excluding  $\tau$  jets), and (v)  $p_T^{\text{ratio}}$  (ratio between the transverse momenta of the  $\tau$  jet and the hardest jet not used for the top quark reconstruction).

The probability density functions (PDFs) have been created for each signal mass point and for the  $t\bar{t}$  sample (with at least one leptonic W decay) using full detector simulation. Slightly less stringent preselection cuts ( $p_T^\tau > 40$  GeV instead of 50 GeV, at least 1  $b$  jet instead of exactly 1, and a maximum W/top reconstruction  $\chi^2$  of 6 instead of 3) and no trigger selection are used to obtain the PDFs in order to keep a sufficiently high number of simulated events. The PDFs for two mass points and the  $t\bar{t}$  background are shown in Fig. 10.

Figure 12:  $gg/gb \rightarrow t[b]H^+ \rightarrow bq\bar{q}[b]\tau(had)\nu$ :  $H^+$  transverse mass distributions for three signal mass points and the corresponding background for  $\tan\beta = 35$ . The signal events are stacked on top of the background events.

The likelihood distributions for two example mass points are shown in Fig. 11. A cut requiring the likelihood to be higher than 0.9 ( $m_{H^+} = 400$  and  $600$  GeV) or 0.95 (other mass cases) is applied and the charged Higgs boson transverse mass of the remaining events is plotted as a final distribution to extract the significance of the  $H^+$  signal. These transverse mass distributions are shown in Fig. 12. A clear excess can be observed for lower  $H^+$  masses, but the shapes are similar for signal and background. Varying cuts to change the signal-to-background ratio would be a quick way to establish the excess if it was statistically unambiguous, followed by data-driven background estimation methods as described in Section 5.2. For higher  $H^+$  masses, sensitivity is only given for higher values of  $\tan\beta$ , but the signal and background shapes are clearly distinguishable.

**Event selection summary:** The following list summarizes the event selection:

- Trigger: Trigger xE40\_3j20\_L1\_TAU30 or xE50\_L1\_TAU30
- Cut A: exactly one  $\tau$  jet with  $p_T^\tau > 50$  GeV, and  $E_T^{miss} > 40$  GeV
- Cut B: at least three additional jets
- Cut C: exactly one of the additional jets  $b$ -tagged
- Cut D: veto on a lepton ( $e, \mu$ ) with  $p_T^\ell > 7$  GeV
- Cut E: W boson and top quark reconstructed with  $\chi^2 < 3$
- Cut F: likelihood value greater than 0.95 (0.9 for  $m_{H^+} = 400$  and  $600$  GeV)
- Cut G:  $m_{H^+}$  in a certain mass window

#### 4.1.3 Results

The cross-section of signal and background events surviving preselection cuts are shown in Table 7. All backgrounds except for  $t\bar{t}$  with at least one leptonic W decay mode are efficiently suppressed at this stage. The QCD dijet selection efficiency is too small to draw definite conclusions due to its high cross-section, but assuming that dijet events in  $p_T$ -bins lower than 140 GeV cannot produce a hard  $\tau$  jet and three jets with the top quark-invariant mass (plus large missing  $E_T$ ), that the numbers presented for Cut B are of the right order of magnitude and that the relative efficiencies for the remaining cuts is smaller than for  $t\bar{t}$  events the conclusion can be drawn that the background from dijet events is negligible.

The efficiencies of the remaining Cuts F (likelihood) and G ( $m_{H^+}$ ) are shown separately in Table 8; as for these cuts the background efficiencies depend on the  $H^+$  mass hypothesis. At this point, all other backgrounds except for  $t\bar{t}$  events with W decays to  $e, \mu$  or  $\tau$  are negligible.

A signal-to-background ratio of the order of 1 has been achieved, resulting in robustness with respect to systematic uncertainties. The cross-section for very heavy  $H^+ \rightarrow \tau\nu$  production is small but a very

Table 7:  $gg/gb \rightarrow t[b]H^+ \rightarrow bqq[b]\tau(had)\nu$ : Preselection cut flow. For each sample, the cross-sections after cuts are given in fb and for  $\tan\beta = 35$  in the first line and the relative cut efficiencies in the second line (in italics). The size of the QCD dijet sample is too small to draw accurate conclusions.

good discrimination against the background can be obtained with the likelihood method. The resulting discovery contours are presented in Fig. 13 and show that a sizable region of the MSSM space which has not been explored experimentally before can be covered. Sensitivity is given for large  $\tan\beta$  and  $m_{H^+} < 500$  GeV.

#### 4.2 $gg/gb \rightarrow t[b]H^+ \rightarrow t[b]tb \rightarrow bW[b]bWb \rightarrow b\ell\nu[b]bqqb$

In this section the analysis strategy for the  $H^+ \rightarrow tb$  channel is outlined. This is a particularly challenging signal final state which includes 3 (or 4)  $b$  quarks, 2 light quarks, 1 high  $p_T$  lepton and one neutrino. The channel has previously been studied for ATLAS using fast detector simulation [16], and several aspects of the previous analysis have been adopted. However, the use of full simulation for the present study showed the need to add several new cuts to improve the signal to background ratio.

##### 4.2.1 Trigger

Events are required to pass one of the following trigger signatures (see Section 2): e22i\_xE30, mu20\_xE30, or xE40\_3j20\_L1\_TAU30.

##### 4.2.2 Preselection

Following the trigger, the events are required to pass a set of preselection criteria which define the minimum requirements needed for the event reconstruction:

- exactly 1 isolated lepton ( $e$  or  $\mu$ ) with  $p_T^e > 25$  GeV,  $p_T^\mu > 20$  GeV and  $|\eta| < 2.5$ .

Table 8:  $gg/gb \rightarrow t[b]H^+ \rightarrow bqq[b]\tau(had)\nu$ : Event selection results. The cross-sections after cuts are given in fb and for  $\tan\beta = 35$  as well as the relative cut efficiencies. The remaining background consists only of  $t\bar{t}$  events with at least one W decay to  $e, \mu$  or  $\tau$  plus  $\nu$ .

Channel	Cut	Signal		Background	
		[fb]	[/]	[fb]	[/]
$H^+$ 170 GeV	LH>0.95	3.8	0.26	2.3	0.012
	$m_T^{H^+} > 100$ GeV	3.8	0.99	2.1	0.91
200 GeV	LH>0.95	3.1	0.42	3.2	0.017
	$m_T^{H^+} > 120$ GeV	2.9	0.92	2.4	0.74

	$m_T^{H^+} > 300$ GeV	0.044	0.58	0.15	0.062

Figure 13:  $gg/gb \rightarrow t[b]H^+ \rightarrow bqq[b]\tau(had)\nu$ : Discovery (left) and exclusion contour (right) for Scenario B ( $m_h$ -max) [1]. Systematic and statistical uncertainties are included. The systematic uncertainty is assumed to be 10% for the background, and 44% for the signal (see Sections 5.2 and 5.1). The lines indicate a  $5\sigma$  significance for the discovery and a 95% CL for the exclusion contour.

- at least 5 jets with  $p_T > 20$  GeV and  $|\eta| < 5$ .
- at least 3  $b$ -tagged jets with  $|\eta| < 2.5$ .

**Lepton selection:** Electron candidates that pass the cuts on transverse momentum and pseudorapidity mentioned above are required to pass further identification and isolation criteria based on the shower shape in the electromagnetic calorimeter and the quality of the track in the inner detector. Concerning isolation, the energy in a cone of  $\Delta R = 0.20$  around the electron is required to be less than 20% of the electron transverse energy. The same isolation criteria is also applied to muon candidates.

**Jet selection and  $b$ -tagging criteria:** Jet multiplicity is one of the main sources of combinatorial background and the  $b$ -tagging efficiency is the major factor reducing the overall efficiency of the preselection. From jets passing the preselection cuts mentioned above, those within the range  $|\eta| < 2.5$  are considered

$b$ -tagged if passing a  $b$ -tagging quality cut leading to a  $b$  jet reconstruction efficiency of about 60%. Only events with at least 3  $b$ -tagged jets are accepted for the rest of the analysis.

#### 4.2.3 Reconstruction

Apart from the objects expected in the event final state, jets from the underlying event are also present leading to an increase of the jet multiplicity.

**Reconstruction of the leptonic  $W$ :** After the preselection is performed, all physics objects necessary for the complete reconstruction of the event are present except for the neutrino coming from the leptonically decaying  $W$ . In order to reconstruct the four-momentum of the neutrino, its transverse component is identified with the missing transverse momentum, and the longitudinal component is computed using the  $W$  mass constraint, leading to 0, 1 or 2 real solutions. In about 25% of the cases no real solution can be found. In order to recover those events, the approximation of neglecting the imaginary part of the solution is applied and has been found to have only a small effect on the top quark mass resolution.

**The Combinatorial Likelihood:** The next step is to associate the reconstructed physics objects with objects of the event, assuming a signal event topology. The number of possible combinations is very large and depends strongly on the number of light jets in the event. In order to overcome this combinatorial background, a likelihood function is defined. The likelihood formalism used in this analysis is based on  $m$  variables and should discriminate between  $n$  classes of events. For each of the  $m$  variables, first the probability density functions  $f_i^j(x_i)$  for each of the  $n$  classes are determined: Then the probability for an event to be of class  $j$  when the value  $x_i$  is measured for variable  $i$  is given by:

$$p_i^j(x_i) = \frac{f_i^j(x_i)}{\sum_{k=1}^n f_i^k(x_i)} \quad (5)$$

The information about all  $m$  variables are combined, ignoring correlations, to define the likelihood  $\mathcal{L}_j$  that an event belongs to class  $j$  when measuring the values  $x_i$  for variables  $i = 1, \dots, m$ :

$$\mathcal{L}_j = \frac{\prod_{l=1}^m p_l^j(x_l)}{\sum_{k=1}^n \prod_{l=1}^m p_l^k(x_l)} \quad (6)$$

A combinatorial likelihood is used to discriminate between the two classes of events: the correct and the wrong combinations. The likelihood is based on 8 variables:

- $m_{jj}$ : The invariant mass of two light jets.
- $m_{jjb}$ : The invariant mass of two light jets and one  $b$  jet.
- $m_{\ell vb}$ : The invariant mass of the lepton, one of the two solutions of the neutrino and one  $b$  jet.
- $p_T(b_H)$ : The transverse momentum of the  $b$  jet associated to the charged Higgs boson decay.
- $\Delta R(j, j)$ : The distance in the azimuthal-pseudorapidity plane ( $\Delta R = \sqrt{\Delta\phi^2 + \Delta\eta^2}$ ) between two light jets.
- $\Delta R(jj, b)$ :  $\Delta R$  between the sum of two light jets and one  $b$  jet.
- $\Delta R(\ell, b)$ :  $\Delta R$  between the isolated lepton and one  $b$  jet.
- $\Delta R(b_H, t_H)$ :  $\Delta R$  between the  $b$  jet and the top quark associated to the charged Higgs boson decay.

The likelihood is computed for each combination, and the combination with the highest likelihood in the event is chosen. If the maximum likelihood in the event is found to be less than 0.7, the event is rejected.

#### 4.2.4 Final Event Selection

After the event reconstruction is complete the physical backgrounds must be suppressed, of which the largest is  $t\bar{t} + jets$ . In order to reduce this background requiring 4  $b$  jets in the event is found to be crucial. The events passing the 4  $b$  jets requirements are then passed to a likelihood cut. The likelihood function used is based on 5 variables:

- $\eta_{bH}$ : The pseudorapidity of the  $b$  jet associated to the charged Higgs boson decay.
- $\sum_b w_b$ : The sum of the  $b$ -tagging weights of the 3  $b$  jets associated to the top quark and charged Higgs boson decay.
- $\langle \mathcal{L} \rangle$ : The average combinatorial likelihood in the event.
- $\Delta R(b_H, b_1 b_t)$ : The distance in the  $(\phi, \eta)$  plane between the  $b$  jet associated to the charged Higgs boson decay and the system of the two  $b$  jets associated to the top quark decays.
- $p_T^{b_1} / p_T^{b_2}$ : The  $p_T$  ratio of the two  $b$  jets not associated to the top quark decay,  $b_1$  being the one with the lowest  $p_T$ .

A cut on the output of this likelihood is applied. Its value is optimized to maximize the charged Higgs boson signal significance. This final step improves the significance by only 10 to 15%. The limited number of simulated events at this stage of the analysis, especially for the backgrounds, made it very difficult to optimize the choice of variables to include in the likelihood. Larger background samples will be needed to be able to define a more performant likelihood as it was done in Reference [16] with parametrized detector simulation.

#### 4.2.5 Results

Table 9 shows the selection cut flow after the different steps of the analysis for all simulated signal masses, and for the background for one  $H^+$  mass hypothesis. Table 10 presents the results for all simulated  $H^+$  hypotheses. In Fig. 14, the reconstructed charged Higgs boson mass for signal and physics background is shown. Since the limited number of simulated events does not allow the construction of a performing final selection likelihood, currently no  $H^+$  discovery or exclusion power can be extracted from this channel on its own and thus no contours are shown. It, however, contributes to the combined  $H^+$  sensitivity.

## 5 Systematic Uncertainties and Background Extraction From Data

The observation of a charged Higgs boson signal will be subject to statistical and systematic uncertainties. The systematic uncertainties stem from two sources: theoretical and experimental, and both are discussed in Section 5.1. Section 5.2 addresses how to extract the dominating  $t\bar{t}$  background from real data using a novel technique with so-called control samples.

### 5.1 Systematic Uncertainties

#### 5.1.1 Theoretical Systematic Uncertainties

Uncertainties in the expected production cross-sections for background and signal processes affect the discovery/exclusion potential of the channels under investigation. For all channels the uncertainty of the  $t\bar{t}$  background is particularly interesting since this is the dominant background. A 12% uncertainty on

Table 9:  $gg/gb \rightarrow t[b]H^+ \rightarrow t[b]tb \rightarrow bW[b]bWb \rightarrow b\ell\nu[b]bqqb$ : Selection cut flow. The cross-sections in fb are given after each cut and for  $\tan\beta = 35$  as well as the relative cut efficiencies. The backgrounds are shown for a charged Higgs mass boson hypothesis of  $m_{H^+} = 250$  GeV.

the NLL calculations is expected<sup>3</sup> leading to  $\sigma_{t\bar{t}} = 833 \pm 100$  pb [17]. Other backgrounds considered have similar or smaller uncertainties.

The branching ratios  $\text{BR}(t \rightarrow H^+ b)$  and  $\text{BR}(H^+ \rightarrow \tau\nu, cs, tb)$  have been determined with the FeynHiggs package, and similar systematic uncertainties apply [18]:

- $\Delta\text{BR}(t \rightarrow H^+ b)/\text{BR} < 10\%$
- $\Delta\text{BR}(H^+ \rightarrow \tau\nu)/\text{BR} < 5\%$
- $\Delta\text{BR}(H^+ \rightarrow cs, tb)/\text{BR} < 10\%$

In the high-mass region, the dominant systematic uncertainties on the charged Higgs boson production cross-section stem from the renormalization scale and factorization scale dependence and are calculated to be smaller than 20% in the whole MSSM space. The decrease of the cross-section due to supersymmetry loop corrections has been taken into account by adjusting the cross-sections with an additional

<sup>3</sup>The  $t\bar{t}$  cross-section will be measured in early LHC studies and transform this theoretical uncertainty into a much smaller experimental uncertainty, despite possible  $H^+$  effects in the measurement.

Figure 14:  $gg/gb \rightarrow t[b]H^+ \rightarrow t[b]tb \rightarrow bW[b]bWb \rightarrow b\ell\nu[b]bqqb$ : Reconstructed  $H^+$  mass. The value of  $\tan\beta$  has been chosen such that the pure statistical significance results in a value of 5.

factor as proposed in Reference [19], reflecting the altered relation between the bottom quark mass and its Yukawa coupling,  $\Delta m_b$ . Remaining supersymmetry loop corrections are shown to be negligible.

### 5.1.2 Experimental Systematic Uncertainties

Several quantities are subject to experimental systematic uncertainties: Tagging and reconstruction efficiencies, energy scales, energy resolutions and the luminosity determination. A detailed list of the systematical uncertainties considered, including their numerical value, is given in Table 11. Each systematic effect has been evaluated individually using the given uncertainty on an event-by-event basis.

The systematic uncertainty of the missing transverse energy is indirectly considered by taking the effects of the other systematic effects in the missing transverse momentum calculation into account. The systematic uncertainty estimates are generally conservative, in particular for the results assuming an integrated luminosity of  $30 \text{ fb}^{-1}$ . However, due to the usage of control samples to estimate the  $t\bar{t}$  background, the uncertainty values have a negligible impact on the  $H^+$  discovery sensitivity. Furthermore, tests have shown that even for the exclusion sensitivity the effect is very small: Assuming that the total experimental systematic uncertainty on the results could be halved, the change in sensitivity would only be of the order of 0.1 in  $\tan\beta$  for fixed values of  $m_{H^+}$ .

The dominant systematic uncertainty for all  $H^+$  channels is the jet energy scale, with values between 10% and 30%. Similarly, channels with hadronic  $\tau$  decays are strongly affected by the  $\tau$  jet energy scale. The channel  $H^+ \rightarrow tb$ , requiring 4  $b$ -tags, is strongly affected by uncertainties in  $b$ -tagging efficiency and rejection of light jets. The total experimental systematic uncertainty for the different  $H^+$  channels is between about 15% and 40% for the signal, affecting mainly the exclusion sensitivity. Similar values apply for the main background,  $t\bar{t}$ , which would remove most of the discovery potential. Thus a technique for a data-driven estimation of the background has been developed, greatly reducing the systematic uncertainty on the background. These “ $t\bar{t}$  control samples” are discussed in the following section.

Table 11: Effects of systematic uncertainties for all channels under investigation. The numbers are given in terms of percentage changes in cross-section. The channels are: 1:  $t\bar{t} \rightarrow bH^+bW \rightarrow b\tau(had)\nu bqq$  (see Section 3.1), 2:  $t\bar{t} \rightarrow bH^+bW \rightarrow b\tau(lep)\nu bqq$  (see Section 3.2), 3:  $t\bar{t} \rightarrow bH^+bW \rightarrow b\tau(had)\nu b\ell\nu$  (see Section 3.3), 4:  $gg/gb \rightarrow t[b]H^+ \rightarrow bqq[b]\tau(had)\nu$  (see Section 4.1) and 5:  $gg/gb \rightarrow t[b]H^+ \rightarrow t[b]tb \rightarrow bW[b]bWb \rightarrow b\ell\nu[b]bqqb$  (see Section 4.2).

## 5.2 $t\bar{t}$ Control Samples

The  $t\bar{t}$  process, in particular with one or more  $\tau$  leptons in the final state, is the dominant background to all analyses presented in this note. As the relative contributions from this background in different jet multiplicities are not known, the subtraction of these backgrounds using a data-driven method is necessary.

The method is data-driven in the sense that it uses  $t\bar{t} \rightarrow WbWb \rightarrow \mu\nu b\mu\nu b$  and  $t\bar{t} \rightarrow WbWb \rightarrow \mu\nu bqqb$  events collected by ATLAS to model the  $t\bar{t}$  backgrounds with one or more taus in the final state. After applying a minimal set of event selection criteria on the data (optimized for both efficiency and purity), one or two leptons from the events are removed and the 4 momenta of the removed objects are scaled into tau leptons with corrections for the mass. The tau leptons are fed into TAUOLA [20] for decay and the decay products are passed to the ATLAS detector simulation and reconstruction software. Finally the result is merged with the original event from which the leptons were removed to constitute a control sample.

The result is a data-driven control sample for each of the  $t\bar{t}$  final states which potentially constitute a background to one of the  $H^+$  analyses, using events from data that can be easily and efficiently triggered. With this method both the shape and the normalization of these backgrounds for all  $\tau$  decays (i.e., leptonic and hadronic decays, or in the case of analyses requiring two taus the lepton-hadron and hadron-hadron modes) can be modelled.

### 5.2.1 Obtaining $t\bar{t}$ Control Samples from Data

To extract the  $t\bar{t}$  control samples from data a set of selection criteria is applied. These are designed to optimize the efficiency and purity of the samples.

**Dimuonic channel** In order to extract the  $t\bar{t} \rightarrow WbWb \rightarrow \mu\nu b\mu\nu b$  sample, events with at least two isolated muons with  $p_T > 20$  GeV are selected. To reject muons coming from Z decays, events with a dimuonic invariant mass in the range 70-110 GeV are rejected. A further requirement is that the missing transverse energy in the event is larger than 40 GeV.

Table 12 summarizes the result of the above selection. The efficiency of the signal (dimuonic  $t\bar{t}$  events) to survive this selection is 28% and the sample purity is estimated to be 71%.

Table 12: Efficiency and purity for collecting  $t\bar{t}$  dimuonic events. Each  $mu20$  indicates a generator level cut requiring one muon with  $p_T > 20$  GeV.

Process	cross-section [fb]	efficiency	events [fb-1]
$t\bar{t}$ signal	9310	0.284	2641
$t\bar{t}$ background	823690	$4.96 \cdot 10^{-4}$	407
W+Jets	202400	$1.61 \cdot 10^{-4}$	33
Z+Jets	210290	$1.45 \cdot 10^{-3}$	305
$b\bar{b}(mu20mu20)$	261000	$1.23 \cdot 10^{-3}$	322
Total background	-	-	1067

**$\mu$ +jet channel** The selection criteria for the  $t\bar{t} \rightarrow WbWb \rightarrow \mu\nu bqqb$  sample are designed to reject  $b\bar{b} \rightarrow 1\mu + X$  events which have a large cross-section. Events are accepted if an isolated muon is found and two jets in the event with transverse momenta above 40 GeV have an invariant mass within 20 GeV of the nominal W mass. Events with high  $p_T$  muons in the jets are rejected. A missing transverse energy cut of 40 GeV is applied, as well as a requirements of least two more jets with transverse momenta above 40 GeV. At least one of these jets is required to be a  $b$ -tagged. The overall transverse energy of the event is required to be larger than 250 GeV and events with a high  $p_T$  isolated electron are rejected.

The results of the above selection are summarized in Table 13. The selection efficiency for signal events is 8.6% and the signal purity is 74%.

Table 13: Efficiency and purity for collecting  $t\bar{t}$  muon+jets events.

Process	cross-section [fb]	efficiency	events [fb-1]
$t\bar{t}$ signal	119040	$8.62 \cdot 10^{-2}$	10263
$t\bar{t}$ background	713960	$1.80 \cdot 10^{-3}$	1287
W+Jets	202400	$5.61 \cdot 10^{-3}$	1134
Z+Jets	210290	$2.84 \cdot 10^{-4}$	74
$b\bar{b}(mu20)$	13600000	$8.40 \cdot 10^{-5}$	1147
Total background	-	-	3642

### 5.2.2 Method Validation

To thoroughly test the  $t\bar{t}$  control sample method, the produced events have to be run through the different analyses and the obtained shapes and normalizations have to be compared to the ones obtained in these analyses. However, a global check can be done by comparing various distributions from the two cases (a) “real”  $t\bar{t}$  events and (b) “scaled”  $t\bar{t}$  control sample events where muons have been replaced by  $\tau$  leptons. This has been done separately for three final states of interest.

Basic preselection cuts on quantities like transverse momenta have been applied, lower than or at most equal to the preselection cuts applied in the analyses which use the quantities plotted in the following. The MC@NLO event weights have not been taken into account in order to increase the available statistics since this has been shown not to bias the comparison.

Figure 15:  $t\bar{t} \rightarrow b\tau(\text{lep})\nu bqq$ : Left:  $W \rightarrow \tau(\text{lep})\nu$  transverse mass, both for the real and the scaled  $t\bar{t}$  events. Right: The corresponding bin-by-bin ratio. The gray band represents  $\pm 10\%$  around a ratio of 1.

Figure 16:  $t\bar{t} \rightarrow b\tau(\text{had})\nu bqq$ : Left:  $t \rightarrow b\tau(\text{had})\nu$  momentum, both for the real and the scaled  $t\bar{t}$  events. Right: The corresponding bin-by-bin ratio. The gray band represents  $\pm 10\%$  around a ratio of 1.

In Fig. 15, the  $W \rightarrow \tau(\text{lep})\nu$  transverse mass is shown for the  $t\bar{t} \rightarrow b\tau(\text{lep})\nu bqq$  mode. Here, for the scaled events, a muon has been replaced by a leptonically decaying  $\tau$ . For the modes  $t\bar{t} \rightarrow b\tau(\text{had})\nu bqq$  and  $t\bar{t} \rightarrow b\tau(\text{had})\nu b\ell\nu$ , in the scaled events a muon has been replaced by a hadronically decaying  $\tau$ . The  $t \rightarrow b\tau(\text{had})\nu$  momentum is shown in Fig. 16, demonstrating the success of this replacement.

The presented plots demonstrate that the dominant background of all  $H^+$  studies,  $t\bar{t}$ , can be modelled with the  $t\bar{t}$  control sample method. Even without the intended further refinement of the method, in the regions of interest quantities of the  $H^+$  analyses can be modelled within a 10% error margin. This is remarkable in particular for complex quantities, i.e. variables extracted from the combination of several objects (like the top quark mass), and gives confidence that the  $t\bar{t}$  control sample method allows to reproduce the relevant correlations in the event. Thus for all results a systematic  $t\bar{t}$  background uncertainty of 10% is assumed (while the signal systematic uncertainty is extracted from Monte Carlo events, see Section 5.1).

## 6 Combined Results

Figure 17: Scenario A: Combined Results. Left: Discovery contour, Right: Exclusion contour. Systematic and statistical uncertainties are included.

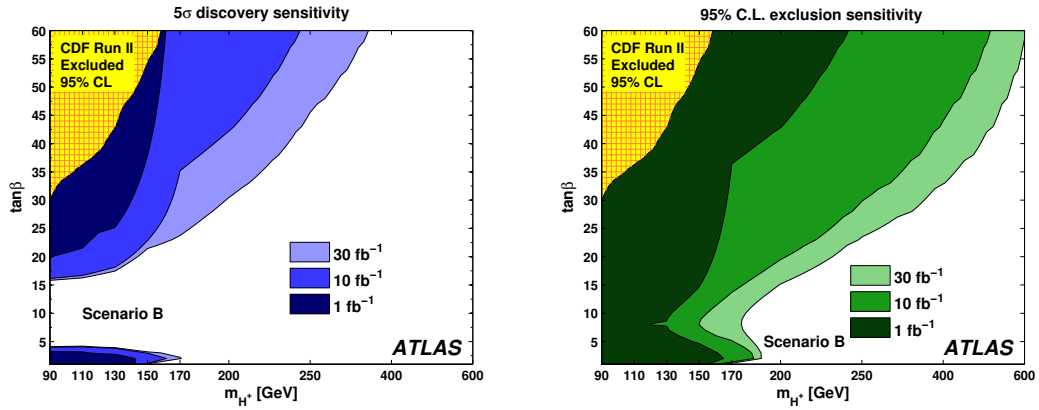

Figure 18: Scenario B ( $m_h$ -max): Combined Results. Left: Discovery contour, Right: Exclusion contour. Systematic and statistical uncertainties are included.

The sensitivities for discovery and exclusion are calculated with the Profile Likelihood method [21–23], which includes statistical and systematic uncertainties. The results are summarized in combined discovery and exclusion contours for all  $H^+$  channels for two MSSM Scenarios A and B [1], and three different integrated luminosities (1, 10, and 30 fb $^{-1}$ ). Figure 17 shows the result for the MSSM Scenario A.  $5\sigma$  discovery contours and 95% CL exclusion contours are shown. Figure 18 shows the same results for the MSSM Scenario B ( $m_h$ -max). Previous studies have shown that the dependence of the  $H^+$  discovery sensitivity on the specific choice of the MSSM parameter values is generally very small, with the exception of the Higgsino mixing parameter  $\mu$  [24, 25]. The discovery significance is calculated for both cases assuming a systematic background uncertainty of 10% following the study of  $t\bar{t}$  control samples (Section 5.2). The signal systematic uncertainties are discussed in Section 5.1. The statistical uncertainties arising from the use of Monte Carlo samples with a finite number of events have been consistently taken into account.

A discovery sensitivity is given for a large part of the  $m_{H^+}$  -  $\tan\beta$  space for both scenarios, but the difficult intermediate  $\tan\beta$  region, where the  $H^+$  cross-section has its minimum, is not covered.

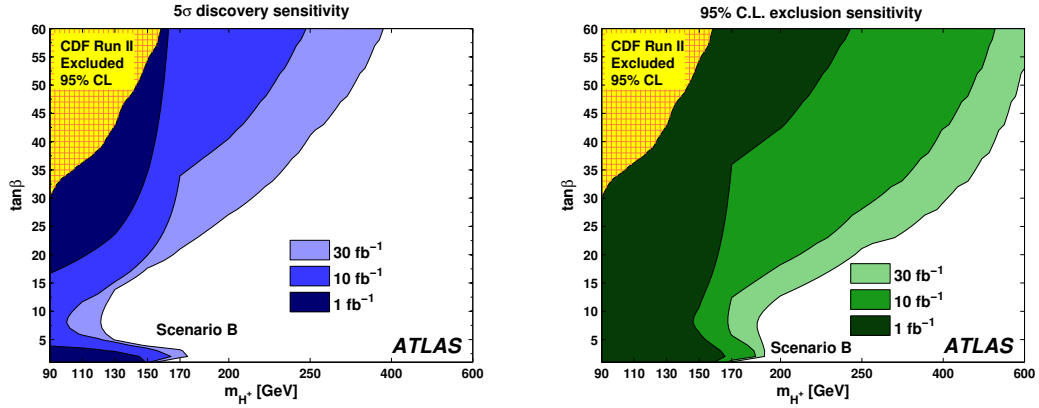

Figure 19: Scenario B ( $m_h$ -max): Combined Results. Left: Discovery contour, Right: Exclusion contour. Statistical errors arising from simulation statistics are neglected.

Figure 20: Model-independent: Combined light  $H^+$  results in the  $(m_{H^+}, \text{BR}(t \rightarrow H^+ b))$ -plane. Left: Discovery contour, Right: Exclusion contour. Systematic uncertainties and statistical uncertainties are included.  $\text{BR}(H^+ \rightarrow \tau \nu) = 1$  is assumed.

Figure 21: Model-independent: Heavy  $H^+$  results in the  $(m_{H^+}, \sigma)$ -plane. Left: Discovery contour, Right: Exclusion contour. Systematic uncertainties and statistical uncertainties are included.

However, a charged Higgs boson in this region could be excluded for values up to the top quark mass. Additional integrated luminosity does not give any further  $H^+$  sensitivity for a low-mass  $H^+$  after a few  $\text{fb}^{-1}$  have been recorded. The reason is the statistical error from the small  $t\bar{t}$  Monte Carlo sample which is equivalent to about  $1 \text{ fb}^{-1}$  at the LHC and makes extrapolation to higher luminosities difficult. Repeating the low-mass  $H^+$  studies with larger Monte Carlo samples is thus expected to lead to a significantly larger discovery and exclusion reach, as can be seen in Fig. 19 in which the statistical uncertainty arising from simulation statistics is neglected (i.e. it is assumed that the number of simulated events is much larger than the number of expected real-data events).

Figure 20 shows the discovery and exclusion contour in terms of the branching ratio  $t \rightarrow H^+ b$  as a function of  $m_{H^+}$ . With one year of low luminosity data, it will be possible to discover the charged Higgs boson if  $\text{BR}(t \rightarrow H^+ b)$  is larger than about 1-3%, and to exclude it even if this branching ratio is well below the percent level. Similar contours for a heavy  $H^+$  are presented in Fig. 21; here the y-axis shows the cross-section for the process  $gg/gb \rightarrow t[b]H^+ \rightarrow t[b]\tau\nu$ . Sensitivity is given for a cross-section of the order of 0.1pb. Both figures are model-independent in the sense that they can be interpreted in the context of any MSSM, other SUSY, or even non-SUSY scenario.

## 7 Conclusions

The ATLAS potential for discovering or excluding the existence of a charged Higgs boson in two different MSSM scenarios has been evaluated for five different final states of the  $H^+$  signal. Significant improvements of present day constraints can already be achieved with limited data (less than  $1 \text{ fb}^{-1}$ , about one month at low luminosity at the LHC) although it may not qualify as early physics due to its dependency on higher level reconstruction objects.

Below the top quark mass charged Higgs bosons are predominantly produced in top quark decays and the main decay mode is  $H^+ \rightarrow \tau\nu$ . Three different signal final states have been studied and analyzed separately, each of them separately outperforming the present sensitivity from the Tevatron experiments already with  $1 \text{ fb}^{-1}$  of data. The combined performance of the three channels yields a discovery reach for  $10 \text{ fb}^{-1}$  which covers  $\tan\beta$  values down to 20 and up to 4 for all charged Higgs boson masses up to about 150 GeV. For intermediate  $\tan\beta$  region (around  $\tan\beta = 7$ ), no discovery sensitivity is present, but a charged Higgs boson could be excluded in this region. The current sensitivity is primarily limited by simulation statistical uncertainties, it is thus expected that a larger production of simulated events will greatly improve the situation and give access to the intermediate  $\tan\beta$  region.

Two analyses have been conducted in the search for a heavy charged Higgs boson ( $m_{H^+} > m_t$ ), a region presently uncovered in direct searches. Here, the main production mode is through  $gb$  fusion ( $gb \rightarrow tH^+$ ) and the decay into a top and a  $b$  quark dominates. However, the dominant  $tb$  decay mode suffers from large irreducible backgrounds, and the combinatorial background. Consequently the discovery potential for a heavy charged Higgs boson is dominated by the  $\tau\nu$  decay mode, which despite its significantly smaller branching ratio allows for more efficient background suppression. The discovery reach in the context of the MSSM ( $m_h$ -max) strongly depends on the charged Higgs boson mass and reaches from ( $m_{H^+} = 200 \text{ GeV}$ ,  $\tan\beta = 28$ ) to ( $m_{H^+} = 350 \text{ GeV}$ ,  $\tan\beta = 58$ ) for an integrated luminosity of  $30 \text{ fb}^{-1}$ . Additionally, the model-independent discovery reach for a charged Higgs boson as a function of its production cross-section has been evaluated. A light  $H^+$  sensitivity for a  $\text{BR}(t \rightarrow H^+ b)$  down to the percent level is given for a discovery, and well below that level for an exclusion. For a heavy  $H^+$  decaying to  $\tau\nu$ , sensitivity is given for cross-sections of the order of 0.1pb.

The results presented in this note give confidence that the LHC and the ATLAS detector will be able to probe an extended Higgs sector over a sizable region of the MSSM parameter space. For a high SUSY mass scale, the charged Higgs boson could be the first signal of New Physics (and indication for Supersymmetry) discovered.

# Statistical Combination of Several Important Standard Model Higgs Boson Search Channels

## Abstract

In this note we describe statistical procedures for combination of results from independent searches for the Higgs boson. Here only the Standard Model Higgs is considered, although the methods can easily be extended to non-standard Higgs models as well as to other searches. The methods are applied to Monte Carlo studies of four important search channels:  $H \rightarrow \tau^+\tau^-$ ,  $H \rightarrow W^+W^- \rightarrow e\nu\mu\nu$ ,  $H \rightarrow \gamma\gamma$  and  $H \rightarrow ZZ^{(*)} \rightarrow 4$  leptons. The statistical treatment relies on a large sample approximation that is expected to be valid for an integrated luminosity of at least  $2 \text{ fb}^{-1}$ . Results are presented for the expected statistical significance of discovery and expected exclusion limits.

## 1 Introduction

Higgs searches will exploit a number of statistically independent decay channels. One wishes to combine all of the information from them to provide a single measure of the significance of a discovery or limits on Higgs production. The approach taken in this paper is based on frequentist statistical methods, where effects of systematic uncertainties are incorporated by use of the profile likelihood ratio.

The statistical procedures used for establishing discovery and setting limits are described in Section 2. These methods are very general and can be applied to the combination of results of essentially any search that will be carried out at the LHC. Section 3 summarizes the four search channels for the Standard Model Higgs boson considered in this note:  $H \rightarrow \tau^+\tau^-$ ,  $H \rightarrow W^+W^- \rightarrow e\nu\mu\nu$ ,  $H \rightarrow \gamma\gamma$  and  $H \rightarrow ZZ^{(*)} \rightarrow 4$  leptons.

The statistical treatment requires knowledge of the distribution of a test statistic based on the profile likelihood ratio. To determine these distributions by Monte Carlo so as to establish discovery at a high level of significance would require an enormous amount of simulated data, which is not practical at present. Therefore the distributions have been estimated using the functional form expected to hold in the large sample limit. Investigations shown in Section 3 indicate that this approximation should be reliable for an integrated luminosity above  $2 \text{ fb}^{-1}$ .

In Section 4 we show the result of the combination. For different values of the integrated luminosity and hypothesized Higgs mass, we present the signal significance expected assuming the Standard Model Higgs production rate, as well as expected upper limits on the Higgs production cross section, under the hypothesis of no Higgs signal.

The channels considered here focus on the search for a Higgs boson in the low-mass range. It is planned to include other channels in the future, e.g., further final states from the  $W^+W^-$  and  $ZZ$  modes. This will improve sensitivity especially at higher Higgs mass values.

## 2 Statistical methods

In this section we describe the general statistical model and likelihood function, first for a single channel and then generalized to multiple channels. In Section 2.2 we give the procedure used to establish discovery based on a frequentist significance test, where the effects of systematic uncertainties are incorporated by use of the *profile likelihood ratio*. Section 2.3 covers the corresponding methods for setting limits. For both discovery and exclusion one requires the sampling distribution of the statistic used in the test; this

is described in Section 2.4. Section 2.5 discusses a series of approximations used to determine expected values of the discovery significance and exclusion limits.

The approach taken in this note is to carry out tests for discovery and exclusion for fixed values of the Higgs mass  $m_H$ . In principle the entire procedure is then repeated for all masses, resulting in limits on or a measurement of  $m_H$ . In practice, an interpolation is made between finite steps in  $m_H$ .

## 2.1 The statistical model and likelihood function

First we consider the case of a single search channel. The measurement results in a set of numbers of events found in kinematic regions where signal could be present. These typically correspond to a histogram of a variable such as the mass of the reconstructed Higgs candidate, with the numbers of entries denoted by  $\mathbf{n} = (n_1, \dots, n_N)$ . In some cases one may consider a histogram with only one bin, i.e., the measured outcome is simply a number of candidate events found. The number of entries in bin  $i$ ,  $n_i$ , is modeled as a Poisson variable with mean value

$$E[n_i] = \mu L \varepsilon_i \sigma_i \mathcal{B} + b_i \equiv \mu s_i + b_i, \quad (1)$$

where  $L$  is the integrated luminosity,  $\varepsilon_i$ ,  $\sigma_i$  and  $\mathcal{B}$  are the signal efficiency, Higgs cross section, and branching ratio, and  $b_i$  is the expected number of background events. Here  $\mu$  is a signal strength parameter defined such that  $\mu = 0$  corresponds to the absence of a signal;  $\mu = 1$  gives the signal rate  $s_i$  expected from the Standard Model. If we consider a fixed Higgs mass  $m_H$ , the only parameter of interest is  $\mu$ . All other adjustable parameters needed to specify the model are called *nuisance parameters*.

In principle the expected background values  $b_i$  can be predicted using Monte Carlo models for Standard Model processes. In the measurements considered here, however, the systematic uncertainty in the Standard Model prediction is in many cases quite large, and this would severely limit the sensitivity of the search. Therefore data regions where one expects only a very small amount of signal (*control regions*) are used to constrain the background in the signal region (see also below).

For the  $i$ th bin of a histogram of a discriminating variable  $x$ , the expected signal and background can be written

$$s_i = s_{\text{tot}} \int_{\text{bin } i} f_s(x; \theta_s) dx, \quad (2)$$

$$b_i = b_{\text{tot}} \int_{\text{bin } i} f_b(x; \theta_b) dx, \quad (3)$$

where  $s_{\text{tot}}$  and  $b_{\text{tot}}$  are the total expected numbers of events in the histograms,  $f_s(x; \theta_s)$  and  $f_b(x; \theta_b)$  are the probability density functions (pdfs) of  $x$  for signal and background, and  $\theta_s$  and  $\theta_b$  represent sets of *shape parameters*.

The parametric forms of the pdfs  $f_s(x; \theta_s)$  and  $f_b(x; \theta_b)$  are determined from Monte Carlo simulations or data control samples. In the following we will use  $\theta = (\theta_s, \theta_b, b_{\text{tot}})$  to refer to all of the nuisance parameters. The signal normalization  $s_{\text{tot}}$  here is not an adjustable parameter, but rather is fixed equal to the Standard Model prediction.

In addition to the measured histogram  $\mathbf{n}$ , some search channels also make use of a set of subsidiary measurements  $\mathbf{m} = (m_1, \dots, m_M)$  in control regions where one expects mainly background events. These can be modeled as being Poisson distributed with mean values

$$E[m_i] = u_i(\theta), \quad (4)$$

where the  $u_i$  are calculable quantities depending on a set of parameters, at least some of which are the same as those entering into the predictions for  $s_i$  and  $b_i$  above. In practice the subsidiary measurements

are constructed so as to provide information on the background normalization  $b_{\text{tot}}$  and sometimes also on its shape.

If the measurement is based on counting events in a given kinematic region, i.e., without using the shape of a distribution, in the formalism above the histograms have a single bin. The value  $s = s_{\text{tot}}$  is then the Standard Model prediction for the signal and  $b = b_{\text{tot}}$  is the (unknown) expected background. There are then no shape parameters, and  $b$  itself plays the role of  $\theta$  as the single nuisance parameter. In this case the subsidiary measurement  $m$  is made in a control region where signal is absent (or can to good approximation be neglected), and has an expectation value

$$E[m] = u = \tau b , \quad (5)$$

where  $\tau$  is a scaling constant whose value can be estimated from a Monte Carlo simulation.

The likelihood function is the product of Poisson probabilities for all bins:

$$L(\mu, \theta) = \prod_{j=1}^N \frac{(\mu s_j + b_j)^{n_j}}{n_j!} e^{-(\mu s_j + b_j)} \prod_{k=1}^M \frac{u_k^{m_k}}{m_k!} e^{-u_k} . \quad (6)$$

Equivalently the log-likelihood is

$$\ln L(\mu, \theta) = \sum_{j=1}^N (n_j \ln(\mu s_j + b_j) - (\mu s_j + b_j)) + \sum_{k=1}^M (m_k \ln u_k - u_k) + C , \quad (7)$$

where  $C$  represents terms that do not depend on the parameters and thus can be dropped. Here and in (6) the parameters  $\theta$  enter through Eqs. (2), (3), and (4).

In the case where the presence of signal in the histogram  $\mathbf{n}$  gives a peak sitting on a smooth background, one does not need a subsidiary measurement  $\mathbf{m}$ . Rather, as long as the number of parameters in the models for the signal and background distributions is smaller than the total number of bins measured, one can determine the strength parameter  $\mu$  from the histogram  $\mathbf{n}$  alone. Here the regions away from the peak (the sidebands) play the role of the subsidiary measurement by providing information on the background level. Of course if an additional subsidiary measurement is available, this will improve the accuracy of the background determination, which will increase the sensitivity of the analysis.

In the case of several independent search channels, the method described above is generalized in a straightforward manner. For each channel  $i$  there is a likelihood function  $L_i(\mu, \theta_i)$ . Its general form is given by Eq. (6), except that all quantities carry an additional index  $i$  to label the channel except the global strength parameter  $\mu$ , which is assumed to be the same for all channels. Since the channels are statistically independent, the full likelihood function is given by the product

$$L(\mu, \theta) = \prod_i L_i(\mu, \theta_i) , \quad (8)$$

where  $\theta$  here represents all of the nuisance parameters.

Systematic uncertainties are effectively included in the analysis through the nuisance parameters  $\theta$ . The model must be sufficiently flexible, i.e., it must contain enough parameters, so that for at least some point in its parameter space it can be regarded as representing the truth. One must exercise some restraint in achieving this, however, as an increasing number of nuisance parameters leads to a decrease in sensitivity to the parameters of interest. Some of the components of  $\theta$  may be common among different channels, e.g., parameters relating to uncertainty in the integrated luminosity. These then represent a common (correlated) systematic uncertainty.

As an example, consider the signal efficiency  $\varepsilon$  that enters in the relation between the cross section and expected number of signal events. Suppose the efficiency has been estimated to have a value  $\hat{\varepsilon}$  and systematic uncertainty  $\sigma_{\hat{\varepsilon}}$ . To incorporate this uncertainty into the model, we can regard the measured

value  $\hat{\varepsilon}$  as a random variable whose true value  $\varepsilon$  is treated as a nuisance parameter. For the pdf  $f_{\varepsilon}(\hat{\varepsilon}; \varepsilon, \sigma_{\varepsilon})$  one could use, e.g., a Gaussian distribution centred about  $\varepsilon$ , or for a quantity such as the efficiency which must lie in the range  $0 \leq \varepsilon \leq 1$  one could use a pdf that automatically satisfies this constraint (e.g., a beta distribution). For whatever choice is deemed appropriate, the likelihood (6) is multiplied by  $f_{\varepsilon}(\hat{\varepsilon}; \varepsilon, \sigma_{\varepsilon})$ , evaluated with the best estimate  $\hat{\varepsilon}$ , and the parameter  $\varepsilon$  is included in the set of nuisance parameters  $\theta$ .

To test a hypothesized value of  $\mu$  we construct the profile likelihood ratio,

$$\lambda(\mu) = \frac{L(\mu, \hat{\theta})}{L(\hat{\mu}, \hat{\theta})} . \quad (9)$$

Here  $\hat{\theta}$  in the numerator denotes the value of  $\theta$  that maximizes  $L$  for the specified  $\mu$ , i.e., it is the conditional maximum-likelihood estimator (MLE) of  $\theta$  (and thus is a function of  $\mu$ ). The denominator is the maximized (full) likelihood function, i.e.,  $\hat{\mu}$  and  $\hat{\theta}$  are the MLEs. The presence of the nuisance parameters broadens the profile likelihood ratio as a function of  $\mu$  relative to what one would have if their values were fixed. This reflects the loss of information about  $\mu$  due to the systematic uncertainties.

The likelihood ratio (9) and procedures for incorporating systematic uncertainties applied here differ somewhat from those used for the searches carried out at LEP. Some of these differences are discussed further in Appendix A.

From the definition of the profile likelihood ratio one can see that  $0 \leq \lambda \leq 1$ , with  $\lambda(\mu) = 1$  implying good agreement between the data and the hypothesized value of  $\mu$ . Equivalently it is convenient to work with the quantity

$$q_{\mu} = -2 \ln \lambda(\mu) , \quad (10)$$

so that high values of  $q_{\mu}$  correspond to poor agreement between the data and the hypothesized  $\mu$ . The statistic  $q_{\mu}$  will have a sampling distribution  $f(q_{\mu}|\mu')$ . Here  $\mu$  refers to the strength parameter used to define the statistic  $q_{\mu}$ , entering in the numerator of the likelihood ratio, and  $\mu'$  is the value used to define the data generated to obtain the distribution (i.e., the ‘true’ value). For the special case  $\mu' = \mu$  and for a sufficiently large data sample, the pdf  $f(q_{\mu}|\mu)$  approaches a limiting form related to the chi-square distribution, discussed further in Section 2.4. For  $\mu' \neq \mu$ , the distribution of  $q_{\mu}$  is shifted to higher values, reflecting the decreased agreement between the data generated with  $\mu'$  and the hypothesis tested by  $q_{\mu}$ , as indicated in Fig. 1. The two cases of particular interest are  $\mu = 0$ , the background-only hypothesis, and  $\mu = 1$ , the hypothesis of background plus signal present at the Standard Model rate.

The level of compatibility between data that give an observed value  $q_{\mu, \text{obs}}$  for  $q_{\mu}$  and a hypothesized value of  $\mu$  is quantified by giving the  $p$ -value

$$p_{\mu} = \int_{q_{\mu, \text{obs}}}^{\infty} f(q_{\mu}|\mu) dq_{\mu} . \quad (11)$$

This is the probability, under the assumption of  $\mu$ , of seeing data with equal or greater incompatibility, as measured by  $q_{\mu}$ , relative to the data actually obtained. This is illustrated in Fig. 1, where the shaded area indicates the  $p$ -value of the hypothesized  $\mu$ . The figure also indicates the median value of  $q_{\mu}$  under the assumption of a different value of the strength parameter  $\mu'$  used to generate the data. For  $\mu$  and  $\mu'$  values that are increasingly different, the median  $\text{med}[q_{\mu}|\mu']$  moves further to the right. An observed value of  $q_{\mu}$  at this median would give a correspondingly small  $p$ -value for  $\mu$ .

## 2.2 Establishing discovery

To establish discovery we try to reject the  $\mu = 0$  (background-only) hypothesis, i.e., that there is no Higgs signal present. To do this we use the statistic  $q_0 = -2 \ln \lambda(0)$ . One expects to find a low value

Figure 1: Illustration of the determination of the  $p$ -value of a hypothesized value of  $\mu$ . The left-hand curve indicates the pdf of  $q_\mu$  for data generated with the same value of  $\mu$  as was used to define the statistic  $q_\mu$ ; this is used to determine the  $p$ -value of  $\mu$ , shown as the shaded region. The right-hand curve indicates the pdf of  $q_\mu$  for data generated with a different value of the strength parameter,  $\mu'$ .

of  $\lambda(0)$  (high  $q_0$ ) if the data include signal. Here even though one is testing the hypothesis that the Higgs does not exist, the definition of  $q_0$  depends on the hypothesized Higgs mass  $m_H$ . It enters through the denominator of the likelihood ratio (9), which contains the maximum-likelihood estimator  $\hat{\mu}$  for the strength of a Higgs signal at the mass  $m_H$ . By defining the test statistic in this way one maximizes the probability of rejecting the  $\mu = 0$  hypothesis if the Higgs boson exists at the specified mass. This search procedure is then carried out for all values of  $m_H$  (in practice an interpolation is carried out between finite steps in  $m_H$ ).

A given data set will result in an observed value  $q_{0,\text{obs}}$  of  $q_0$ . The level of compatibility between the data and the no-Higgs hypothesis is quantified by giving the  $p$ -value

$$p_0 = \int_{q_{0,\text{obs}}}^{\infty} f(q_0|0) dq_0 . \quad (12)$$

This is the probability, under the assumption of  $\mu = 0$  (background only), of seeing data as signal-like or more so relative to the data actually obtained. A small value is interpreted as evidence against  $\mu = 0$ , i.e., a discovery of the signal.

One can define the *significance* corresponding to a given  $p$ -value as the number of standard deviations  $Z$  at which a Gaussian random variable of zero mean would give a one-sided tail area equal to  $p$ . That is, the significance  $Z$  is related to the  $p$ -value by

$$p = \int_Z^{\infty} \frac{1}{\sqrt{2\pi}} e^{-x^2/2} dx = 1 - \Phi(Z) , \quad (13)$$

where  $\Phi$  is the cumulative distribution for the standard (zero mean, unit variance) Gaussian. Equivalently one has

$$Z = \Phi^{-1}(1 - p) , \quad (14)$$

where  $\Phi^{-1}$  is the quantile of the standard Gaussian (inverse of the cumulative distribution). In (13) and (14) the subscript 0 was dropped as these relations hold for all  $p$ -values, not only those of the  $\mu = 0$  hypothesis. The relation between  $Z$  and  $p$  is illustrated in Fig. 2.

A significance of  $Z = 5$  corresponds to  $p = 2.87 \times 10^{-7}$ . For a sufficiently large data sample, one would obtain a  $p$ -value of 0.5 for data in perfect agreement with the expected background. With the definition of  $Z$  given above, this gives  $Z = 0$ . If the data fluctuate below the expected background,  $Z$  becomes negative.

Note that according to the definition (14), a  $p$ -value of 0.05 corresponds to  $Z = 1.64$ . This should not be confused with a  $1.96\sigma$  fluctuation of a Gaussian variable that gives 0.05 for the two-sided tail area.

The significance of a discovery  $Z$  depends on the data obtained. To quantify our ability to discover a hypothesized signal in advance of seeing the data, we report the *median* significance under the assumption that the signal is present at the Standard Model rate,  $\mu = 1$ . Since  $Z$  is a monotonic function of  $p_0$ , and  $p_0$  is also a monotonic function of  $q_0$ , we have for the median significance,

Figure 2: Illustration of the correspondence between the significance  $Z$  and a  $p$ -value.

$$Z_{\text{med}} = \Phi^{-1}(1 - p_{0_{\text{med}}}) = \Phi^{-1}(1 - p_0(q_{0_{\text{med}}})) . \quad (15)$$

This can be obtained from the median value of  $q_0$  found using data generated under the assumption of  $\mu = 1$ .

A complete evaluation of the median significance is computationally difficult, as it requires a large number of repeated simulations of the full set of experimental outputs and determination of  $Z(q_0)$  from the combination of all channels. Therefore in this note we have used the approximate methods described in Section 2.5, which allow one to estimate quickly the median significance.

### 2.3 Setting limits

In addition to establishing discovery by rejecting the  $\mu = 0$  hypothesis, we can consider the alternative hypothesis of some non-zero  $\mu$  and try to reject it. A  $p$ -value is computed for each  $\mu$ , and the set of  $\mu$  values for which the  $p$ -value is greater than or equal to a fixed value  $1 - \text{CL}$  form a confidence interval for  $\mu$ , where typically one takes a *confidence level*  $\text{CL} = 95\%$ . The upper end of this interval  $\mu_{\text{up}}$  is the upper limit (i.e.,  $\mu \leq \mu_{\text{up}}$  at 95% CL).

To compute the  $p$ -value for a hypothesized  $\mu$  we first consider again the test statistic  $q_\mu = -2 \ln \lambda(\mu)$  as initially defined in (9) and (10). For purposes of computing limits, we introduce a modification to this definition as described below.

If the data are incompatible with the hypothesized  $\mu$ , one expects a large value of  $-2 \ln \lambda(\mu)$ , i.e.,  $\lambda(\mu)$  close to zero. If a data set generated according to the hypothesis  $\mu$  gives a large value of  $-2 \ln \lambda(\mu)$ , this can be the result of either an upward or downward fluctuation in  $\hat{\mu}$  relative to  $\mu$ . This is illustrated in the scatterplot of  $\hat{\mu}$  versus  $-2 \ln \lambda(\mu)$  shown in Fig. 3(a), which is from a toy Monte Carlo study with  $\mu = 0.8$ . The projection of the points on the  $\hat{\mu}$  axis is shown in Fig. 3(b). Note that  $\hat{\mu} \geq 0$  is imposed; the reasons for and consequences of this requirement are discussed in Section 2.4.

For purposes of setting an upper limit, however, we want to determine the smallest  $\mu$  such that there is a fixed small probability (one minus the confidence level) to find data as compatible with that value of  $\mu$  or less, relative to the degree of compatibility found with the real data. Therefore the data with upward fluctuations in  $\hat{\mu}$  are not counted when computing the  $p$ -value, because they would be compatible with some larger  $\mu$ . Therefore for purposes of computing limits we redefine  $q_\mu$  to be<sup>1</sup>

$$q_\mu = \begin{cases} -2 \ln \lambda(\mu) & \hat{\mu} \leq \mu , \\ 0 & \text{otherwise.} \end{cases} \quad (16)$$

The distribution of the new  $q_\mu$  thus corresponds to the lower branch only of the U-shaped scatterplot shown in Fig. 3(a).

<sup>1</sup>Equivalently, one could retain the definition  $q_\mu = -2 \ln(L(\mu, \hat{\theta})/L(\hat{\mu}, \hat{\theta}))$  by placing an upper bound on  $\hat{\mu}$  equal to  $\mu$ , i.e., by imposing  $0 \leq \hat{\mu} \leq \mu$ . In this way, when  $\hat{\mu} = \mu$  then one has  $q_\mu = 0$  just as in the case of discovery when testing  $\mu = 0$ .

Figure 3: (a) Scatterplot of  $\hat{\mu}$  versus  $-2 \ln \lambda(\mu)$ ; (b) the distribution of  $\hat{\mu}$  (see text).

Using the new definition (16), the  $p$ -value is given by the integral of  $f(q_\mu|\mu)$  from the observed value  $q_{\mu,\text{obs}}$  to infinity as in Eq. (11) and as illustrated in Fig. 1. The  $p$ -value is computed in this manner for all values of  $\mu$ , and the upper limit  $\mu_{\text{up}}$  at 95% confidence level is the largest value of  $\mu$  for which the  $p$ -value is at least 0.05.

The result can be summarized by giving the upper limit on  $\mu$  as a function of the Higgs mass  $m_H$ . Specifically, if we can reject the hypothesis  $\mu = 1$  at a certain confidence level, then the corresponding value of  $m_H$  is regarded as excluded for a Standard Model Higgs. The lowest mass value not excluded is the lower limit  $m_{\text{lo}}$ .

One is also interested in the median limit under the assumption that there is no Higgs. As in the case of the discovery significance, a full calculation of the median limit is difficult as it requires a large number of repeated simulations based on the full profile likelihood ratio. For purposes of this note, therefore, we use the approximation techniques described in Section 2.5.

## 2.4 Sampling distribution of the likelihood ratio

To determine the  $p$ -values required for both discovery and exclusion we need the sampling distribution, assuming data generated according to a given value of  $\mu$ , of the statistic  $q_\mu$ , i.e.,  $f(q_\mu|\mu)$ . For the case of discovery significance we use  $q_0 = -2 \ln \lambda(0)$ , and for setting limits we use  $q_\mu = -2 \ln \lambda(\mu)$  for  $\hat{\mu} \leq \mu$  and  $q_\mu = 0$ , otherwise.

To claim discovery we require  $p$ -values for  $\mu = 0$  down to around  $10^{-7}$ , and therefore to do this with a Monte Carlo simulation requires an extremely large number of simulated measurements. In practice this is only carried out for simple test cases. Even for setting limits at 95% confidence level, it is often not practical to use Monte Carlo.

Under a set of regularity conditions and for a sufficiently large data sample, *Wilks' theorem* says that for a hypothesized value of  $\mu$ , the pdf of the statistic  $-2 \ln \lambda(\mu)$  approaches the chi-square pdf for one degree of freedom [2]. More generally, if there are  $n$  parameters of interest, i.e., those parameters that do not get a double hat in the numerator of the likelihood ratio (9), then  $-2 \ln \lambda(\mu)$  asymptotically follows a chi-square distribution for  $n$  degrees of freedom. A proof and details of the regularity conditions can be found in standard texts such as [3].

In the searches considered here, the data samples are generally large enough to ensure the validity of the asymptotic formulae for the likelihood-ratio distributions. In our case, however, the distributions are modified because of constraints imposed on the expected number of events.

Usually when searching for a new type of particle reaction one regards the mean number of events contributed to any bin from any source, signal or background, to be greater than or equal to zero. In

some analyses it could be meaningful to consider a new effect that suppresses the expected number of events, e.g., the presence of a new decay channel could mean that the number of decays to known channels is reduced. Here, however, we will regard any contribution to an expected number of events as non-negative.

Assuming only non-negative event rates, the maximum-likelihood estimators for the parameters are constrained, e.g.,  $\hat{\mu} \geq 0$ . As a consequence, if the observed number of events is below the level predicted by the background alone, then the maximum of the likelihood occurs for  $\mu = 0$ , i.e., negative  $\mu$  is not allowed. We can consider the effect of having  $\hat{\mu} = 0$  on the distribution of  $q_\mu$  for two cases:  $\mu = 0$  and  $\mu > 0$ .

For  $\mu = 0$ , i.e., when computing the discovery significance, if  $\hat{\mu} = 0$  one has (see (9)),

$$\lambda(0) = \frac{L(0, \hat{\hat{\theta}})}{L(\hat{\mu}, \hat{\hat{\theta}})} = \frac{L(0, \hat{\hat{\theta}})}{L(0, \hat{\theta})} = 1, \quad (17)$$

since  $\hat{\mu} = 0$  and therefore  $\hat{\hat{\theta}} = \hat{\theta}$ . The statistic  $q_0 = -2\ln \lambda(0)$  is therefore equal to zero. This can be seen in the scatterplot of  $q_0$  versus  $\hat{\mu}$  in Fig. 4(a). Figure 4(b) shows the corresponding  $q_0$  distribution with the peak visible at  $q_0 = 0$ . The superimposed curve is a chi-square distribution multiplied by one half, corresponding to the half of the events with  $\hat{\mu} > 0$ .

Figure 4: (a) Scatterplot of  $\hat{\mu}$  versus  $q_\mu$  from a Monte Carlo study with  $\mu = 0$ ; (b) the distribution of  $q_0$  (see text).

From Fig. 4(b) one can see that except for the spike at  $q_0 = 0$  (when  $\hat{\mu} = 0$ ), the pdf of  $q_0$  can be well approximated by the chi-square pdf. Assuming a fraction  $w$  for the cases with  $\hat{\mu} > 0$  one has the pdf

$$f(q_0|0) = wf_{\chi_1^2}(q_0) + (1 - w)\delta(q_0). \quad (18)$$

In the usual case where upward and downward fluctuations of  $\hat{\mu}$  are equally likely we have  $w = 1/2$ . The  $p$ -value of the background-only hypothesis given an observation  $q_{0,\text{obs}}$  greater than zero is therefore

$$p = \int_{q_{0,\text{obs}}}^{\infty} wf_{\chi_1^2}(q_0) dq_0 = w(1 - F_{\chi_1^2}(q_{0,\text{obs}})), \quad (19)$$

where  $F_{\chi_1^2}$  is the cumulative chi-square distribution for one degree of freedom.

The second case to consider is  $\mu > 0$ , e.g., when one wants to set an upper limit on  $\mu$ . Under the hypothesis  $\mu$ , one obtains  $\hat{\mu} > \mu$  and  $\hat{\mu} \leq \mu$  with approximately equal probability. Figure 5 shows the distributions of  $q_\mu$  for both cases  $\hat{\mu} > \mu$  and  $\hat{\mu} \leq \mu$  obtained from the scatterplot Fig. 3(a), from a Monte Carlo study with  $\mu = 0.8$ .

Figure 5: Distributions of  $-2\ln\lambda(\mu)$  for (a)  $\hat{\mu} > \mu$  and (b)  $\hat{\mu} \leq \mu$ . The superimposed curves are chi-square distributions for one degree of freedom normalized to half the number of entries in the original distribution (see Fig. 3(a)).

From Fig. 5(a) one can see that for  $\hat{\mu} > \mu$ , the data follow the chi-square pdf quite accurately. This portion of the distribution is ignored, however, when setting upper limits on  $\mu$ , because of the modified definition of  $q_\mu$  (20) used for limits,

$$q_\mu = \begin{cases} -2\ln\lambda(\mu) & \hat{\mu} \leq \mu, \\ 0 & \text{otherwise.} \end{cases} \quad (20)$$

Suppose now  $\hat{\mu} \leq \mu$  with a probability  $w$ ; in practice this is close to one half. (Note for the case of  $q_0$ ,  $w$  is the probability of  $\hat{\mu} > \mu$ . The different definitions of  $w$  are used so as to give similar forms for  $f(q_0|0)$  and  $f(q_\mu|\mu)$ .) Thus for  $\hat{\mu} > \mu$  one has from (20)  $q_\mu = 0$ , and therefore the distribution has a delta function at  $q_\mu = 0$  with weight  $1 - w$ . The pdf of  $f(q_\mu|\mu)$  can therefore be written

$$f(q_\mu|\mu) = wf(q_\mu|\mu, \hat{\mu} \leq \mu) + (1 - w)\delta(q_\mu). \quad (21)$$

where  $f(q_\mu|\mu, \hat{\mu} \leq \mu)$  is the conditional pdf for  $q_\mu$  given  $\hat{\mu} \leq \mu$ .

For  $\hat{\mu} \leq \mu$ , one may sometimes find  $\hat{\mu}$  equal to zero, i.e., the lower edge of the allowed range, as can be seen in the scatterplot of  $\hat{\mu}$  versus  $q_\mu$  shown in Fig. 3(a). Although for the case  $\mu = 0$  this gave a peak at  $q_0 = 0$ , here it gives

$$\lambda(\mu) = \frac{L(\mu, \hat{\theta})}{L(\hat{\mu}, \hat{\theta})} = \frac{L(\mu, \hat{\theta})}{L(0, \hat{\theta})}, \quad (22)$$

which in contrast to (17) is not equal to unity. The effect of having  $\hat{\mu} = 0$  on the distribution of  $q_\mu$  is therefore more complicated than was the case for  $q_0$ .

In general for  $\hat{\mu} \leq \mu$ , the distribution of  $q_\mu$  falls off more steeply than the chi-square distribution. This is seen in Fig. 5(b). Therefore a  $p$ -value based on the chi-square formula will be larger than the true  $p$ -value, and the corresponding significance  $Z$  will be smaller. The upper limits obtained for  $\mu$  are therefore larger, i.e., a smaller set of  $\mu$  values is excluded.

If  $\mu$  is sufficiently large, then  $\hat{\mu}$  is very rarely pushed to zero and  $f(q_\mu|\mu, \hat{\mu} \leq \mu)$  approaches a chi-square distribution for one degree of freedom. For purposes of the present study, the chi-square approximation is adequate, but gives somewhat conservative limits. That is, we take the distribution of  $q_\mu$  to be

$$f(q_\mu|\mu) = wf_{\chi^2_1}(q_\mu) + (1 - w)\delta(q_\mu) \quad (23)$$

and use  $w = 0.5$ . One has therefore the same pdf for  $q_\mu$  using the modified definition (20) as was found in (18) for  $q_0$  based on the original definition,  $q_0 = -2\ln\lambda(0)$ .

To summarize the result above, the pdf of  $q_\mu$  can be approximated by a mixture of a chi-square pdf for one degree of freedom with weight  $w$  and a delta function at zero with weight  $1 - w$ . This holds both for discovery ( $\mu = 0$ ) and setting limits ( $\mu > 0$ ).

Consider now the variable

$$u = \sqrt{q_\mu} = \sqrt{-2\ln\lambda(\mu)}, \quad (24)$$

which has the pdf

$$f(u) = \Theta(u)w\sqrt{\frac{2}{\pi}}e^{-u^2/2} + (1-w)\delta(u), \quad (25)$$

where  $\Theta(u) = 1$  for  $u \geq 0$  and is zero otherwise. The second term in (25) follows from the fact that the values  $q_0 = 0$  and  $u = 0$  occur with equal probability,  $1 - w$ . Furthermore if a variable  $x$  follows the standard Gaussian distribution, then one can show  $x^2$  follows a chi-square distribution for one degree of freedom. Therefore if  $x^2$  follows a  $\chi^2$  distribution, then  $\sqrt{x^2}$  follows a Gaussian scaled up by a factor of two for  $x > 0$  so as to have a total area of unity.

The  $p$ -value of the hypothesis  $\mu$  for a non-zero observation  $q_{\mu,\text{obs}}$  is therefore

$$p = P(q_\mu \geq q_{\mu,\text{obs}}) = P(u \geq \sqrt{q_{\mu,\text{obs}}}) = 2w \int_{\sqrt{q_{\mu,\text{obs}}}}^{\infty} \frac{1}{\sqrt{2\pi}} e^{-u^2/2} du = 2w(1 - \Phi(\sqrt{q_{\mu,\text{obs}}})) . \quad (26)$$

Combining this with Eq. (14) for the significance  $Z$  gives

$$Z = \Phi^{-1}(1 - 2w(1 - \Phi(\sqrt{q_{\mu,\text{obs}}})) . \quad (27)$$

In the usual case where the weights of the chi-square and delta-function terms are equal, i.e.,  $w = 1/2$ , Eq. (27) reduces to the simple formula

$$Z = \sqrt{q_{\mu,\text{obs}}} . \quad (28)$$

## 2.5 Approximate methods

To determine the discovery significance or to set limits using a given data set, one must carry out the global fit described above. For this one needs first to combine the likelihood functions for the individual channels into the full likelihood function containing a single strength parameter  $\mu$ , and use this to find the profile likelihood ratio. It is possible, however, to find approximate values for the *median* discovery significance and limits in a way that only requires as input the separate profile likelihood ratio values from each of the channels. This is very useful especially in the planning phase of a search that combines multiple channels.

The procedure relies on two separate approximations. First, we estimate the median value of the profile likelihood ratio  $\lambda(\mu)$  by evaluating the likelihood function with a single, artificial data set in which all statistical fluctuations are suppressed, as described in Section 2.5.1. Second, to determine the significance values from the likelihood ratios, we use the asymptotic form of the distribution of  $-2\ln\lambda(\mu)$  valid for sufficiently large data samples. This is described in Section 2.5.2, and its validity is checked for the individual channels in Section 3. Here the limitations of the approximation are investigated and for one case where it is found to be insufficiently accurate (the discovery significance for the channel  $H \rightarrow W^+W^-$  plus no jets), an alternate procedure is followed.

### 2.5.1 Approximation for the median likelihood ratio

To find the median discovery significance and limits, the median likelihood ratios  $\lambda_i(\mu)$  are first found for each channel separately, and then combined to give the full median likelihood ratio. One can estimate the median  $\lambda_i(\mu)$  by the value of the likelihood ratio evaluated with a single artificially constructed data set, in which all statistical fluctuations are suppressed and the data values  $\mathbf{n}$  and  $\mathbf{m}$  are replaced by their expectation values for a given integrated luminosity and a hypothesized strength parameter  $\mu_A$ . We refer to this as an ‘Asimov’ data set.<sup>2</sup> It replaces having to simulate a large number of experiments from which one would determine the median.

As before,  $\mu_A = 0$  is the background only hypothesis and  $\mu_A = 1$  corresponds to background plus signal present at the Standard Model rate. The median referred to thus pertains to what one would obtain with a large number of experiments generated under the assumption of  $\mu_A$ . The approximation is in fact more accurate if one uses noninteger values for numbers of events in the log-likelihood (the factorial terms are in any case absent) so that the Asimov likelihood  $L_A$  is found by substituting

$$n_j = \mu_A s_j + b_j \quad (29)$$

$$m_k = u_k, \quad (30)$$

into the likelihood function (6) for each channel. Here for  $s_j$ ,  $b_j$  and  $u_k$ , one needs in principle the expectation values, i.e., these quantities should have no statistical errors. In practice they are estimated using a Monte Carlo sample corresponding to an integrated luminosity substantially larger than what is considered for the data. The numbers of signal and background events are then scaled to the desired luminosity. The other nuisance parameters such as shape parameters are estimated as would be done with any other data set; we refer below to the resulting values as  $\theta_A$ . Because the Asimov data set has no statistical fluctuations, the  $\theta_A$  are simply the values one would derive from a very large Monte Carlo data sample.

The estimate of the median likelihood ratio used for the  $i$ th channel is therefore

$$\lambda_{A,i}(\mu) = \frac{L_{A,i}(\mu, \hat{\theta})}{L_{A,i}(\hat{\mu}, \hat{\theta})} \approx \frac{L_{A,i}(\mu, \hat{\theta})}{L_{A,i}(\mu_A, \theta_A)}, \quad (31)$$

where  $L_{A,i}$  denotes the likelihood function (6) evaluated with the Asimov data values (29) and (30). The approximation used for the final step in (31) exploits the fact that ML estimate of  $\hat{\mu}$  is very close to the input value  $\mu_A$  when the likelihood function is constructed using the Asimov data set.

Note that if the likelihood functions for the individual channels were to be constructed with data containing statistical fluctuations rather than with the artificial Asimov data, then the ML estimate of the strength parameter,  $\hat{\mu}$ , would in general be different for each channel. The full likelihood function (8) used for the combination, however, contains a single global  $\mu$ . We can now exploit the fact that for the Asimov data one has  $\hat{\mu} \approx \mu_A$  for all of the channels and thus obtain the median likelihood ratio for the combination as the product of the individual  $\lambda_{A,i}(\mu)$ ,

$$\lambda_A(\mu) = \prod_i \lambda_{A,i}(\mu). \quad (32)$$

Monte Carlo studies show that Eq. (32) provides an excellent approximation to the median value one would find from data generated with  $\mu_A$  as the strength parameter.

<sup>2</sup>The name of the Asimov data set is inspired by the short story *Franchise*, by Isaac Asimov [1]. In it, elections are held by selecting a single voter to represent the entire electorate.

For purposes of quantifying how likely we are to discover the Higgs if it exists, we report the significance obtained from the  $p$ -value of  $\mu = 0$  with an Asimov data set that corresponds to  $\mu_A = 1$ ,

$$\lambda_{s+b}(0) = \prod_i \frac{L_{s+b,i}(0, \hat{\theta})}{L_{s+b,i}(1, \theta_A)} . \quad (33)$$

Here the subscript  $s+b$  refers to the Asimov data set; the argument 0 denotes the value of  $\mu$  being tested. That is, Eq. (33) approximates what one would obtain with data generated with signal and background for the median value of  $\lambda(0)$ , which is used to test the background-only ( $\mu = 0$ ) hypothesis. Equation (33) provides the median  $q_{0\text{med}} = -2\ln \lambda_{s+b}(0)$ , and from this the  $p$ -value and significance  $Z$  are found using equation (15).

To determine the limits on  $\mu$  that we expect to set if the Higgs does not exist (or is beyond our reach), we find the  $p$ -value of a hypothesized  $\mu$  using the likelihood ratio  $\lambda(\mu)$  based on Asimov data for background only ( $\mu_A = 0$ ),

$$\lambda_b(\mu) = \prod_i \frac{L_{b,i}(\mu, \hat{\theta})}{L_{b,i}(0, \theta_A)} . \quad (34)$$

That is,  $\lambda_b(\mu)$  approximates the median value of  $\lambda(\mu)$  one would obtain from data generated according to the background-only hypothesis. The value of  $\lambda_b(\mu)$  is used to determine the median  $q_{\mu\text{med}}$ , which is used to find the median  $p$ -value,  $p_{\mu\text{med}}$ . This is computed for all  $\mu$  and the point where  $p_{\mu\text{med}} = 0.05$  gives the 95% CL upper limit.

Because  $\hat{\mu} \approx \mu_A$  holds for each channel individually when using Asimov data, it is possible to determine the values of the likelihood ratio entering into (32) separately for each channel, which simplifies greatly the task of estimating the median significance that would result from the full combination. It should be emphasized, however, that the discovery significance or exclusion limits determined from real data require one to construct the full likelihood function containing a single parameter  $\mu$ , and this must be used in a global fit to find the profile likelihood ratio.

Furthermore, some systematic errors, e.g., the uncertainty in the integrated luminosity, are common to all channels and correspond to a common nuisance parameter. When using Asimov data, the values of such parameters will be fitted to the same values in all channels. Thus the correlations between common systematics are taken into account just as they would be in a global fit of all channels.

A limitation of the procedure with Asimov data is that it only provides an estimate of the median likelihood ratio. To obtain an uncertainty band on the expected (median) discovery and exclusion sensitivities as a function of  $m_H$  one would have to simulate a large number of experiments.

### 2.5.2 Approximate relation between likelihood ratio and significance

To compute the  $p$ -values we need the distribution  $f(q_\mu|\mu)$  of  $q_\mu = -2\ln \lambda(\mu)$ . For a sufficiently large data sample the pdf of  $q_\mu$  takes on a well defined limiting form related to the chi-square distribution, as discussed in Section 2.4. Assuming this form, the  $p$ -value of the hypothesis  $\mu$  is found to be

$$p_\mu \approx 1 - \Phi(\sqrt{q_\mu}) , \quad (35)$$

and the significance  $Z$  is given by the formula

$$Z = \Phi^{-1}(1 - p_\mu) \approx \sqrt{-2\ln \lambda(\mu)} . \quad (36)$$

For estimating the median discovery significance we use equations (35) and (36) together with the equation (33), the likelihood ratio based on Asimov data containing signal and background. To find the

median limit on  $\mu$ , we use again equations (35) and (36) but with the likelihood ratio based on Asimov background data only, equation (34).

The validity of this approximation is investigated for each channel by generating distributions of  $q_\mu$  for  $\mu = 0, 1$  using a fast Monte Carlo simulation and comparing the resulting histograms with the expected asymptotic form. These comparisons are shown in Section 3.

## 2.6 Consequences of testing many Higgs mass values

The statistical significance of a potential discovery is quantified by giving the  $p$ -value of the no-Higgs hypothesis, i.e., the probability, under the assumption of background only, that that one would see data with equal or less compatibility with this hypothesis relative to the data obtained. Finding this probability below a specified threshold (e.g., the  $5\sigma$  threshold, or  $p < 2.87 \times 10^{-7}$ ) corresponds to claiming discovery of a Higgs boson.

The approach taken in this analysis is to compute the  $p$ -value of the no-Higgs hypothesis separately as a function of the Higgs mass. The threshold  $p$ -value is thus the false discovery rate for Higgs boson of a given mass. Further one should also estimate the probability, under the assumption of background only, that this  $p$ -value will fall below the discovery threshold for *any* mass within the range considered. By searching for the Higgs within a broad range of hypothetical masses, one increases the probability of observing what appears to be a signal at some mass, and so the effective significance of the discovery is reduced. In HEP this is sometimes referred to as the “look-elsewhere effect”.

To first approximation the effective increase in the false-discovery rate is given by the number of statistically separate mass ranges explored. If a certain data set would give a  $p$ -value of  $m_H$  below the discovery threshold, then the same data would in general also indicate discovery for other masses very close by. Roughly speaking, the mass range in which a given data set would indicate discovery is set by the mass resolution for the Higgs candidate. So the factor by which the  $p$ -value is inflated is given by the mass range explored divided by the average mass resolution. Monte Carlo studies can be used to validate and refine this approximation; this approach is planned for future analyses.

An alternative to considering fixed Higgs masses is to treat both the strength parameter  $\mu$  and the Higgs mass  $m_H$  as free parameters in the likelihood ratio. For example, to establish discovery one computes the  $p$ -value of the no-Higgs hypothesis. As before, this is the probability, under the assumption of no Higgs, of finding data with equal or lesser compatibility with  $\mu = 0$  relative to the data obtained. In contrast to the fixed-mass case, however, “less compatible” here means having a lower likelihood ratio for any allowed value of the Higgs mass; the lowest value comes when the denominator contains the fitted maximum-likelihood estimator  $\hat{m}_H$ . In practice the fitted value of the Higgs mass is restricted to lie within a stated range. This has been done for the Higgs searches using the  $\gamma\gamma$  [4] and  $W^+W^-$  [5] channels, with the aim of extending this method to a combination of all channels.

## 3 Combination of Higgs search channels

In this section a brief description of each of the four search channels is given. For each channel, the method used to obtain the likelihood ratio is described, and values of the test variable  $q_\mu$  as defined by Eq. (10) for discovery and by Eq. (16) for limits are tabulated for several values of the integrated luminosity  $L$  and Higgs mass  $m_H$ . For the discovery sensitivity where one tests  $\mu = 0$ , the median value of  $q_0$  is given under the assumption of  $\mu = 1$ ; for exclusion sensitivity, the median of  $q_1$  is given under the assumption of  $\mu = 0$ .

In addition, for each channel we show distributions of  $q_\mu$  under the assumption of  $\mu$  for the two cases  $\mu = 0$  and  $\mu = 1$ . For the approximations used in this note to be valid, these should be close to the asymptotic form described in Section 2.4. This limiting form for the distribution  $f(q_\mu|\mu)$  is a mixture of

a delta function at  $q_\mu = 0$  and a chi-square distribution for one degree of freedom, where each component has equal weight. We refer to this as a  $\frac{1}{2}\chi_1^2$  distribution. For the case of  $\mu = 0$  we compare directly the Monte Carlo distribution of  $q_0$  with the  $\frac{1}{2}\chi_1^2$  distribution and the delta-function term at  $q_0 = 0$  is clearly visible. For  $\mu = 1$  we show the equivalent comparison but for reasons of convenience only the events with  $\hat{\mu} \leq \mu$  are shown, i.e., the events with  $\hat{\mu} > \mu$  that contribute to the delta function at  $q_1 = 0$  are left off. That is, for exclusion it is the conditional pdf  $f(q_1|\mu = 1, \hat{\mu} \leq 1)$  that is compared to a chi-square distribution for one degree of freedom; there is no delta function term.

All channels use data driven background estimation methods. This way, the uncertainties in the background shape and normalization are treated within the framework of the profile likelihood as nuisance parameters. Using control samples the effect of many uncertainties like energy scales and fake rates on the background estimate can be constrained by the control samples. Uncertainties on the signal efficiency do not affect the discovery sensitivity which is testing the presence or absence of a signal; however, this is not the case for exclusion sensitivity. As one would expect, uncertainty in the signal efficiency does reduce the exclusion sensitivity. This uncertainty was incorporated into the profile likelihood calculation by adding an extra term to the likelihood function for every channel as described in Section 2.1: a Gaussian relating the nominal efficiency estimated in an auxiliary measurement, the true efficiency, and the uncertainty of that auxiliary measurement.

### 3.1 $H \rightarrow \gamma\gamma$

Details on the  $H \rightarrow \gamma\gamma$  channel are given in Ref. [4]. We perform an unbinned maximum-likelihood fit to extract the signal and background event yields by using the diphoton invariant mass,  $m_{\gamma\gamma}$ , as a discriminating variable. The  $H \rightarrow \gamma\gamma$  distribution of  $m_{\gamma\gamma}$  forms a Gaussian peak with tails to lower values from photon energy losses before the calorimeter. It is well modelled by a *Crystal Ball* function. The signal probability density function,  $p_H(m_{\gamma\gamma})$ , is given by

$$p_H(m_{\gamma\gamma}) = N \cdot \begin{cases} \exp(-t^2/2), & \text{for } t > -\alpha, \\ (n/|\alpha|)^n \cdot \exp(-|\alpha|^2/2) \cdot (n/|\alpha| - |\alpha| - t)^{-n}, & \text{otherwise,} \end{cases} \quad (37)$$

where  $t = (m_{\gamma\gamma} - m_H - \delta m_H)/\sigma(m_{\gamma\gamma})$ ,  $N$  is a normalisation parameter,  $m_H$  is the Higgs boson mass,  $\delta m_H$  is an offset and  $\sigma$  represents the diphoton invariant mass resolution. The non-Gaussian tail is parametrised by  $n$  and  $\alpha$ . We include an additional, broader Gaussian term in Eq. 37 to improve the description of the tails of the distribution. Within a sufficiently narrow mass window, the background of  $m_{\gamma\gamma}$  is modeled by an exponential distribution with a single slope parameter  $\xi$ .

The resulting median profile likelihood ratios for discovery,  $\lambda(\mu = 0)$  (using toy  $s + b$  Monte Carlo experiments and taking the median of the  $\lambda(\mu = 0)$  distribution) are given in Table 1 for a few Higgs masses at some given luminosities.

The distribution of the test statistic  $q_0$  under the null background only hypothesis, for  $m_H = 120$  GeV with an integrated luminosity of 2 and 10 fb<sup>-1</sup>, is shown in Fig. 6. A  $\frac{1}{2}\chi_1^2$  distribution is superimposed, showing the validity of the asymptotic approximation.

The median profile likelihood ratio for exclusion,  $-2\ln\lambda(\mu)$  (using toy background-only Monte Carlo experiments and taking the median of the  $\lambda(\mu)$  distribution) is given in Table 2 for a few Higgs masses at several integrated luminosities and for a signal strength  $\mu = 1$ , corresponding to a Standard Model Higgs Boson.

The distribution of the test statistic  $q_1$  for  $\hat{\mu} \leq 1$  under the  $s + b$  hypotheses for  $m_H = 150$  GeV with an integrated luminosity of 2 and 10 fb<sup>-1</sup> is shown in Figures 7. A  $\chi_1^2$  distribution is superimposed, showing the validity of the asymptotic approximation.

Table 1: Median values of  $-2\ln\lambda(\mu)$  (evaluated at  $\mu = 0$ ) obtained from fits to simulated data generated with  $H \rightarrow \gamma\gamma$  signal plus background ( $\mu = 1$ ) for several values of the Higgs mass and integrated luminosity.

A  $\chi_1^2$  distribution is superimposed.

### 3.2 $H \rightarrow W^+W^-$

The  $H \rightarrow W^+W^-$  search is divided into two topologies, production of a Higgs with no jets ( $H + 0j$ ) and with two additional jets ( $H + 2j$ ), using in both cases the decay mode  $H \rightarrow WW \rightarrow e\nu\mu\nu$ . The present study does not yet consider the final states  $e\nu e\nu$  or  $\mu\nu\mu\nu$ , nor those with hadronic W decays. Future inclusion of these channels is expected to improve the search sensitivity particularly for the high Higgs mass region. The search is described in detail in Ref. [5].

#### 3.2.1 $H + 0j$

The analysis of the  $H + 0j$  channel uses a two dimensional maximum-likelihood fit of the transverse mass and the transverse momentum of the WW system in two bins of the dilepton opening angle in the transverse plane. The fit includes control samples to measure the backgrounds from  $t\bar{t}$  and  $Z \rightarrow \tau\tau$ .

The QCD WW background requires particular attention. Its distributions of Higgs-candidate transverse mass and  $p_T$  are described with functions containing several adjustable (nuisance) parameters, and several others whose values are determined from a full Monte Carlo simulation and thereafter treated as fixed. The distribution of the test statistic  $q_0$  under the background-only ( $\mu = 0$ ) hypothesis is shown in Fig. 8(a) for  $m_H = 150$  GeV for an integrated luminosity of  $10 \text{ fb}^{-1}$ . The same fixed QCD WW shape parameters are used both to generate the data and for calculating the likelihood ratio. A  $\frac{1}{2}\chi_1^2$  distribution is superimposed, showing the level of agreement of the asymptotic approximation.

For this channel, further investigation of the systematic uncertainties was carried out. For the fixed shape parameters related to  $p_T$  and transverse mass distributions for the QCD WW background, the values used to generate the data were varied relative to what was used when determining the likelihood ratio. This was done in a manner that minimized the sensitivity of the resulting  $q_0$  distribution to variations in other fixed parameters such as the QCD  $Q^2$  scale. The resulting distributions of  $q_0$  are thus no longer expected to follow the  $\frac{1}{2}\chi_1^2$  form, as can be seen in Fig. 8(b).

Because the chi-square approximation is not valid in this case, the  $p$ -values are calculated using the  $q_0$  distribution obtained directly from the Monte Carlo. An exponential is fitted to the tail region in order to extrapolate to large  $q_0$  values, and the median value of  $q_0$  under the hypothesis of signal plus background is determined using the same variation of the background parameters. It was found that the median  $p$ -value of the background-only hypothesis, with the median computed under assumption of the  $s + b$  hypothesis, is very similar to the original case where the QCD shape parameters are not varied and the  $\frac{1}{2}\chi_1^2$  distribution is used.

Figure 8: The distribution of the test statistic  $q_0$  for  $H + 0j \rightarrow WW + 0j$ , under the background-only hypothesis, with the same fixed QCD WW shape parameters used at both the generator and the fit level, for  $m_H = 150$  GeV and for an integrated luminosity of  $10 \text{ fb}^{-1}$  (a) with the same shape parameters for event generation and fitting; (b) with altered shape parameters. A  $\frac{1}{2}\chi^2_1$  distribution is superimposed.

For the combination of results for discovery (i.e., testing  $\mu = 0$ ), we have used the  $p$ -values as described above for the case of the  $H + 0j$  channel. The same variation of QCD WW parameters was also investigated for the case of exclusion (i.e., testing  $\mu > 0$ , and in particular  $\mu = 1$ ), and it was done as well for the  $H + 2j$  channel. In those studies, however, the distributions, under the assumption of  $\mu$ , of the test statistic  $q_\mu$  were found to agree quite well with the expected  $\frac{1}{2}\chi^2_1$  distribution, even after the parameter variation. Therefore for these cases we have based the combination of results on the asymptotic approximations for the  $q_\mu$  distributions (as done in this paper for the other Higgs channels).

To simplify the comparison with the other channels, the median  $p$ -values of the background-only ( $\mu = 0$ ) hypothesis for the  $H + 0j$  channel were converted into effective values of the variable  $q_0 = -2\ln\lambda(0)$  according to  $q_0 = Z^2 = (\Phi^{-1}(1 - p))^2$ . These are given in Table 3 for several Higgs masses and integrated luminosities.

Table 3: Median values of  $-2\ln\lambda(\mu = 0)$  obtained from  $H + 0j$  fits using data simulated under the assumption of signal plus background ( $\mu = 1$ ) for several values of the Higgs mass and integrated luminosity.

The median profile likelihood ratio for exclusion,  $\lambda(\mu)$  (using background-only MC experiments and taking the median of the  $\lambda(\mu)$  distribution), is given in Table 4 for several Higgs masses and integrated luminosities for the signal strength  $\mu = 1.0$ , corresponding to a SM Higgs Boson.

The distribution of the statistic  $q_1$  for  $\hat{\mu} \leq 1$  under the  $s + b$  hypothesis is shown in Fig. 9 for  $m_H = 150$  GeV and for an integrated luminosity of 2 and  $10 \text{ fb}^{-1}$ . A  $\chi^2_1$  distribution is superimposed, showing the validity of the asymptotic approximation.

Table 4: Median values of  $-2\ln\lambda(\mu = 1)$  obtained from  $H + 0j$  fits using simulated background-only ( $\mu = 0$ ) data for several values of the Higgs mass and integrated luminosity.

Figure 9: The distribution of the test statistic  $q_1$  for  $\hat{\mu} \leq 1$  under the  $s + b$  hypothesis for  $H + 0j \rightarrow WW + 0j$ , for  $m_H = 150$  GeV with an integrated luminosity of (a)  $2 \text{ fb}^{-1}$  and (b)  $10 \text{ fb}^{-1}$ . A  $\chi^2_1$  distribution is superimposed.

### 3.2.2 $H + 2j$

The  $H + 2j$  analysis uses a two-dimensional fit based on the transverse mass and the output of a Neural Network, which takes as input several kinematic variables related to the jet activity in the event. The fit is performed simultaneously in signal-enriched and background-enriched regions distinguished by lepton angular variables, which are nearly uncorrelated to the jet variables used in the Neural Network.

The median profile likelihood ratios for discovery,  $-2\ln\lambda(\mu = 0)$  (using toy  $s + b$  MC experiments and taking the median of the  $\lambda(\mu = 0)$  distribution), are given in Table 5 for several Higgs masses and integrated luminosities.

Table 5: Median values of  $-2\ln\lambda(\mu)$  for  $\mu = 0$  obtained from  $H + 2j$  fits to simulated data with signal plus background ( $\mu = 1$ ) for several values of the Higgs mass and integrated luminosity.

$L$ (fb <sup>-1</sup> )	$m_H$ (GeV)						
	130	140	150	160	170	180	190
1	0.39	0.89	1.61	2.73	2.89	1.85	1.23

Figure 11: The distribution of the test statistic  $q_1$  for  $\hat{\mu} \leq 1$  under the  $s + b$  ( $\mu = 1$ ) hypothesis (for  $H + 2j \rightarrow WW + 2j$ ), for  $m_H = 150$  GeV with an integrated luminosity of (a)  $2\text{fb}^{-1}$  and (b)  $10\text{fb}^{-1}$ . A  $\chi^2_1$  distribution is superimposed.

### 3.3 $H \rightarrow \tau^+ \tau^-$

The sensitivity of the ATLAS detector to a Higgs boson produced via Vector Boson Fusion and decaying to tau leptons has been investigated [6].

Two tau decay channels are considered:  $ll$  and  $lh$ . Although there are several neutrinos in the event, it is possible to reconstruct the  $\tau^+ \tau^-$  invariant mass,  $m_{\tau\tau}$ , by making the collinear approximation, in which the decay products of the  $\tau$  are assumed to be collinear with the  $\tau$  direction in the laboratory frame. After other event selection criteria are imposed, the spectrum of  $m_{\tau\tau}$  is used to extract the signal. Particular care has been given to the incorporation of uncertainty in both the rate and shape for the signal and backgrounds.

A data-driven background estimation technique has been established for the major backgrounds. Each technique has been developed to address the aspects of the background estimation which are most relevant for the analysis: the shape of the  $m_{\tau\tau}$  tail from the irreducible  $Z \rightarrow \tau\tau$ , the fake tau contribution in the  $lh$ -channel, and the normalization of the QCD backgrounds.

In addition to the  $m_{\tau\tau}$  spectrum from the  $Z \rightarrow \tau\tau$  and QCD control samples, a track multiplicity distribution is used to constrain the fraction of QCD events in the  $lh$ -channel. This likelihood term is denoted  $L_{\text{track}}(r_{\text{QCD}}, r_{\text{tau}})$ , where  $r_{\text{tau}}$  ( $r_{\text{QCD}}$ ) denotes the fraction of real taus (fakes from jets) in the sample. The track multiplicity distribution for the QCD jets is modelled from samples of QCD di-jets that produce tau candidates.

The shape of the  $m_{\tau\tau}$  distribution for signal and  $Z \rightarrow \tau\tau$  events is dictated by the resolution of  $\cancel{E}_T$  and the kinematics of the collinear approximation. The parameterization of  $m_{\tau\tau}$  for the signal and  $Z \rightarrow \tau\tau$  background are based on the kinematics of the collinear approximation and reproduces an asymmetric distribution with non-Gaussian tails. This distribution is dependent on the overall width,  $\sigma_{H/Z}$ , and a mean,  $m_{H/Z}$ .

A  $Z \rightarrow \tau\tau$  control sample is used to constrain the mean,  $m_Z$ , and the overall width of the distribution,  $\sigma_Z$ , which are the only free parameters in the  $Z \rightarrow \tau\tau$  background model. The error bars in the control sample were scaled to 10% to account for the 10% shape uncertainty in the  $\mu \rightarrow \tau$  rescaling method.

The shapes for  $W$ +jets and  $t\bar{t}$  are very similar and are modelled with a single distribution. A conservative 50% error is applied to each bin in the combined QCD (i.e.,  $t\bar{t}$  and  $W$ +jets) control sample to reflect uncertainty in how this shape changes as the remainder of the analysis cuts are applied.

The shape of the QCD background was parametrized with the following equation:

$$L_{\text{QCD}}(m_{\tau\tau}|a_1, a_2, a_3) = \mathcal{N} \left( \frac{1}{m_{\tau\tau} + a_1} \right)^{a_2} m_{\tau\tau}^{a_3}. \quad (38)$$

The form is motivated by a competition between the parton distribution functions and the matrix element. In the  $lh$ -channel, the normalization of the backgrounds with fake taus can be constrained by using the track multiplicity method described above. We apply a conservative 50% systematic on this fraction.

By fitting the  $m_{\tau\tau}$  spectrum to a model that accurately describes the signal and various backgrounds it is possible to directly incorporate uncertainty in the background shape and take advantage of the shape of the signal within the mass window. We utilize the profile likelihood ratio as our test statistic. The likelihood function corresponding to the simultaneous fit is simply a product of the likelihoods from the individual measurements:

$$\begin{aligned} L(\text{data}|\mu, m_H, \nu) &= L_{\text{track}}(\text{track multiplicity}|r_{\text{QCD}}) \times L_Z(Z + \text{jets control}|m_Z, \sigma_Z) \\ &\times L_{\text{QCD}}(\text{QCD control}|a_1, a_2, a_3) \\ &\times L_{s+b}(\text{signal candidates}|\mu, m_H, \sigma_H, m_Z, \sigma_Z, r_{\text{QCD}}, a_1, a_2, a_3), \end{aligned} \quad (39)$$

where the  $a_i$  are the parameters used to parametrize the QCD background and  $\nu$  represents all nuisance parameters of the model:  $\sigma_H, m_Z, \sigma_Z, r_{\text{QCD}}, a_1, a_2, a_3$ .

The data-driven background estimation methods described above have been developed so that uncertainty in the background shape and normalization are included directly into the significance calculation. Because the discovery criterion is simply testing the presence or absence of the signal, it is not sensitive to some of the sources of systematic uncertainty. In contrast, measurement and exclusion of  $\sigma(pp \rightarrow qqH) \times BR(H \rightarrow \tau\tau)$  are sensitive to the uncertainty on the signal selection efficiency. Both experimental and theoretical sources of uncertainty on the signal efficiency have been evaluated. The jet energy scale uncertainty dominates in this channel, and a signal efficiency uncertainty of 18% was used when estimating the exclusion sensitivity.

The median profile likelihood ratios for discovery,  $\lambda(\mu = 0)$  (using the Asimov data sets with  $\mu_A = 1$ ), are given in Table 7 for a few Higgs masses at some given luminosities. The distribution of the test statistic  $q_0$  under the null background only hypothesis, for  $m_H = 130$  GeV with an integrated luminosity of 2 and  $10 \text{ fb}^{-1}$ , is shown in Figure 12. A  $\frac{1}{2}\chi_1^2$  distribution is superimposed, showing the validity of the asymptotic approximation.

Table 7: Median values of  $-2\ln\lambda(\mu = 0)$  obtained from  $H \rightarrow \tau^+\tau^-$  simulated data generated with signal plus background ( $\mu = 1$ ) for several values of the Higgs mass and integrated luminosity.

L ( $\text{fb}^{-1}$ )	$m_H$ (GeV)			
	110	120	130	140
1	0.59	0.88	0.72	0.46
2	1.18	1.74	1.40	0.89
5	2.91	4.43	3.34	2.08
10	5.81	8.23	6.37	3.91
30	17.2	23.6	17.6	10.6

The resulting median profile likelihood ratio for exclusion,  $\lambda(\mu)$  (using the Asimov data sets,  $\mu_A = 0$ ), is given in Table 8 for a few Higgs masses at some given luminosities and signal strength  $\mu = 1.0$  corresponding to a Standard Model Higgs Boson.

The distribution of the test statistic  $q_1$  for  $\hat{\mu} \leq 1$  under the  $s + b$  hypotheses for  $m_H = 130 \text{ GeV}$  with an integrated luminosity of 2 and  $10 \text{ fb}^{-1}$  is shown in Figures 13. A  $\chi_1^2$  distribution is superimposed, showing the validity of the asymptotic approximation.

Table 8: Median values of  $-2\ln\lambda(\mu = 1)$  obtained from  $H \rightarrow \tau^+\tau^-$  background-only ( $\mu = 0$ ) simulated data for several values of the Higgs mass and integrated luminosities.

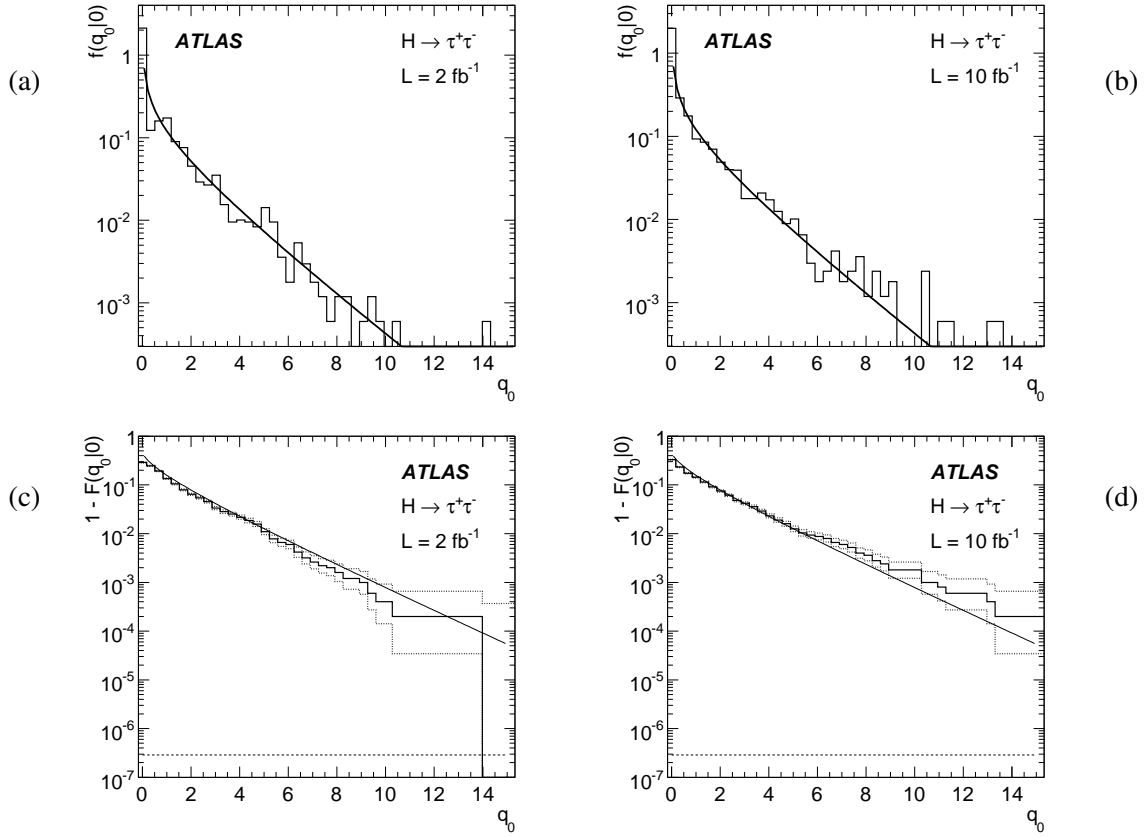

Figure 12: The distribution of the test statistic  $q_0$  for  $H \rightarrow \tau^+\tau^-$  under the null background-only hypothesis, for  $m_H = 130 \text{ GeV}$  with an integrated luminosity of 2 (a) and 10 (b)  $\text{fb}^{-1}$ . A  $\frac{1}{2}\chi^2_1$  distribution is superimposed. Figures (c) and (d) show  $1 - F(q_0)$  where  $F(q_0)$  is the corresponding cumulative distribution. The small excess of events at high  $q_0$  is statistically compatible with the expected curves, as can be seen by comparison with the dotted histograms that show the 68.3% central confidence intervals for  $p = 1 - F(q_0|0)$ . The lower dotted line at  $2.87 \times 10^{-7}$  shows the  $5\sigma$  discovery threshold.

Figure 13: The distribution of the test statistic  $q_1$  for  $\hat{\mu} \leq 1$  under the  $s+b$  hypothesis for  $H \rightarrow \tau^+\tau^-$ , for  $m_H = 130 \text{ GeV}$  with an integrated luminosity of (a)  $2 \text{ fb}^{-1}$  (b) and  $10 \text{ fb}^{-1}$ . A  $\chi^2_1$  distribution is superimposed.

### 3.4 $H \rightarrow ZZ^{(*)} \rightarrow 4l$

Details of the  $H \rightarrow ZZ^{(*)} \rightarrow 4l$  channel can be found in Ref. [7]. The main challenge of this channel for what concerns statistical analysis is its relevance over a very wide mass range (from  $m_H$  around 120 GeV up to 700 GeV), over which the shapes and cross sections of both signal and background show considerable variations.

While in principle it would be possible to divide the mass range in different regions and use separate models for each of them, using a unique background model for the whole phase space is a better approach, since it allows to estimate discovery and exclusion significance at any mass, without having to worry about boundaries between different models. This will be needed of course when the analysis is performed using real data, where  $m_H$  is unknown.

The main background after event filtering in this channel is the irreducible  $ZZ \rightarrow 4l$  process. Reducible backgrounds such as  $Zb\bar{b} \rightarrow 4l + X$  or  $t\bar{t}$  give a negligible contribution to the overall shape, with the only exception of the  $m_H = 120$  GeV case, where  $Zb\bar{b} \rightarrow 4l + X$  modifies the background shape in the low mass region, and it must therefore be taken into account.

The irreducible background has been modelled using a combination of Fermi functions which are suitable to describe both the plateau in the low mass region and the broad peak corresponding to the second Z coming *on shell*. The chosen model is described by the following function:

$$\frac{p0}{(1 + e^{\frac{p6 - M_{ZZ}}{p7}})(1 + e^{\frac{M_{ZZ} - p8}{p9}})} + \frac{p1}{(1 + e^{\frac{p2 - M_{ZZ}}{p3}})(1 + e^{\frac{p4 - M_{ZZ}}{p5}})} . \quad (40)$$

The first plateau, in the region where only one of the two Z bosons is *on shell*, is modelled by the first term, and its suppression, needed for a correct description at higher masses, is controlled by the  $p8$  and  $p9$  parameters. The second term in the above formula accounts for the shape of the broad peak and the tail at high masses. This function can describe with a negligible bias the  $ZZ$  background shape with good accuracy over the full mass range.

As already mentioned, the  $Zb\bar{b}$  contribution is relevant only when searching for very light Higgs bosons (in this study, only  $m_H = 120$  GeV). In this case, an additional term is added to the  $ZZ$  continuum, with a functional form similar to the second part of equation 40. For what concerns signal modelling, a simple Gaussian shape has been used for  $m_H \leq 300$  GeV, while a relativistic Breit-Wigner formula was needed to properly describe the big tails arising at higher values of the Higgs mass.

In the fits to determine the profile likelihood ratio,  $m_H$  is fixed to the hypothesized value, while  $\sigma_H$  is allowed to float in a  $\pm 20\%$  range around the value obtained from the signal Monte Carlo distributions. All the parameters describing the background shape are floating within sensible ranges. Given the complexity of the model involved, the fit can from time to time get trapped into local minima. While there is no easy way to avoid this problem, the fake measurements obtained in this case are easy to distinguish from the correct ones, and a repetition of the fit from a different starting point is enough to solve the problem.

The resulting median profile likelihood ratios for discovery,  $-2 \ln \lambda(\mu = 0)$ , with the median computed using toy  $s + b$  MC data (i.e., with  $\mu = 1$ ), are given in Table 9 for several values of the Higgs mass and integrated luminosity.

The distribution of the test statistic  $q_0$  under the null background-only hypothesis, for  $m_H = 200$  GeV with an integrated luminosity of 2 and  $10 \text{ fb}^{-1}$ , is shown in Fig. 14. A  $\frac{1}{2} \chi_1^2$  distribution is superimposed, showing the validity of the asymptotic approximation.

The resulting median profile likelihood ratio for exclusion,  $\lambda(\mu)$  (using toy background-only MC experiments and taking the median of the  $\lambda(\mu)$  distribution), is given in Table 10 for several Higgs masses and luminosities using a signal strength  $\mu = 1.0$  corresponding to a Standard Model Higgs boson.

The distribution of the test statistic  $q_1$  for  $\hat{\mu} \leq 1$  under the  $s + b$  hypothesis for  $m_H = 200$  GeV with

### 3.5 Limitations of the approximations used

The distributions shown in Sections 3.1 through 3.4 show varying levels of agreement between the asymptotic chi-square form and the results of Monte Carlo simulations. For the  $WW$  (0 jet) channel (Fig. 8), the discrepancy in the distribution of  $q_0$  is very large, and this is understood to arise from the special manner in which the systematic uncertainties for this channel were treated. The distribution of  $q_0$  for the  $WW$  (0 jet) channel therefore does not use the asymptotic formula. This is the only channel for which the approximation was not applied.

For other cases such as the distribution of  $q_1$  for the  $H \rightarrow \gamma\gamma$  channel shown in Fig. 7, the Monte Carlo distribution falls off significantly faster than the chi-square curve. This means that the significance with which one excludes the tested hypothesis will be less when estimated from the chi-square curve, leading to conservative limits. As the integrated luminosity increases, one expects the asymptotic formula to become more accurate.

In some of the distributions such as that of  $q_0$  for the  $H \rightarrow ZZ^{(*)} \rightarrow 4l$  channel shown in Fig. 14, the Monte Carlo simulation indicates a slight excess over the chi-square curve in the tail region. The level of the excess is not statistically significant in the part of the distribution that can be meaningfully assessed

given the amount of Monte Carlo data available (out to  $q_0$  between around 9 to 16, i.e., to the level of a 3 to  $4\sigma$  discovery). At present it is not practical to verify directly that the chi-square formula remains valid to the  $5\sigma$  level (i.e., out to  $q_0 = 25$ ). Thus the results on discovery significance presented here rest on the assumption that the asymptotic distribution is a valid approximation to at least the  $5\sigma$  level.

The validation exercises carried here out indicate that the methods used should be valid, or in some cases conservative, for an integrated luminosity of at least  $2 \text{ fb}^{-1}$ . At earlier stages of the data taking, one will be interested primarily in exclusion limits at the 95% confidence level. For this the distributions of the test statistic  $q_\mu$  at different values of  $\mu$  can be determined with a manageably small number of events. It is therefore anticipated that we will rely on Monte Carlo methods for the initial phase of the experiment.

## 4 Results of the combination

### 4.1 Combined discovery sensitivity

The full discovery likelihood ratio for all channels combined,  $\lambda_{s+b}(0)$ , is calculated using Eq. 33. This uses the median likelihood ratio of each channel,  $\lambda_{s+b,i}(0)$ , found either by generating toy experiments under the  $s+b$  hypothesis and calculating the median of the  $\lambda_{s+b,i}$  distribution or by approximating the median likelihood ratio using the Asimov data sets with  $\mu_{A,i} = 1$ . Both approaches were validated to agree with each other. The discovery significance is calculated using Eq. 36, i.e.,  $Z \approx \sqrt{-2 \ln \lambda(0)}$ , where  $\lambda(0)$  is the combined median likelihood ratio.

The resulting significances per channel and the combined one are shown in Fig. 16 for an integrated luminosity of  $10 \text{ fb}^{-1}$ .

Figure 16: The median discovery significance for the various channels and the combination with an integrated luminosity of  $10 \text{ fb}^{-1}$  for (a) the lower mass range (b) for masses up to 600 GeV.

The median discovery significance as a function of the integrated luminosity and Higgs mass is shown colour coded in Fig. 17. The full line indicates the  $5\sigma$  contour. Note that the approximations used do not hold for very low luminosities (where the expected number of events is low) and therefore the results below about  $2 \text{ fb}^{-1}$  should be taken as indications only. In most cases, however, the approximations tend to underestimate the true median significance.

### 4.2 Combined exclusion sensitivity

The full likelihood ratio of all channels used for exclusion for a signal strength  $\mu$ ,  $\lambda_b(\mu)$ , is calculated using Eq. 34 with the median likelihood ratios of each channel,  $\lambda_{b,i}(\mu)$ , calculated, either by generating

Figure 17: Significance contours for different Standard Model Higgs masses and integrated luminosities. The thick curve represents the  $5\sigma$  discovery contour. The median significance is shown with a colour according to the legend. The hatched area below  $2 \text{ fb}^{-1}$  indicates the region where the approximations used in the combination are not accurate, although they are expected to be conservative.

toy experiments under the  $b$ -only hypothesis and calculating the median of the  $\lambda_{b,i}$  distribution or approximating the median likelihood ratio using the Asimov data sets with  $\mu_{A,i} = 0$ . Both approaches were checked to agree with each other. A signal strength  $\mu = 1$  corresponds to the Standard Model Higgs boson.

Any exclusion of  $\mu(m_H)$  smaller than 1 corresponds to an exclusion of a Standard Model Higgs boson with a mass  $m_H$ . To probe the median sensitivity for excluding a Standard Model Higgs boson we follow Eq. 35 and calculate the corresponding  $p$ -value for  $\mu = 1$ ,  $p_1$  for a given luminosity at a given Higgs mass. A  $p$ -value of 0.05 corresponds to a significance (Eq. 36) of 1.64. The resulting  $p_1$  for the various channels as well as for the combination, for a luminosity of  $2 \text{ fb}^{-1}$ , are shown in Fig. 18. Note that any  $p$ -value below 0.05 indicates an exclusion. We therefore conclude that with a luminosity of  $2 \text{ fb}^{-1}$  ATLAS has the median sensitivity to exclude a Standard Model Higgs boson heavier than 115 GeV at the 95% Confidence Level. This can also be seen from Fig. 19, which shows the luminosity required to exclude a Higgs boson with a mass  $m_H$  at a given confidence level from the combination of the four channels explored in this note.

The sharp increase in the required luminosity for lower  $m_H$  seen in Fig. 17 reflects the decrease in sensitivity to the Higgs when using only the set of channels considered here. Further developments will increase the sensitivity in this region. For example, improved analysis methods for the  $H \rightarrow \gamma\gamma$  channel are described in Ref. [4], including a separation of the events into those with zero or two accompanying jets. Additional final states such as  $t\bar{t}H$  with  $H \rightarrow b\bar{b}$  will help somewhat, although the contribution to the sensitivity will be small because of the large uncertainties in the background.

For the  $WW$  channel, the present study includes only the  $e\nu\mu\nu$  decay mode, but it is planned to include  $e\nu e\nu$ ,  $\mu\nu\mu\nu$  and  $qql\nu$  as well. The  $ZZ^{(*)}$  channel here only includes  $Z$  decays to  $ee$  and  $\mu\mu$ , but in future analyses  $qq\nu\nu$  will be included. The additional  $WW$  and  $ZZ^{(*)}$  modes have been found to have sensitivity for a high-mass Higgs. Finally, combination with the results from ATLAS with those of CMS will of course result in an overall increase in sensitivity.

Figure 18: The median  $p$ -value obtained for excluding a Standard Model Higgs Boson for the various channels as well as the combination for (a) the lower mass range (b) for masses up to 600 GeV.

Figure 19: The expected luminosity required to exclude a Higgs boson with a mass  $m_H$  at a confidence level given by the corresponding colour. The hatched area below  $2 \text{ fb}^{-1}$  indicates the region where the approximations used in the combination are not accurate, although they are expected to be conservative.

## 5 Conclusions

The procedure for combination of search results based on the profile likelihood ratio has been applied to a study of the search for the Standard Model Higgs boson using four search channels:  $H \rightarrow \tau^+\tau^-$ ,  $H \rightarrow W^+W^- \rightarrow e\nu\mu\nu$ ,  $H \rightarrow \gamma\gamma$  and  $H \rightarrow ZZ^{(*)} \rightarrow 4$  leptons. The combination method is very general and can be applied to essentially any search that will be carried out at the LHC.

The study here has not exploited all of the search channels that will be investigated and therefore the current estimates of the sensitivity can be regarded as conservative. For example, using further decay modes in the  $ZZ$  and  $WW$  channels will provide additional sensitivity especially for a Higgs boson in the higher mass range.

The studies have exploited a series of useful approximations that allow one to determine the median discovery and exclusion sensitivities from a combined fit in a manner that only requires separate input ingredients from the individual channels. The determination of the significance for a given (e.g., real) data set, however, will require a simultaneous fit of all of the channels.

It is not practical at present to generate enough Monte Carlo data to verify directly that the tail of the profile likelihood distribution is well described to the level required for discovery at the  $5\sigma$  level, corresponding to an upper tail area of  $2.87 \times 10^{-7}$ . The estimates of discovery significance presented here therefore rely on the assumption that the large-sample approximation used remains valid out to this level.

The validation studies shown in Section 3 indicate that the approximations used should be reasonably accurate or lead to conservative limits for an integrated luminosity of at least  $2 \text{ fb}^{-1}$ . For the earlier stages of the experiment it is expected that one will need to rely on Monte Carlo methods, which should be feasible for exclusion limits at the 95% confidence level.

The profile likelihood ratio treats systematic errors by associating the uncertainties with adjustable (nuisance) parameters. Other methods for treating systematic uncertainties can also be considered. Using Bayesian methods, for example, one would associate a prior probability density with the nuisance parameters. We plan to develop and use this and other approaches in parallel with the profile likelihood method for searches at the LHC.

The study presented in this paper provides the discovery significance for a Higgs boson of a specific mass. That is, the traditional discovery threshold  $p$ -value of  $2.87 \times 10^{-7}$  corresponding to a  $5\sigma$  effect for a given hypothesized Higgs mass refers to the false discovery rate for a Higgs of that mass. The false discovery rate for a Higgs of *any* mass is higher, and several approaches are being pursued to quantify this (the so-called ‘look-elsewhere effect’). The most mature of these methods involves using a simultaneous fit of the Higgs mass  $m_H$  and the strength parameter  $\mu$  (or equivalently the Higgs production rate), as has been discussed in the studies of  $H \rightarrow \gamma\gamma$  [4] and  $H \rightarrow W^+W^-$  [5].

To summarize, the studies based on the four channels considered in this note confirm the good discovery and exclusion sensitivities already shown in the ATLAS Technical Design Report (TDR) [10]. Furthermore the results here are based on better knowledge and a more realistic simulation of the detector than what is described in the TDR. Because of the approximations used, the present studies are valid only for luminosities above  $2 \text{ fb}^{-1}$ . With a luminosity of  $2 \text{ fb}^{-1}$  the expected (median) sensitivity is at the  $5\sigma$  level or greater for discovery of a Higgs boson in the mass range between 143 and 179 GeV, and the expected upper limit at 95% confidence level on the Higgs mass is 115 GeV.

## A Comparison with procedures used at LEP

In this appendix we compare the procedures described in the present analysis with those used in searches carried out at LEP. More details on these methods be found in [8]. The important differences involve the definition of the test statistic used and the treatment of systematic uncertainties. In addition, the LEP

analyses adopted a special procedure to prevent spurious exclusion due to a downward fluctuation of the number of events (the  $\text{CL}_s$  method, see below).

In the LEP Higgs searches, a hypothesized value of the Higgs mass  $m_H$  was tested by constructing the statistic

$$Q = \frac{L_{s+b}}{L_b} = \frac{L(\mu = 1)}{L(\mu = 0)}, \quad (41)$$

where as before  $b$  ( $\mu = 0$ ) represents the background-only hypothesis and  $s + b$  ( $\mu = 1$ ) refers to background plus signal at the rate predicted by the Standard Model. For convenience the equivalent logarithmic variable  $q = -2 \ln Q$  was used.

The sampling distribution of  $Q$  was determined by Monte Carlo simulation. The Monte Carlo was also used to incorporate systematic errors by sampling values of the corresponding nuisance parameters from pdfs that reflected their uncertainties. That is, one effectively integrated the product of the likelihood and prior pdfs for the nuisance parameters.

For a give observed value  $q_{\text{obs}} = -2 \ln Q_{\text{obs}}$ , the  $p$ -values for the  $s$  and  $s + b$  hypotheses were determined as

$$p_{s+b} = \int_{q_{\text{obs}}}^{\infty} f(q|s+b) dq \equiv \text{CL}_{s+b}, \quad (42)$$

$$p_b = \int_{-\infty}^{q_{\text{obs}}} f(q|b) dq \equiv 1 - \text{CL}_b. \quad (43)$$

Having determine the  $p$ -values, the LEP analyses then based exclusion of the  $s + b$  hypothesis not on the  $p$ -value of  $s + b$  but rather on the ratio  $\text{CL}_s$ , defined as

$$\text{CL}_s = \frac{\text{CL}_{s+b}}{\text{CL}_b} = \frac{p_{s+b}}{1 - p_b}. \quad (44)$$

The signal-plus-background hypothesis was said to be excluded at confidence level  $\text{CL} = 1 - \alpha = 0.95$  if one finds

$$\text{CL}_s < \alpha. \quad (45)$$

Since  $\text{CL}_b \leq 1$ , one has  $\text{CL}_s \geq \text{CL}_{s+b}$ . Therefore the  $\text{CL}_s$  method will not exclude as large a region of parameter space as that based on the signal-plus-background  $p$ -value ( $\text{CL}_{s+b}$  method). As the  $\text{CL}_{s+b}$  method was designed to provide an interval that brackets the true value of the parameter with a probability of at least  $1 - \alpha$ , the  $\text{CL}_s$  limit must cover the true parameter with a greater probability; it is in this sense conservative. The  $\text{CL}_s$  method was devised so as to avoid the problem where a downward fluctuation in the number of background events can lead to exclusion of the Higgs mass considered, even for hypothesized mass values where one does not expect to be sensitive to Higgs production [9].

In contrast, in the present analysis we test a hypothesized value of the strength parameter  $\mu$  using

$$q_\mu = -2 \ln \frac{L(\mu, \hat{\hat{\theta}})}{L(\hat{\mu}, \hat{\theta})}, \quad (46)$$

as described in Section 2. With this definition, the sampling distribution of the test statistic  $f(q_\mu|\mu)$  approaches a well defined form related to the chi-squared distribution for a sufficiently large data sample. The ability to exploit this approximate form is very useful as the relevant  $p$ -value for a  $5\sigma$  discovery is  $2.87 \times 10^{-7}$ , and therefore to determine this from Monte Carlo would require an extremely large

number of simulated experiments. At LEP this was not a crucial issue as the statistical treatment focused primarily on exclusion limits at 95% CL, not on discovery at the  $5\sigma$  level.

Systematic uncertainties here have been incorporated using the profile likelihood, rather than with the integrated likelihoods used at LEP. For the uncertainties most relevant to the analyses at the LHC, the broadening of the likelihood function obtained by both procedures is similar. It is the profile likelihood ratio and not the ratio of integrated likelihoods, however, that approaches the chi-squared form in the large sample limit in accordance with Wilks' theorem.

The  $CL_s$  method has not been applied in the present analysis but studies of its application to searches in ATLAS are ongoing.

A final difference with the LEP procedures concerns the definition of significance  $Z$ . Here we have defined its relation to the  $p$ -value as the number of standard deviations of a Gaussian variable that would give a one-sided tail area of  $p$ , as described in Section 2.1. A significance of  $Z = 5$  corresponds to  $p = 2.87 \times 10^{-7}$ . The LEP Higgs group defined this relation using a two-sided fluctuation of a Gaussian variable, i.e., a  $5\sigma$  significance corresponded to  $p = 5.7 \times 10^{-7}$ .

# Supersymmetry Searches

## Abstract

This chapter serves as an introduction to a collection of six articles that detail the strategy foreseen to search for Supersymmetry with the ATLAS detector at the Large Hadron Collider, concentrating on the initial data taking period with an expected integrated luminosity of about  $1 \text{ fb}^{-1}$ . We review here the phenomenology of Supersymmetry with ATLAS and discuss how events are simulated and reconstructed, concentrating on aspects related to Supersymmetry searches. We also introduce many of the experimental variables that are used throughout this collection.

## 1 Introduction

Supersymmetry (SUSY) is one of the theoretically favoured candidates for physics beyond the Standard Model. The main motivation is to protect the Higgs boson mass from quadratically diverging radiative corrections, in a theory where the Standard Model is valid only up to a high scale  $\Lambda$ . The proposed solution postulates the invariance of the theory under a symmetry which transforms fermions into bosons and vice-versa.

The basic prediction of SUSY is thus the existence, for each Standard Model particle degree of freedom of a corresponding sparticle, with spin different by half a unit. The SUSY generators commute with the  $SU(2) \times U(1) \times SU(3)$  symmetries of the Standard Model, and with the Poincaré group. It follows that with unbroken SUSY the partner particles would have the same quantum numbers and masses as the Standard Model particles. Since no superpartner has been observed to date, SUSY must be broken. A common approach to the phenomenological study of SUSY is to assume the minimal possible particle content, and to parametrise the SUSY-breaking Lagrangian as the sum of all the terms which do not reintroduce quadratic divergences into the theory. The model thus obtained is called Minimal Supersymmetric Standard Model (MSSM) and is characterised by a large number of parameters ( $\sim 100$ ). In order to warrant the conservation of baryonic and leptonic quantum numbers, a new multiplicative quantum number,  $R$ -parity, is introduced, which is 1 for particles and -1 for the SUSY partners. Models where  $R$ -parity is violated can be formulated, but in the current volume we concentrate on models with  $R$ -parity conservation.

The consequences of  $R$ -parity conservation are that sparticles must be produced in pairs, and that each will decay to the lightest SUSY particle (LSP) which must be stable. Cosmological arguments suggest that stable LSPs should be weakly interacting and so would escape direct detection at ATLAS, resulting in the characteristic feature expected for SUSY events – an imbalance of the transverse energy measured in the detector, abbreviated here as  $E_T^{\text{miss}}$ . The associated signatures will provide sensitivity to a large class of models. The aim of the simulation studies is to ensure that the ATLAS experiment will have rapid sensitivity to a large ensemble of SUSY models, and to develop a general search strategy. It is not possible to explore in full the 100-dimensional parameter space of the MSSM. It is therefore necessary to adopt some specific assumptions for the SUSY breaking, resulting in models defined by a small number of parameters at the SUSY breaking scale. Two models will be studied in detail:

- mSUGRA, where SUSY breaking is mediated by gravitational interaction;
- GMSB, where SUSY breaking is mediated by a gauge interaction through messenger gauge fields.

These two models give quite different topologies, due to the different nature of the lightest SUSY particle, which is the lightest neutralino for the mSUGRA case and the gravitino for the GMSB case. For each

of these models a set of benchmark points has been defined, on which full simulation studies have been performed.

The analysis work presented in the different SUSY notes is a coherent body of work based on an agreement among the many groups performing the analyses on many subjects both theoretical and experimental. All of the analyses are based on a common implementation of the SUSY model, common background datasets have been used, and all of the analyses apply a common definition of the physics objects in the detectors, optimised for the specific environment of the SUSY searches. In the following sections a quick overview of these common issues will be given, which should be read before approaching the detailed studies documented in the different notes.

## 2 Signal and Background generation

The simulated data used for the studies documented here have been produced by Monte Carlo simulation inside the official ATLAS software and production frameworks, and for all of the samples a detailed simulation of the detector has been performed.

### 2.1 Signal samples

For the detailed SUSY analysis a set of benchmark points in the mSUGRA and GMSB frameworks were chosen, with the aim of exploring sensitivity to a wide class of final-state signatures.

For the mSUGRA points, the principle that the predicted cosmological relic density of neutralinos should be consistent with the observed density of cold dark matter was used for guidance. In order to reproduce the observed relic density, the model parameters must result in a spectrum which ensures efficient annihilation of the neutralinos in the early universe. In the mSUGRA scenario this is possible only in restricted regions of the parameter space where annihilation is enhanced either by a significant higgsino components in the lightest neutralino or through mass relationships. The points chosen are defined in terms of the mSUGRA parameters at the unification scale:

- SU1  $m_0 = 70$  GeV,  $m_{1/2} = 350$  GeV,  $A_0 = 0$ ,  $\tan\beta = 10$ ,  $\mu > 0$ . Coannihilation region where  $\tilde{\chi}_1^0$  annihilate with near-degenerate  $\tilde{\ell}$ .
- SU2  $m_0 = 3550$  GeV,  $m_{1/2} = 300$  GeV,  $A_0 = 0$ ,  $\tan\beta = 10$ ,  $\mu > 0$ . Focus point region near the boundary where  $\mu^2 < 0$ . This is the only region in mSUGRA where the  $\tilde{\chi}_1^0$  has a high higgsino component, thereby enhancing the annihilation cross-section for processes such as  $\tilde{\chi}_1^0 \tilde{\chi}_1^0 \rightarrow WW$ .
- SU3  $m_0 = 100$  GeV,  $m_{1/2} = 300$  GeV,  $A_0 = -300$  GeV,  $\tan\beta = 6$ ,  $\mu > 0$ . Bulk region: LSP annihilation happens through the exchange of light sleptons.
- SU4  $m_0 = 200$  GeV,  $m_{1/2} = 160$  GeV,  $A_0 = -400$  GeV,  $\tan\beta = 10$ ,  $\mu > 0$ . Low mass point close to Tevatron bound.
- SU6  $m_0 = 320$  GeV,  $m_{1/2} = 375$  GeV,  $A_0 = 0$ ,  $\tan\beta = 50$ ,  $\mu > 0$ . The funnel region where  $2m_{\tilde{\chi}_1^0} \approx m_A$ . Since  $\tan\beta \gg 1$ , the width of the pseudoscalar Higgs boson  $A$  is large and  $\tau$  decays dominate.
- SU8.1  $m_0 = 210$  GeV,  $m_{1/2} = 360$  GeV,  $A_0 = 0$ ,  $\tan\beta = 40$ ,  $\mu > 0$ . Variant of coannihilation region with  $\tan\beta \gg 1$ , so that only  $m_{\tilde{\tau}_1} - m_{\tilde{\chi}_1^0}$  is small.
- SU9  $m_0 = 300$  GeV,  $m_{1/2} = 425$  GeV,  $A_0 = 20$ ,  $\tan\beta = 20$ ,  $\mu > 0$ . Point in the bulk region with enhanced Higgs production

The SUSY particle mass spectra for each of these points are listed in Table 2.

The leading-order and next-to-leading-order cross-sections at 14 TeV center of mass for the chosen points are given in Table 1. These have been calculated with the program PROSPINO 2.0.6 [1–3], using the default settings, and the parton distribution set CTEQ6M [4].

$H^+$	521.90	3530.61	518.15	378.90	401.15	440.23	638.88
$t$	175.00	175.00	175.00	175.00	175.00	175.00	175.00

Even though the SUSY benchmark points are all based on the mSUGRA scenario, they provide a rather wide range of possible decay topologies. They share some common features, for example for all these points the gluino mass is less than 1 TeV, and the ratio  $m_{\tilde{g}}/m_{\tilde{\chi}_1^0} = 6\text{--}8$ . For all points except SU2, the squark and gluino masses are comparable. Hence gluinos and squarks would be copiously produced and would decay giving relatively high  $p_T$  jets, possibly leptons, and  $E_T^{\text{miss}}$ . These features are relatively general – although not guaranteed – but the cold dark matter density predictions are very specific to mSUGRA.

The signatures from GMSB models are often very different because the  $\tilde{\chi}_1^0$  is no longer the lightest supersymmetric particle, so it would be expected to decay, and (depending on its lifetime) may do so within the detector. Given its particular experimental signature, a dedicated article of this chapter is devoted to the relevant signatures [5], where the GMSB benchmarks are discussed in detail.

## 2.2 Backgrounds

The Standard Model background processes most relevant to SUSY searches are  $t\bar{t}$ ,  $W + \text{jets}$ ,  $Z + \text{jets}$ , jet production from QCD processes and diboson production.

Different Monte Carlo generators were used for different processes, in the attempt of optimising the reliability of the estimate for the Standard Model backgrounds. See Ref. [6] for a more detailed description.

For  $t\bar{t}$  production, which is the dominant background for many of the signatures, the MC@NLO [7,8] generator was used. It includes full next-to-leading order QCD corrections, affording a quite stable absolute cross-section prediction and a good description of the final state kinematics for events with up to one additional QCD jet. QCD showering and fragmentation are performed using the HERWIG [9,10] program. Single top production is expected to add a very small contribution [11], but has also been investigated.

Typically SUSY analyses require large jet multiplicities. It is very important to simulate correctly the kinematics of the additional jets for processes like  $W + \text{jets}$  and  $Z + \text{jets}$ . For these processes we therefore used the ALPGEN [12] generator, which at leading order in QCD and electroweak interactions, calculates the exact matrix elements for multiparton hard processes in hadronic collisions. Showering and hadronisation are provided through the HERWIG program. In order to achieve a correct description of the jet multiplicities, it is necessary to perform a correct match between the jets produced by the matrix-element generator and the ones produced by parton showering. This topic is the subject of active theoretical work. Background samples of  $W$  and  $Z$  containing at least four jets were produced with ALPGEN, using MLM matching [13] and with the jet matching cut set at 40 GeV. Contributions from processes with matrix-element parton multiplicities between one and five were summed to produce the multi-jet sample. A filter was applied at the generator level requiring at least four jets with transverse momentum above 40 GeV, with at least one of these having a transverse momentum above 80 GeV, and with missing transverse energy above 80 GeV.

The leading-order cross-sections were normalised to the results from next-to-next-leading-order calculations by applying a  $k$  factor of 1.15 (1.27) for  $W$  ( $Z$ ) production respectively. The  $k$  factor was calculated by comparing the inclusive leading-order cross-section to the NNLO calculation of [14]. For topologies involving fewer than four jets, the PYTHIA generator [15] was used for the generation of the  $W$  and  $Z$  boson backgrounds.

For the simulation of QCD multi-jet samples, ALPGEN would also be an appropriate choice. For practical reasons, however, it was impossible to generate ALPGEN samples with sufficiently large numbers of events to simulate the backgrounds for these studies. As a backup solution we have used a shower Monte Carlo, PYTHIA, for which adequate statistics could be generated by producing samples in slices of the  $p_T$  of the hard scattering. A filter at generation level is applied to the PYTHIA events, requiring for the hardest jet a transverse momentum above 80 GeV, for the second jet transverse momentum above

Table 3: Kinematic boundaries, number of events and integrated luminosity of the PYTHIA QCD background samples.

Label	$p_T$ range (GeV)	N	Int. Lumi ( $\text{pb}^{-1}$ )
J4	140-280	18 k	19.6
J5	280-560	60 k	168.4
J6	560-1120	20 k	296.6
J7	1129-2240	4 k	754.7
J8	>2240	4 k	181000

40 GeV and missing transverse energy above 100 GeV. The numbers of events which were used for detailed simulation, and the corresponding integrated luminosity for each  $p_T$  slice are shown in Table 3.

The contributions of the diboson processes  $WW$ ,  $ZZ$  and  $WZ$  are almost negligible for multi-jet analyses as they are strongly suppressed by typical SUSY selections requiring a large number of jets with high transverse momenta and large missing transverse energy. However they are very important when searching for direct gaugino production [16]. The corresponding data samples were generated at leading order with the HERWIG Monte Carlo, including the full off-shell structure for  $Z/\gamma$ . The cross-sections were then normalised to the next-to-leading-order cross-sections calculated with the MCFM code [17].

For all the samples except QCD jet production a sample corresponding to at least  $1 \text{ fb}^{-1}$  of integrated luminosity was simulated.

Pile-up and cavern background simulations were generally not included in the signal and background samples except in a few cases where this is specifically indicated.

### 3 Object Identification for SUSY analysis

Supersymmetric events are expected to be characterised by several high-momentum jets and missing transverse energy. Leptons<sup>1</sup> and taus are also present in a large fraction of the events for the benchmark points considered. The analyses documented in this Chapter use common particle identification criteria, which are briefly described in this section.

#### 3.1 Jets

Because of the relatively large multiplicity of jets in SUSY events, a narrow cone is preferable in the reconstruction of jets. The algorithm used to reconstruct jets in the analysis documented here is the cone algorithm [18] with a cone size of 0.4. Most analyses presented do not rely on secondary-vertex tagging (“ $b$  tagging”) but when it is applied, standard ATLAS algorithms [19] are used.

#### 3.2 Missing transverse energy

The measurement of the transverse energy imbalance in the detector plays a crucial role in the searches for Supersymmetry with R-parity conservation, and the requirement of a large value of  $E_T^{\text{miss}}$  is a common feature of all the analyses presented in this chapter.

<sup>1</sup>Except where explicitly indicated, in this Chapter the word “lepton” and the corresponding symbol  $\ell$  should be understood to mean  $\ell \in \{e, \mu\}$ , i.e. they do *not* include taus.

For the studies presented here, the  $E_T^{\text{miss}}$  is calculated from the calorimeter cells, with calibration weights derived separately for cells associated to different objects (jets, electrons, photons, taus, and non-associated clusters due to the soft part of the event) [20]. Sources of fake missing energy, such as dead or noisy parts of the calorimeter, fake muons, beam-gas and beam-halo events, cosmic rays and electronics problems are not considered here. A detailed discussion of the strategies to remove sources of fake  $E_T^{\text{miss}}$  in early data and to measure the  $E_T^{\text{miss}}$  resolution and scale can be found in [20].

The contribution from non-gaussian tails in the  $E_T^{\text{miss}}$  measurement can be strongly suppressed by requiring a minimum angular separation between the  $E_T^{\text{miss}}$  vector and the jets in the event. This cut also suppresses the contributions from jets containing hard neutrinos from the leptonic decays of charmed and beauty mesons. This issue is discussed in detail in Ref. [21].

### 3.3 Electrons

In SUSY searches, the requirement of a high  $p_T$  electron is normally associated with additional requirements on jets and  $E_T^{\text{miss}}$ . For typical SUSY analyses the background from the production of QCD jets can be reduced by cuts other than those requiring any lepton(s). Therefore stringent rejection against jets is not needed in SUSY studies, and relatively mild electron identification cuts can be applied, leading to a significant gain in efficiency especially for searches involving many leptons. Jets reconstructed within a cone<sup>2</sup> of  $\Delta R = 0.2$  of an identified electron are discarded from the jet list. This procedure prevents the same object being reconstructed both as a jet and as an electron.

A standard algorithm called “eGamma” [22] was used for the electron identification and reconstruction, using the “medium” purity cuts.

The transverse isolation energy in a cone of  $\Delta R < 0.2$  around the electron, computed using the calorimetric information, is used to select isolated electrons. This quantity is required to be smaller than 10 GeV. In the available data-sets this variable was incorrectly calculated, but a significant bias is introduced by this problem only in the crack region  $1.37 < |\eta| < 1.52$ . In this region the electron identification and measurement are also degraded because of the large amount of material in front of the calorimeter and the crack between the barrel and extended barrel of the calorimeters [23]. Events with an electron reconstructed in this region are therefore rejected.

Finally, an electron is rejected if it is found within a distance  $0.2 < \Delta R < 0.4$  of a jet, since such candidates are likely to be associated with the decay of a particle within that jet.

### 3.4 Muons

Muons were reconstructed using an algorithm (STACO), which performs a statistical combination of a track reconstructed in the muon spectrometer with its corresponding track in the inner detector [24]. A reasonable quality of combination was guaranteed with a loose requirement that the tracks should match with  $\chi^2 < 100$ . If more than one Inner Detector track matched a track from the Muon Spectrometer, only the one with best match (smallest distance  $\Delta R$ ) was kept. The total calorimeter energy deposited in a cone of  $\Delta R < 0.2$  around the muon was required to be less than 10 GeV. Finally, muons found within a distance  $\Delta R < 0.4$  of a jet were discarded.

### 3.5 Taus

As will be described in subsequent analyses, final states containing taus are one of the possible signatures to be expected within the SUSY rich phenomenology. Taus are challenging objects to identify. When taus undergo leptonic decays, their products can be detected in electron- or muon-specific analyses. However, in approximately 65% of cases, a tau decays hadronically and the resultant jet needs to be disentangled

<sup>2</sup>The cone is defined by  $\Delta R^2 = \Delta\eta^2 + \Delta\phi^2$ , where  $\eta$  and  $\phi$  are the pseudorapidity and azimuthal angle respectively.

from the overwhelming jet backgrounds expected in ATLAS. In addition, tau signatures always contain an important source of missing energy in the form of neutrinos which usually make it impossible to fully reconstruct the tau-jet energy.

Elsewhere in this volume [25] two tau reconstruction algorithms, one calorimeter-based and the other one track-based, are described. Unless otherwise stated, taus being used in this Chapter follow the recommendations from [25], with a likelihood discriminant of 4, within the fiducial region  $|\eta| < 2.5$  and  $p_T > 15$  GeV. In addition, although not crucial for the results, an overlap removal procedure has been applied. Since the electron identification efficiency is higher than the tau identification efficiency, a tau object found in a vicinity ( $\Delta R < 0.4$ ) of an electron object (following the prescriptions defined in the electron performance section of the present note) is considered to be a fake and is removed. Also, since hadronically decaying taus are also usually reconstructed as jets, when a calorimeter jet is found within  $\Delta R < 0.4$  of a reconstructed tau-jet, then the non-tau jet is disregarded.

### 3.6 Treatment of systematic uncertainties

#### 3.6.1 Detector uncertainties

Supersymmetry searches and measurements will inevitably be subject to uncertainties due to the imperfect understanding of the behaviour of the detector. Many of the performance characteristics of the detector will be constrained from the data themselves, with an accuracy which will depend on the size of the data-set available. In this chapter, we have used estimations of these uncertainties based on the precision which is likely to be achievable with  $1 \text{ fb}^{-1}$  of integrated luminosity. The detector systematics – energy scale, resolution, or efficiency variations – are applied both to the “true” backgrounds and to the control samples; data-driven methods will therefore be less sensitive to detector systematics than purely Monte Carlo-driven estimates.

**Jets and  $E_T^{\text{miss}}$**  We assume an overall uncertainty on the jet energy scale of 5%. We apply this as a global uncertainty, independently of jet  $p_T$  and  $\eta$ , and identically for light-quark jets and jets from  $b$  quarks.

The jet energy resolution will be studied on di-jet samples and jets from  $W$  boson decay in  $t\bar{t}$  events. After such measurements we expect a residual uncertainty of 10% on the resolution.

The missing transverse energy of the event,  $E_T^{\text{miss}}$ , is calculated from the transverse vector sum of high  $p_T$  objects like leptons and jets with a further component from unclustered energy. Part of the uncertainty in  $E_T^{\text{miss}}$  is thus correlated with jet energy scale uncertainties, but also a wrong calibration of unclustered energy can affect  $E_T^{\text{miss}}$ . When jets are rescaled or smeared, the  $E_T^{\text{miss}}$  is recalculated with the new jets. This takes into account the part of the  $E_T^{\text{miss}}$  uncertainty that is correlated with the jets. For the low  $p_T$  part related to the unclustered energy, we first subtract leptons and jets with  $p_T > 20$  GeV from the  $E_T^{\text{miss}}$ , apply a 10% uncertainty on the remainder, and then add the leptons and jets back in.

**Electrons** For electrons we estimate an uncertainty on the identification efficiency (including the trigger) of 0.5%. Furthermore, we assume an uncertainty on the electron energy scale of 0.2%, and on the energy resolution of 1%. All these uncertainties are assumed to be independent of  $p_T$  and  $\eta$ .

**Muons** For muons we estimate an uncertainty on the identification efficiency of 1% for muons with  $p_T < 100$  GeV, plus a 3% extrapolation uncertainty to a  $p_T$  of 1 TeV. Furthermore, we assume an uncertainty on the muon  $p_T$  scale of 0.2%, and on the  $p_T$  resolution of 4% below 100 GeV, whereas the  $p_T$  resolution at 1 TeV is assumed to be  $10 \pm 1\%$ . All these uncertainties are assumed to be independent of  $\eta$ .

**Heavy-flavour tagging** Where  $b$  tagging is used, we assume a relative uncertainty of 5% on the  $b$ -tagging efficiency, and 10% on the light-quark rejection.

### 3.6.2 Monte Carlo uncertainties

Although data-driven background estimation methods try to use Monte Carlo simulations as little as possible by construction, some dependence remains for example when trying to understand the composition of control samples when Monte Carlo-based corrections, distribution shapes or redeca methods are used.

We estimate uncertainties from the use of Monte Carlo samples by comparing different event generators, particularly Alpgen and MC@NLO, and by variation of generator parameters. For the vector boson ( $V \in W, Z$ ) + jets Alpgen samples used in this note, the standard value for the renormalization and factorization scales was  $Q^2 = M_{\ell\ell}^2 + p_T^2(V)$  where the two leptons are the vector boson decay products. The  $p_T$  threshold of the partons in the matrix-element calculation was 40 GeV, the minimum distance  $\Delta R_{jj}$  between partons was 0.7, and the parton distribution function used was CTEQ6L.

For systematic studies we vary:

- The renormalization and factorization scales between  $0.5Q$  and  $Q$  as defined above. We have also used a sample with a different scale definition  $Q^2 = \sum p_T^2(\text{partons})$ .
- The  $p_T$  threshold of partons in the matrix-element calculation, between 15 and 40 GeV.
- The distance in  $\Delta R$  between partons in the matrix-element calculation, between 0.35 and 0.7.
- The parton distribution function, comparing CTEQ6L to MRST2001J.

## 4 Global Variables

The SUSY analyses use some global event variables, built out the momenta of jets, leptons and  $\mathbf{p}_T^{\text{miss}}$ , which have a good signal discriminating power. We give here a detailed definition of these variables as used in the work described in the SUSY notes.

### 4.1 Effective mass

The **effective mass** ( $M_{\text{eff}}$ ) is a measure of the total activity in the event. It is defined as:

$$M_{\text{eff}} \equiv \sum_{i=1}^4 p_T^{\text{jet},i} + \sum_{i=1} p_T^{\text{lep},i} + E_T^{\text{miss}}$$

where the sums run respectively over the four highest  $p_T$  jets within  $|\eta| < 2.5$ , and over all of the identified leptons. This variable is useful in discriminating SUSY from Standard Model events. It has also the interesting properties that for SUSY events it the  $M_{\text{eff}}$  distribution peaks at a value which is strongly correlated with the mass of the pair of SUSY particles produced in the proton-proton interaction. It can therefore be used to quantify the mass-scale of SUSY events [26].

### 4.2 Transverse sphericity

The **transverse sphericity** ( $S_T$ ) is defined as:

$$S_T \equiv \frac{2\lambda_2}{(\lambda_1 + \lambda_2)} \quad (1)$$

where  $\lambda_1$  and  $\lambda_2$  are the eigenvalues of the  $2 \times 2$  sphericity tensor  $S_{ij} = \sum_k p_{ki} p^{kj}$ . The tensor is computed using all jets with  $|\eta| < 2.5$  and  $p_T > 20$  GeV, and all selected leptons.

SUSY events tend to be relatively spherical ( $S_T \sim 1$ ) since the initial heavy particles are usually produced approximately at rest in the detector and their cascade decays emit particles in many different directions. QCD events are dominated by back-to-back configurations ( $S_T \sim 0$ ).

### 4.3 Transverse mass

The **transverse mass**  $M_T$  is defined by:

$$M_T^2(\mathbf{p}_T^\alpha, \mathbf{p}_T^{\text{miss}}, m_\alpha, m_\chi) \equiv m_\alpha^2 + m_\chi^2 + 2(E_T^\alpha E_T^{\text{miss}} - \mathbf{p}_T^\alpha \cdot \mathbf{p}_T^{\text{miss}}) \quad (2)$$

where

$$E_T^\alpha \equiv \sqrt{(\mathbf{p}_T^\alpha)^2 + m_\alpha^2}, \quad E_T^{\text{miss}} \equiv \sqrt{(\mathbf{p}_T^{\text{miss}})^2 + m_\chi^2}, \quad (3)$$

$m_\alpha$  and  $\mathbf{p}_T^\alpha$  are the mass and transverse momentum of some visible particle and  $\mathbf{p}_T^{\text{miss}}$  is the missing-transverse-energy two-vector. The parameter  $m_\chi$  is the mass of the invisible particle, which is usually assumed to be zero.

This variable is useful when one parent particle decays to one visible and one invisible daughter particle, for example  $W \rightarrow e\nu$  where it is clear that the mass of the invisible particle (neutrino) can indeed be safely neglected.

### 4.4 Stransverse mass

The **stransverse mass**  $m_{T2}$  variable can be defined in terms of the transverse mass (Eq. (2)) by:

$$m_{T2}^2(\mathbf{p}_T^\alpha, \mathbf{p}_T^\beta, \mathbf{p}_T^{\text{miss}}, m_\alpha, m_\beta, m_\chi) \equiv \min_{\mathbf{q}_T^{(1)} + \mathbf{q}_T^{(2)} = \mathbf{p}_T^{\text{miss}}} \left[ \max \left\{ M_T^2(\mathbf{p}_T^\alpha, \mathbf{q}_T^{(1)}; m_\alpha, m_\chi), M_T^2(\mathbf{p}_T^\beta, \mathbf{q}_T^{(2)}; m_\beta, m_\chi) \right\} \right] \quad (4)$$

where  $m_\chi$  is the trial mass for the lightest SUSY particle and  $\mathbf{p}_T^{\alpha, \beta}$  are the transverse momenta of two visible particles (each of which is a candidate decay product of one of the two SUSY parent particles). The vector sum of the dummy variables  $\mathbf{q}_T^{(1)}$  and  $\mathbf{q}_T^{(2)}$  is constrained to equal the total  $\mathbf{p}_T^{\text{miss}}$  2-vector, so the missing transverse momentum is required as an input to the  $m_{T2}$  calculation. One can consider  $m_{T2}$  to be a variable formed from dividing  $\mathbf{p}_T^{\text{miss}}$  into two parts in all possible combinations that satisfy the kinematics of the event (for some  $m_\chi$ , which is here taken to be zero) and calculating the transverse mass for each decay branch. The resulting value is the best lower limit on the mass of a pair-produced SUSY particle that could have decayed to the observed final state with the given  $\mathbf{p}_T^\alpha$ ,  $\mathbf{p}_T^\beta$  and  $\mathbf{p}_T^{\text{miss}}$ .

The original purpose for  $m_{T2}$  was to provide information on the masses of pair-produced SUSY particles, decaying semi-invisibly [27, 28]. The variable was first proposed to determine SUSY particle masses in “simple” two-body decays, such as two-jet or two-lepton final states, but it can also be used in more complicated cases, especially if it is possible to unambiguously determine which particles came from which branch of the decay.

## 5 SUSY Studies in ATLAS

In this collection of papers we review the techniques that will be used to search for SUSY with ATLAS at the LHC turn-on. Most of the studies presented are based on a total integrated luminosity of  $1\text{fb}^{-1}$  that may be collected during the first year of operation of the LHC. Larger datasets are assumed for studies that investigate SUSY models with a lower cross-section as an illustration of studies that can be carried out once the LHC is in full operation.

The first two articles in this collection concentrate on the background estimation for SUSY searches:

- “Data-driven determinations of  $W$ ,  $Z$ , and top backgrounds to Supersymmetry” [11],
- “Estimation of QCD backgrounds to Searches for Supersymmetry” [21].

The following two articles discuss SUSY searches and measurements:

- “Prospects for Supersymmetry Discovery Based on Inclusive Searches” [29],
- “Measurements from Supersymmetric events” [30].

The last two papers focus on searches for specific signatures:

- “Multi-lepton Supersymmetry searches” [16],
- “Supersymmetry signatures with high- $p_T$  photons or long-lived heavy particles” [5].

# Data-Driven Determinations of $W$ , $Z$ and Top Backgrounds to Supersymmetry

## Abstract

The Standard Model processes of  $W$  boson,  $Z$  boson and top quark production each in association with jets constitute major backgrounds to searches for Supersymmetry at the LHC. In this note, we estimate the contribution of these backgrounds for a basic SUSY selection, and discuss methods to derive them from the initial  $1 \text{ fb}^{-1}$  of integrated luminosity at ATLAS.

## 1 Introduction

### 1.1 Motivation

The Large Hadron Collider (LHC) will provide excellent opportunities to search for new physics beyond the Standard Model, and the ATLAS detector [1] is a general purpose experiment to explore such new physics. Supersymmetry (SUSY) is a theoretically attractive model for new physics beyond the Standard Model, and searching for Supersymmetry is one of the main objectives of ATLAS. The actual search strategy is described elsewhere in this volume [2].

It is clear, however, that any discovery of new physics can only be claimed when the Standard Model backgrounds are understood and are under control. It is expected that at the LHC, Monte Carlo predictions will not be sufficient to achieve this: the backgrounds will have to be derived from the data themselves, possibly helped by Monte Carlo. The development and description of such data-driven background estimation is the topic of this note. We note that for a complete understanding of the backgrounds, multiple, independent methods are desired. Each of these may be sensitive to a specific background source, and affected by specific systematic effects. Only their consistency in combination allows for sufficient confidence in the control of the background to claim a discovery when a signal appears to be present.

### 1.2 Data-driven methods: scope of this note

The general aim of data-driven methods is to estimate from the data the Standard Model backgrounds and their uncertainties in a “signal” region, in which new physics may be present. Such a signal region is typically obtained after applying selection cuts, or multivariate methods, and the new physics is searched for as an excess in the number of selected events over background, or as an excess in certain regions of certain distributions.

The background estimation is performed by selection of “control samples”, from which predictions in the signal region are derived. Good control samples should be as close as possible to the signal region, yet free of SUSY signal, give an unbiased estimate of background in the signal region, have sufficient statistics, and small theoretical uncertainties. This note intends to describe a number of ideas on selection of such control samples for SUSY searches. Good control of the composition of control samples is important for a correct extrapolation into the signal region.

The methods described in this note should not be regarded as the final word on these procedures, but rather present a number of ideas. Each of these ideas will have to be pursued further, and the effect of other systematic uncertainties will need to be studied. Furthermore, SUSY selection cuts will evolve, and so the methods will need to evolve too. We do believe, however, that a first indication of the uncertainties that can be expected can be given.

This note deals with top,  $W$  and  $Z$  backgrounds to SUSY searches with primary squark or gluino production, and assuming  $R$ -parity conservation. The initial priority is to simulate results for  $1 \text{ fb}^{-1}$  of integrated luminosity, and for the understanding of the detector expected. The other important QCD background of quark (other than top) and gluon jet production is treated elsewhere in this volume [3]. Backgrounds to alternative production models are also described elsewhere: direct gaugino production [4], and photonic and long-lived particle (such as  $R$  hadron) signatures [5].

### 1.3 SUSY contamination

If SUSY is discoverable, it is likely that SUSY events will creep into the control samples, thereby affecting the background estimates. In general, SUSY events, mistakenly regarded as Standard Model physics, will lead to an overestimation of the background, and thus to a reduced SUSY event excess. The extent to which this happens will be analysis- and SUSY model-dependent.

Since we do not know whether SUSY exists, we quote the SUSY contamination effects separately from the other systematics. We will do so by running each data-driven estimation method not only over background samples, but also on a number of SUSY signal samples [6]. The samples represent various regions of mSUGRA parameter space, and together give an impression of the effects. The SU1 sample is a point in the stau coannihilation region, the SU2 sample in the focus point region, and the SU3 sample in the bulk region. The SU4 point is a low-mass point, just above the Tevatron limits. It has a very large cross-section, and kinematic distributions that are typically only slightly harder than the Standard Model background. As will be shown, this model has the largest SUSY contamination effect on the background estimates.

There are a number of ways that the data-driven methods can take the presence of SUSY into account:

1. Iteration. The Standard Model background is evaluated under the assumption that there is no SUSY. This will overestimate the background if there is SUSY, and reduce any excess. Nevertheless, if an excess is seen, the underlying assumption in the background estimation has been proven wrong, and a correction can be applied. This correction can be derived from the properties of the observed excess, and will lead to a new background estimate. An example of such a procedure is the “new MT method” described in section 3.3.3. However, other implementations are possible, and perhaps necessary, as well.
2. A combined fit determining the composition of the control sample, allowing for a possible SUSY contribution.

Both methods are investigated in this note. Nevertheless it is clear that these are preliminary ideas that require further investigation. Most likely, some form of iteration on the background determinations will be necessary.

### 1.4 Layout of this note

A number of important prerequisites for the studies presented here are described in an introductory note [6]:

- the physics processes that form the background to SUSY searches and how they are simulated, as well as a few SUSY event samples (SU1–SU8) that serve to estimate the effect of SUSY on our background estimates;
- the definition of objects like electrons, muon, taus, jets and missing transverse energy, and common variables like the effective mass  $M_{\text{eff}}$  ;

- the origin and common treatment of various systematic uncertainties, both from the simulation and from the performance of the detector.

Furthermore, the trigger menu that was used is described elsewhere [7]. In this note we then discuss the  $W$ ,  $Z$ , and top-quark backgrounds and their data-driven estimation for two different SUSY search modes:

1. the mode with one isolated electron or muon (section 2);
2. the no-lepton mode, with a veto against isolated leptons (section 3).

## 2 One-lepton search mode

### 2.1 Selection

The one-lepton search mode is expected to play a major role in the SUSY search, since the requirement of an isolated lepton will be effective in suppressing QCD background. In this search mode, we require one isolated electron or muon, with a  $p_T$  of more than 20 GeV. We veto events with a second identified lepton with a  $p_T$  of more than 10 GeV, so that we have no overlap with the di-lepton search mode.

We demand at least four jets with  $|\eta| < 2.5$  and  $p_T > 50$  GeV, at least one of which must have  $p_T > 100$  GeV. The transverse sphericity  $S_T$  should be larger than 0.2, and the missing transverse energy  $E_T^{\text{miss}}$  should be larger than 100 GeV and larger than  $0.2M_{\text{eff}}$ , where  $M_{\text{eff}}$  is the effective mass<sup>1</sup>. The transverse mass  $M_T$  reconstructed from the lepton and  $E_T^{\text{miss}}$  should be larger than 100 GeV.

### 2.2 Backgrounds in Monte Carlo

In many SUSY models after the selection cuts have been applied clear excesses will be observed in the high  $E_T^{\text{miss}}$  and high effective mass regions, as shown in Figure 1. The dominant background process for the one-lepton mode is  $t\bar{t}$  (90%), with  $W^\pm + \text{jets}$  (10%) being the subdominant process. The neutrino emitted from the  $W^\pm$  decays produces the  $E_T^{\text{miss}}$  in the both processes. Smaller contributions come from  $Z + \text{jets}$ , diboson and single top events and from QCD processes. It is interesting to note that the major  $t\bar{t}$  background does not come from the semileptonic ( $t\bar{t} \rightarrow b\bar{b}\ell\nu q\bar{q}'$ ) top pair events which are reduced by the  $M_T$  and  $E_T^{\text{miss}}$  cuts, but rather from the double leptonic ( $t\bar{t} \rightarrow b\bar{b}\ell\nu\ell\nu$ ) top decay where one lepton is not identified.

### 2.3 Data-driven estimation strategies

We discuss a variety of different methods to estimate the background from data. These methods differ in their approach and therefore are influenced by different systematic uncertainties, and they focus on different aspects of the background:

1. estimation of  $W$  and  $t\bar{t}$  background from a control sample formed by reversing one of the selection cuts (on  $M_T$ ) (section 2.3.1);
2. estimation of the semileptonic  $t\bar{t}$  background by explicit kinematic reconstruction and selection on top mass (“top box”) (section 2.3.2);
3. estimation of the double leptonic  $t\bar{t}$  background, where one lepton is missed, by explicit kinematic reconstruction of a control sample of the same process with both leptons identified (section 2.3.3);

---

<sup>1</sup>The variables  $S_T$ ,  $M_{\text{eff}}$  and  $M_T$  are defined elsewhere in this volume [6].

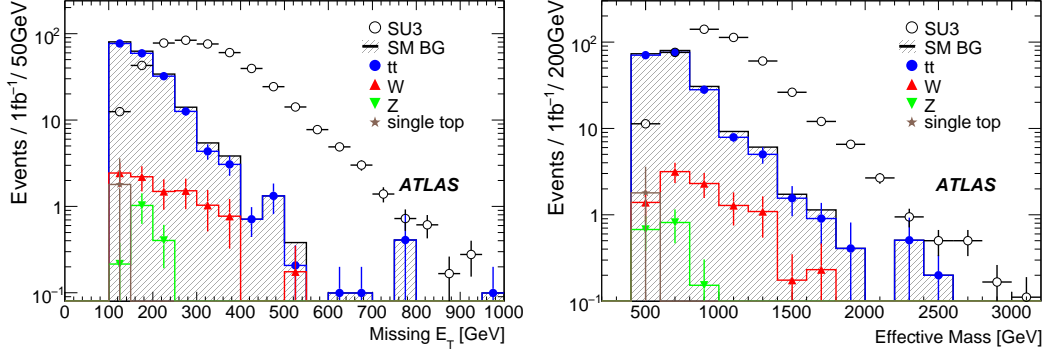

Figure 1: The  $E_T^{\text{miss}}$  and effective mass distributions for the background processes and for an example SUSY benchmark point (SU3) in the one-lepton mode for an integrated luminosity of  $1 \text{ fb}^{-1}$ . The black circles show the SUSY signal. The hatched histogram show the sum of all Standard Model backgrounds; also shown in different colours are the various components of the background.

4. estimation of that same double leptonic  $t\bar{t}$  background from a control sample derived by a cut on a new variable HT2 (section 2.3.4);
5. estimation of  $t\bar{t}$  background by Monte Carlo redecay methods (section 2.3.5);
6. estimation of  $W$  and  $t\bar{t}$  background using a combined fit to control samples (section 2.3.6).

### 2.3.1 Creating a control sample by reversing the $M_T$ cut

The transverse mass  $M_T$  is constructed from the identified lepton and the missing transverse energy. In the narrow-width limit  $M_T$  is constrained to be less than  $m_W$  for the semileptonic  $t\bar{t}$  and the  $W^\pm$  processes. Figure 2 shows that  $M_T$  is only weakly dependent on  $E_T^{\text{miss}}$ . This variable is therefore suitable for the estimation of the background distribution itself. Events with small  $M_T$  ( $< 100 \text{ GeV}$ ) are selected as the control sample, in which the  $t\bar{t}$  ( $\sim 84\%$ ) and  $W^\pm$  ( $\sim 16\%$ ) processes are enhanced over the SUSY and the other background processes. The large  $M_T$  ( $> 100 \text{ GeV}$ ) region is referred to as the signal region. Since, for the control sample, the other selection criteria are identical to those for events in the signal region, the same kinematic distributions including  $E_T^{\text{miss}}$  can be obtained. The number of events for the various processes in signal region and control sample is summarized in the Table 1.

Table 1: Number of background events and estimated numbers for  $t\bar{t}$ ,  $W^\pm$  and QCD processes without SUSY signal, normalized to  $1 \text{ fb}^{-1}$ .

	Signal Region	Control Sample
$t\bar{t}(\ell\nu q\bar{q})$	51 (25%)	1505 (77%)
$t\bar{t}(\ell\nu\ell\nu)$	140 (70%)	132 (7%)
$W^\pm(\ell\nu)$	10 (5%)	305 (16%)
SUSY(SU3)	450	317

The normalization factor is obtained from the event numbers of the signal region and the control sample ( $100 < E_T^{\text{miss}} < 200 \text{ GeV}$ ), in which the SUSY signal contribution is expected to be relatively

Figure 2: The  $E_T^{\text{miss}}$  distribution for  $t\bar{t}$  (left) and SUSY (SU3, right) signal. In both figures, the solid and dashed histograms show the  $E_T^{\text{miss}}$  distribution for  $M_T > 100$  GeV and  $< 100$  GeV, respectively. The numbers are normalized to  $1 \text{ fb}^{-1}$ .

small. Figure 3 shows the  $E_T^{\text{miss}}$  and  $M_{\text{eff}}$  distributions which are obtained using this method to estimate the size of these backgrounds, and, for comparison, the true background distributions. The numbers of events with  $E_T^{\text{miss}} > 100$  GeV and  $> 300$  GeV are listed in Table 2. The prediction and the true values agree within the uncertainties, although somewhat less well for high  $E_T^{\text{miss}}$ .

The  $t\bar{t}$  event composition of the control sample differs from that of the signal sample, since the  $M_T$  cut removes a much larger proportion of the semileptonic  $t\bar{t}$  events. The control sample is still able to predict the background in the signal sample within statistical uncertainties. Nevertheless, the resulting systematic shift needs to be investigated, and would be desirable to obtain independent estimates of the fully-leptonic and semileptonic  $t\bar{t}$  backgrounds separately.

Figure 3: The  $E_T^{\text{miss}}$  and effective mass distributions of the background processes for the one-lepton mode with an integrated luminosity of  $1 \text{ fb}^{-1}$ . The open circles show the estimated distributions with the  $M_T$  method. The hatched histogram shows the true sum of all Standard Model backgrounds; different symbols show the various contributions to the background.

**SUSY signal contamination** If supersymmetric particles are produced they are also likely to contribute to the control samples. The estimated  $E_T^{\text{miss}}$  distribution with the presence of a SUSY signal (SU3 point) is shown in Figure 4 (left), and the numbers are listed in Table 3. The background is overestimated due to the SUSY contamination, and the inferred  $E_T^{\text{miss}}$  distribution is biased towards larger values. However,

Table 2: Numbers of background events and estimated numbers for the sum of all background processes without SUSY signal, normalized to  $1 \text{ fb}^{-1}$ 

	$E_T^{\text{miss}} > 100 \text{ GeV}$	$E_T^{\text{miss}} > 300 \text{ GeV}$
True BG	$203 \pm 6$	$12.4 \pm 1.6$
Estimated BG	$190 \pm 8$	$9.4 \pm 0.7$
Ratio(Est./True)	$0.93 \pm 0.05$	$0.76 \pm 0.11$

the amount of the over-estimation is smaller than the SUSY signal itself, and a clear excess can still be observed, as shown in the figure. The same exercise was repeated for other SUSY signal points, as also shown in Table 3.

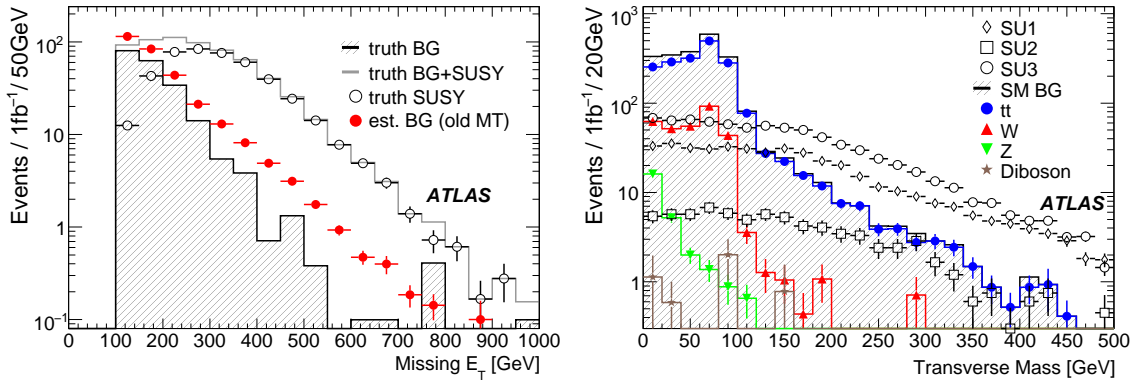

Figure 4: Left: the  $E_T^{\text{miss}}$  distribution of the background processes for the one-lepton mode with an integrated luminosity of  $1 \text{ fb}^{-1}$ . The red dots show the estimated distributions with the  $M_T$  method, with SUSY signal (SU3) present. The hatched histogram shows the sum of all Standard Model backgrounds, and the OPEN histogram shows the SUSY signal (SU3). Right: the transverse mass distributions of the various SUSY signals (SU1, SU2 and SU3) with an integrated luminosity of  $1 \text{ fb}^{-1}$ . Background processes are superimposed for comparison. The hatched histogram shows the sum of all Standard Model backgrounds.

**Correcting for SUSY signal: “New MT method”** If, even for overestimated backgrounds, the presence of a concrete SUSY excess is observed in data, we can try to correct the background estimates.

One possible procedure is described here, referred to as the “new MT method”. More advanced implementations of such a correction procedure are possible and should be studied.

The new MT method makes use of the observation that in the one-lepton search mode, the  $M_T$  distribution of backgrounds falls off steeply beyond  $\sim 100 \text{ GeV}$ , whereas for many SUSY signal models this distribution falls only slowly. This is illustrated in Figure 4 (right). By making a general ansatz for the shape of the SUSY  $M_T$  distribution, and neglecting to first order the Standard Model background at high  $M_T$ , the SUSY contamination can be subtracted from the control sample. Obviously, remaining Standard Model background in the high  $M_T$  region and variations in the  $M_T$  shape for various SUSY signals are to be treated as systematic uncertainties on the method. Nevertheless, the data itself will tell what the  $M_T$  shape is.

Table 3: Number of background events and estimated numbers for all background processes with SUSY signal, normalized to  $1 \text{ fb}^{-1}$ . Also the total number of events (SUSY + background) is shown.

	$E_T^{\text{miss}} > 100 \text{ GeV}$	$E_T^{\text{miss}} > 300 \text{ GeV}$	$E_T^{\text{miss}} > 100 \text{ GeV}$	$E_T^{\text{miss}} > 300 \text{ GeV}$
True BG	$203 \pm 6$	$12.4 \pm 1.6$	$203 \pm 6$	$12.4 \pm 1.6$
Estimated BG True BG+SUSY	SU1		SU4	
	$225 \pm 9$ $463 \pm 7$	$21.6 \pm 1.1$ $194 \pm 4$	$2366 \pm 102$ $3177 \pm 79$	$165 \pm 12.7$ $415 \pm 29$
Estimated BG True BG+SUSY	SU2		SU6	
	$200 \pm 9$ $249 \pm 7$	$10.9 \pm 0.7$ $34 \pm 2$	$213 \pm 9$ $365 \pm 9$	$16.3 \pm 0.9$ $129 \pm 5$
Estimated BG True BG+SUSY	SU3		SU8	
	$296 \pm 10$ $653 \pm 8$	$33.3 \pm 1.4$ $245 \pm 4$	$206 \pm 9$ $354 \pm 8$	$13.7 \pm 0.8$ $115 \pm 5$

In the simplest ansatz used here, the ratio of SUSY signal between the control sample  $M_T < 100 \text{ GeV}$  and signal region  $M_T > 100 \text{ GeV}$  is assumed to be constant for all SUSY signal samples. The normalization factor is obtained from the number of events in the signal region and the corrected control sample in the interval  $100 \text{ GeV} < E_T^{\text{miss}} < 150 \text{ GeV}$  (instead of  $100 - 200 \text{ GeV}$ ) to suppress the SUSY contribution in the normalization region. The statistical error becomes relatively larger when the narrow band is used for normalization, but the over-estimation of the normalization factor due to the SUSY signal can be suppressed. A lower  $E_T^{\text{miss}}$  region, such as  $E_T^{\text{miss}} = 70 - 100 \text{ GeV}$ , could be used for the normalization in future studies.

Figure 5 shows the  $E_T^{\text{miss}}$  and the effective mass distributions of the estimated background processes. The true distributions of the background processes are also superimposed. The numbers in regions of  $E_T^{\text{miss}} > 100 \text{ GeV}$  and  $300 \text{ GeV}$  are listed in Table 4. A reasonable agreement between the prediction and the true values is observed. For high values of  $E_T^{\text{miss}}$ , the method tends to subtract too much SUSY contamination and underestimates the background. More study is needed. The SU4 benchmark point is a special case because it has a particularly light SUSY particle spectrum.

Figure 5: The  $E_T^{\text{miss}}$  and effective mass distributions of the background processes for one lepton mode with an integrated luminosity of  $1 \text{ fb}^{-1}$ . The red dots show the estimated distributions with the “new  $M_T$ ” method. The hatched histogram show the sum of all Standard Model backgrounds. The open circles indicate the SUSY (SU3) signal.

Table 4: Numbers of background events and estimated numbers for all background processes in the presence of various SUSY signals, using the new MT method. The numbers are normalized to  $1 \text{ fb}^{-1}$ .

	$E_T^{\text{miss}} > 100 \text{ GeV}$	$E_T^{\text{miss}} > 300 \text{ GeV}$	$E_T^{\text{miss}} > 100 \text{ GeV}$	$E_T^{\text{miss}} > 300 \text{ GeV}$
True BG	$203 \pm 6$	$12.4 \pm 1.6$	$203 \pm 6$	$12.4 \pm 1.6$
Estimated BG True BG+SUSY	SU1		SU4	
	$186 \pm 11$	$8.9 \pm 0.8$	$1382 \pm 98$	$48.3 \pm 12.7$
	$463 \pm 7$	$194 \pm 4$	$3177 \pm 79$	$415 \pm 29$
Estimated BG True BG+SUSY	SU2		SU6	
	$183 \pm 11$	$8.8 \pm 0.8$	$185 \pm 11$	$8.1 \pm 0.9$
	$249 \pm 7$	$34 \pm 2$	$365 \pm 9$	$129 \pm 5$
Estimated BG True BG+SUSY	SU3		SU8	
	$212 \pm 11$	$12.3 \pm 1.0$	$180 \pm 11$	$6.6 \pm 0.8$
	$653 \pm 8$	$245 \pm 4$	$354 \pm 8$	$115 \pm 5$

The systematic uncertainties<sup>2</sup> for the MT method are summarized in Table 5. As well as variation of jet energy scale and lepton identification efficiency, the ALPGEN Monte Carlo was compared to MC@NLO, and parameters in ALPGEN (minimum  $p_T$  of partons and minimum  $\Delta R$  between partons) were varied. This method is stable against these systematic uncertainties at the  $\sim 15\%$  level. More work is needed to estimate the SUSY contamination effects.

 Table 5: Systematic uncertainties of the one-lepton background estimations with the MT method, excluding those related to SUSY signal contamination. Numbers are normalized to  $1 \text{ fb}^{-1}$ 

	Syst. error
Jet energy scale	$< 5\%$
Lepton ID efficiency	$7\%$
MC@NLO vs ALPGEN	$8\%$
Monte Carlo parameter variation (ALPGEN)	$< 5\%$

### 2.3.2 Topbox: a control sample for semileptonic top-pair background

**Top mass reconstruction and “topbox” cuts** This section describes a data-driven method, denoted the “topbox method”, for estimating the  $t\bar{t}$  background where one top decays leptonically, and the other hadronically.

For semileptonic  $t\bar{t}$  events, the invariant mass of the leptonically decaying  $W$  boson can usually be reconstructed by assuming that the neutrino from the  $W$  decay is responsible for all missing energy. This is a fair assumption; after removal of fake  $E_T^{\text{miss}}$  (noisy/dead calorimeter cells etc.) in the event-cleaning procedure, the resolution on  $E_T^{\text{miss}}$  is expected to be approximately equal to  $0.55\sqrt{\sum E_T}$  [1], which is much smaller in a typical  $t\bar{t}$  event than the  $E_T^{\text{miss}}$  from the escaping neutrino. The fact that the mass of the leptonically decaying top can be reconstructed satisfactorily (see below) further justifies the assumption.

The core of the method is to construct both the semileptonic and the hadronic top decays in a  $t\bar{t}$  event following the procedure below:

<sup>2</sup>Throughout this note systematic uncertainties have been calculated according to the procedures outlined in the introduction to this chapter [6].

- The leptonic  $W$  is assumed to decay into the observed lepton and a neutrino which is responsible for all missing energy. The  $p_x$  and  $p_y$  components of the neutrino momentum are hence taken to be the  $x$  and  $y$  components of  $E_T^{\text{miss}}$ . The  $p_z$  component of the neutrino can be calculated using a  $W$  mass ( $m_W$ ) constraint. The four-vector of the leptonic  $W$  is the sum of the four-vectors of the lepton and the reconstructed neutrino. For events with transverse mass  $M_T$  less than  $m_W$ , two solutions can be found. In the case of  $M_T > m_W$  no real solution is possible and, in such cases, the momentum of the leptonic  $W$  is taken from the transverse components of the lepton and  $E_T^{\text{miss}}$ .
- The leptonic top is then reconstructed by taking the solution with the best reconstructed top mass ( $m_{\text{top-lep}}$ ) from combinations of a jet and one of the above leptonic  $W$  solutions. The jet is taken from the pool of the four highest- $p_T$  jets in the event. The best reconstructed top mass is defined to be the one that is closest to the nominal top mass  $m_t$ .
- The hadronic  $W$  is then taken to be formed from the best reconstructed  $W$  mass ( $m_{W\text{-had}}$ ) among the two-jet combinations from the remaining three jets in the pool. The best reconstructed  $W$  mass is defined to be the invariant closest to  $m_W$ .
- Finally, the hadronic top is taken to be the one with the best reconstructed top mass ( $m_{\text{top-had}}$ ) among combinations of the hadronic  $W$  and one of the remaining jets.

The plots in Figure 6 show the distributions of the reconstructed masses  $m_{\text{top-lep}}$ ,  $m_{W\text{-had}}$ , and  $m_{\text{top-had}}$  after the mass reconstruction procedure described above. The distributions are made for  $t\bar{t}$ , SU3 and  $W$  + jets event samples with standard one-lepton cuts, except for a modified  $M_T$  requirement (see below in the control sample section). As expected, the topbox mass reconstruction procedure offers a very good separating power between  $t\bar{t}$  and other processes.

The topbox cuts are then defined as follows:  $|m_{\text{top-lep}} - m_t| < 25$  GeV,  $|m_{W\text{-had}} - m_W| < 15$  GeV, and  $|m_{\text{top-had}} - m_t| < 25$  GeV.

**Topbox control sample** To make the topbox control sample, events are selected with the standard SUSY search cuts in the one-lepton mode, with the exception that  $M_T > 100$  GeV is replaced by  $M_T < m_W$ . In addition, the above topbox cuts are applied.

Table 6 shows the number of events of various processes in the topbox control sample. The  $t\bar{t}$  + jets process makes up more than 95% of the topbox control sample if no SUSY signal is present.

Table 6: Composition of the topbox control sample. Numbers shown correspond to an integrated luminosity of  $1 \text{ fb}^{-1}$ . The last five columns show the number of SUSY events which would enter into the topbox control sample.

Process	$t\bar{t}$ + jets	$W$ + Jets	SU1	SU2	SU3	SU4	SU6
Events	340.9	6.8	1.8	0.4	4.9	243.6	0.4

**SUSY signal contamination** Table 6 also shows the number of SUSY events, for various signal samples, in the topbox control sample, for  $1 \text{ fb}^{-1}$ . In this method, SUSY contamination is in general small. This fact makes the topbox method a good supplement to the other methods (e.g. the MT method). The exception is the SU4 benchmark point, which has a larger contribution because its light spectrum makes it rather similar to the  $t\bar{t}$  background.

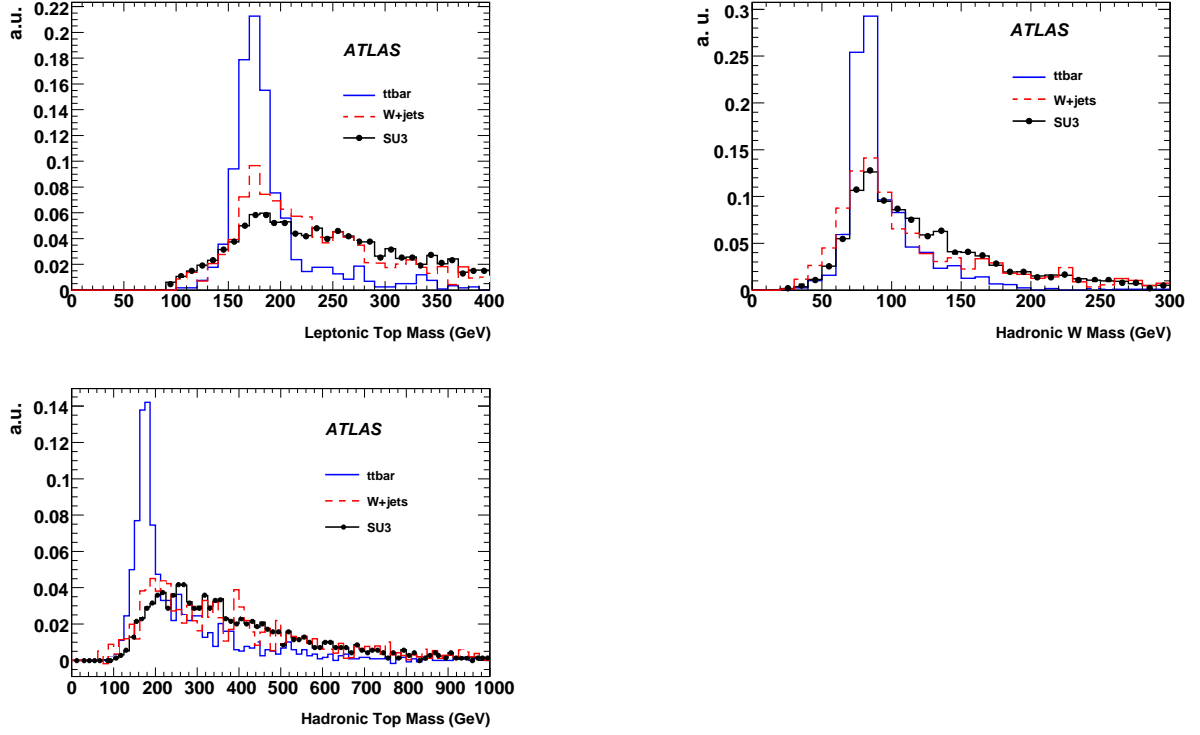

Figure 6: Normalized distributions for reconstructed  $m_{\text{top-lep}}$ ,  $m_{W\text{-had}}$ , and  $m_{\text{top-had}}$  for  $t\bar{t}$ ,  $W + \text{jets}$ , and SU3 SUSY events, using the “topbox” method.

**Estimation of the  $t\bar{t}$  background in the signal region** The  $t\bar{t}$  contamination in the signal region is estimated by multiplying the number of events in the data topbox by a scaling factor  $R_{tt}$ .  $R_{tt}$  is defined as the ratio of the number of Monte Carlo  $t\bar{t}$  events in the signal region (those that pass the one-lepton cuts) to that in the topbox control sample. The procedure is summarized by the following equations:

$$N_{t\bar{t}}^{\text{signal-region}}(\text{data}) = N_{t\bar{t}}^{\text{topbox}}(\text{data}) \cdot R_{tt} \quad (1)$$

$$R_{tt} \equiv N_{t\bar{t}}^{\text{signal-region}}(\text{MC}) / N_{t\bar{t}}^{\text{topbox}}(\text{MC}) \quad (2)$$

With fully simulated Monte Carlo samples,  $R_{tt}$  is determined to be 0.386. The model dependence (variation of Monte Carlo generator and generator parameters) of this number is treated as a systematic uncertainty.

**Systematics** The systematic uncertainties of the topbox method are summarized in Table 7. The largest source of uncertainty is from the jet energy scale uncertainty; this is expected since the method relies heavily on the reconstruction of top and  $W$  masses. The Monte Carlo model dependency of  $R_{tt}$  is estimated by comparing MC@NLO and ALPGEN, and by variation of the ALPGEN parameters, and amounts to 8%. Finally, it is expected that extra jets due to event pile-up may affect the mass reconstruction resolution. However, this is relevant only in high luminosity scenarios, beyond the scope of this note. The statistical uncertainty on the topbox control sample normalization is estimated to be 5% for  $1 \text{ fb}^{-1}$  given that the effective cross-section of  $t\bar{t}$  in the topbox is about 400 fb.

Table 7: Systematic uncertainties of the topbox method for  $1 \text{ fb}^{-1}$ .

Source	Contribution [%]
Jet energy scale	20
$E_T^{\text{miss}}$ scale	2
Monte Carlo Model dependence of $R_{tt}$	8
Total	22

### 2.3.3 Di-leptonic top with one lepton missed: kinematic reconstruction

**Introduction** Fully leptonic  $t\bar{t}$  events may contribute to the one-lepton SUSY search sample if one of the two leptons originating from the  $W$  decay is not identified. Such events can be classified as: (1) events with one tau (51%); (2) events where one lepton is misidentified due to inefficiency of the lepton identification algorithms (20%); (3) events where one lepton is lost inside a jet (17%); (4) events where one lepton is not in the  $p_T$  or  $\eta$  acceptance (9%); and (5) events with two tau leptons (3%).

The method discussed here is based on the selection of a sample enhanced in  $t\bar{t} \rightarrow b\bar{b}\ell\nu\ell\nu$  events by requiring that the events satisfy a set of kinematic constraints particular to the  $t\bar{t} \rightarrow b\bar{b}\ell\nu\ell\nu$  process. This sample, denoted as the control sample, with two isolated identified leptons, is used to estimate the contribution from the first two categories of events listed above. The contribution from category (1) is estimated by replacing one of the leptons in the control sample with a tau, and category (2) is estimated by removing one of the two leptons. The contribution from the categories (3)–(5) is not estimated from the control sample. Events were required to fire either the 4j50 multi-jet trigger or the j80\_xE50 jet plus  $E_T^{\text{miss}}$  trigger [7].

**Selection of the control sample** The following requirements are imposed to select events in the control sample: two isolated oppositely-charged leptons (electron or muon), with  $p_T > 10 \text{ GeV}$  and at least one with  $p_T > 20 \text{ GeV}$ ; at least three jets with  $|\eta| < 2.5$  and  $p_T > 50 \text{ GeV}$  at least one of which must have  $p_T > 100 \text{ GeV}$ . Note that in contrast to the SUSY one-lepton search selection given in Sec. 2.1 only three jets are required, since the misidentified lepton or tau can produce the fourth jet.

For  $t\bar{t} \rightarrow b\bar{b}\ell\nu\ell\nu$  events the two leptons, two  $b$  jets and the  $x$ - and  $y$ -components of the  $E_T^{\text{miss}}$ -vector satisfy the following kinematic constraints:

$$\begin{aligned}
 (p_\nu + p_{\ell^+})^2 &= m_W^2, \\
 (p_{\bar{\nu}} + p_{\ell^-})^2 &= m_W^2, \\
 (p_\nu + p_{\ell^+} + p_b)^2 &= m_t^2, \\
 (p_{\bar{\nu}} + p_{\ell^-} + p_{\bar{b}})^2 &= m_t^2, \\
 p_{\nu_x} + p_{\bar{\nu}_x} &= E_{T,x}^{\text{miss}}, \\
 p_{\nu_y} + p_{\bar{\nu}_y} &= E_{T,y}^{\text{miss}},
 \end{aligned} \tag{3}$$

where  $p_{\ell^\pm}$ ,  $p_{\nu/\bar{\nu}}$ ,  $p_{b/\bar{b}}$  are the lepton, neutrino and  $b$ -quark momenta respectively and  $m_W$  and  $m_t$  are the  $W$  boson and top quark masses. We assume that the only source of  $E_T^{\text{miss}}$  is a pair of neutrinos, which is a fair assumption as shown in the previous section.

The final state contains two unknown neutrino momenta and the above system of equations has a two- or four-fold ambiguity, as the solution is given by a quartic equation which can be solved with standard analytical techniques [8]. Since there are at least three jets in each event, all possible combinations of

jet pairs made from the three highest  $p_T$  jets are considered. Jet pairs for which the above system of equations has real solutions are denoted as  $b$ -jet pairs<sup>3</sup>. Figure 7 (left) shows the number of  $b$ -jet pairs for the various processes contributing to the control sample.

Figure 7: Left: distribution of number of  $b$ -jet pairs for events passing the control sample requirements in the kinematic reconstruction method. The fraction of  $t\bar{t} \rightarrow b\bar{b}l\nu l\nu$  events with no  $b$ -jet pairs is dominated by events with at least one  $b$  jet which is not among the three highest- $p_T$  jets. Right: distribution of  $E_T^{\text{miss}}$  for  $t\bar{t} \rightarrow b\bar{b}l\nu l\nu$  events with one tau lepton and events with a misidentified lepton compared to the estimation from resimulated events with an integrated luminosity of  $1 \text{ fb}^{-1}$ . The requirement on the number of  $b$ -jet pairs is not applied to the resimulated events. The distribution of all  $t\bar{t} \rightarrow b\bar{b}l\nu l\nu$  events is also shown.

**Replacement procedure** Each event in the control sample is used as a seed for producing a series of resimulated events. One of the two identified leptons in the seed event is replaced by tau lepton and a set of 1000 tau decays are simulated using the TAUOLA package [9]. The same procedure is repeated for the second lepton in the seed event, yielding a total of 2000 events for every seed event. Each resimulated event is weighted by a factor of  $1/\varepsilon$ , where  $\varepsilon$ , the identification efficiency for the replaced lepton, is estimated from simulations.

The contribution of events where one lepton evades identification is estimated as follows. If the replaced lepton is an electron then a jet with the same momentum is substituted instead of it. If the lepton is a muon it is replaced by a so-called stand-alone muon (defined as a track in the muon spectrometer with no match to a track in the inner detector) justified by the fact that most muons not passing the muon definition are stand-alone muons. This procedure is applied to each of the two leptons in the seed events, resulting in two resimulated events for each seed event. The resimulated events are re-weighted with  $\frac{1-\varepsilon}{\varepsilon}$ .

For both kinds of resimulated events, the SUSY one-lepton search selection are subsequently applied.

As a closure test of the replacement procedures described above, the  $E_T^{\text{miss}}$  distribution for resimulated  $t\bar{t} \rightarrow b\bar{b}l\nu l\nu$  events passing the control sample selection apart from the requirement of  $b$ -jet pairs, is compared to the Monte Carlo prediction. The result is shown in Fig. 7 (right) and shows good agreement.

**Normalization** The number of  $t\bar{t} \rightarrow b\bar{b}l\nu l\nu$  events in the signal region is estimated by scaling of the sum of described above contributions with two scaling factors. The first factor takes into account the other categories of  $t\bar{t} \rightarrow b\bar{b}l\nu l\nu$  events that are not estimated by this method. This first factor is

<sup>3</sup>Note that within this section only kinematical conditions have used to identify these  $b$ -jet pairs – no secondary-vertex requirement is used.

Table 8: Estimated background corresponding to an integrated luminosity of  $1 \text{ fb}^{-1}$  for different mSUGRA benchmark points. The second column shows the relative increase of the estimated background with respect to the estimation without contamination from the SUSY signal. The third column shows the number of SUSY events. The Monte Carlo prediction of  $t\bar{t} \rightarrow b\bar{b}\ell\nu\ell\nu$  background in the one lepton search mode is 136 events. The errors in the first column are statistical only.

SUSY point	Estimated Background	Relative change [%]	True Signal Events
No signal	$120 \pm 14$		
SU1	$137 \pm 15$	15	260
SU2	$127 \pm 15$	5.9	45
SU3	$176 \pm 18$	47	454
SU4	$604 \pm 38$	405	2960
SU6	$129 \pm 16$	7.8	162
SU8	$124 \pm 14$	3.8	100

estimated from Monte Carlo to be  $R^{\text{MC}} = 1.4 \pm 0.1$ . The second normalization factor,  $R^{b\text{-jet pair}}$ , takes into account the efficiency of  $t\bar{t} \rightarrow b\bar{b}\ell\nu\ell\nu$  events to pass the requirement on the number of  $b$ -jet pairs; it is defined as the ratio of resimulated events before and after the  $b$ -jet pair selection in a normalization region,  $80 \leq E_{\text{T}}^{\text{miss}} \leq 120 \text{ GeV}$ , and found to have the value  $R^{b\text{-jet pair}} = 1.4 \pm 0.1(\text{stat}) \pm 0.1(\text{syst})$ .

**Presence of SUSY** A possible SUSY signal could have an effect on the background estimation in two ways: 1) by satisfying the kinematic constraints in Eq. 3 and therefore enter the control sample and 2) by entering the normalization region giving a systematic contribution to the scale factor  $R^{b\text{-jet pair}}$ . In Fig. 8 the estimated  $t\bar{t} \rightarrow b\bar{b}\ell\nu\ell\nu$  background is shown with and without the contamination of a SUSY signal (SU3) while Tab. 8 gives the estimated number of  $t\bar{t} \rightarrow b\bar{b}\ell\nu\ell\nu$  events in the presence of different SUSY signals.

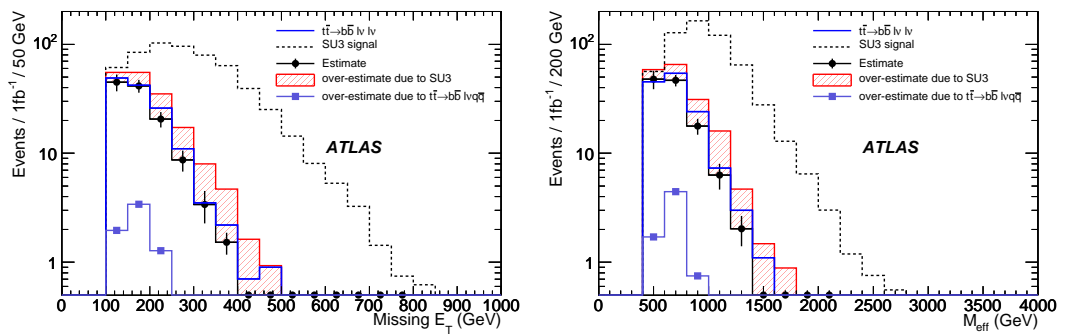

Figure 8: The  $E_{\text{T}}^{\text{miss}}$  (left) and  $M_{\text{eff}}$  (right) distributions for the estimated and true  $t\bar{t} \rightarrow b\bar{b}\ell\nu\ell\nu$  contribution for the one-lepton SUSY search. Black points (red area) represent the estimation without (with) the presence of a signal from SUSY (SU3).

**Systematic Uncertainties** The systematic uncertainties for this method are summarized in Tab. 9. The uncertainty from the replacement procedure is estimated by comparing number of resimulated events to the Monte Carlo prediction, see Fig. 7(right). The uncertainty of  $R^{\text{MC}}$  is estimated by comparing

MC@NLO and ALPGEN. The statistical uncertainty of  $R^{b\text{-jetpair}}$  is calculated using binomial errors. The systematic uncertainty of this factor takes into account the difference in the shapes between  $E_T^{\text{miss}}$  distribution of the resimulated samples with and without applying the kinematical constraints in Eq. 3. The uncertainty due to background subtraction is dominated by the presence of  $t\bar{t} \rightarrow b\bar{b}q\bar{q}\ell\nu$  events in the control sample. The systematic effects resulting from uncertainties in the lepton identification efficiency, the trigger efficiencies and the energy scale and resolution are expected to be much smaller.

#### 2.3.4 Dileptonic top with one lepton missed: HT2

**Introduction** In this section we describe a method, denoted the “HT2 method”, to estimate background from dileptonic  $t\bar{t}$  production where one of the leptons is not identified. It relies on the (near) independence of  $E_T^{\text{miss}}$  and the variable HT2. This variable is defined as:

$$\text{HT2} \equiv \sum_{i=2}^4 p_T^{\text{jet } i} + p_T^{\text{lepton}}. \quad (4)$$

In the HT2 method, the shape of the  $E_T^{\text{miss}}$  distribution is estimated from dileptonic  $t\bar{t}$  events with low HT2. This distribution is then normalized to the number of events at large HT2, but with low missing  $E_T$ , and can then be used to estimate the remaining backgrounds in the signal region of large HT2 and large  $E_T^{\text{miss}}$ .

For this method to work, the shape of the  $E_T^{\text{miss}}$  distribution needs to be independent of HT2. Note that in Equation 4, the leading jet  $p_T$  was excluded from the sum in order to reduce the correlation with  $E_T^{\text{miss}}$ . The correlation between the highest- $p_T$  jet and  $E_T^{\text{miss}}$  is likely to be due to simple kinematics, i.e. to first approximation, the rest of the event recoils against this leading jet. This is illustrated in Figure 9 which shows the  $E_T^{\text{miss}}$  distribution (at Monte Carlo “truth level”) in slices of leading and sub-leading jet  $p_T$ . The reduced dependence of the  $E_T^{\text{miss}}$  shape on the jet  $p_T$  in the second-leading jet case is apparent, and will be further diminished by detector resolution effects.

To further reduce the correlation between HT2 and  $E_T^{\text{miss}}$ , the  $E_T^{\text{miss}}$  significance was used. This is to remove the correlation which arises from the fact that the  $E_T^{\text{miss}}$  resolution depends on  $\sum E_T$ , where  $\sum E_T$  is clearly related to HT2. A simple form of  $E_T^{\text{miss}}$  significance was used here, defined as  $E_T^{\text{miss}}$  significance =  $E_T^{\text{miss}} / [0.49 \cdot \sqrt{\sum E_T}]$ .

The results shown here are from a data sample consisting of the sum of  $t\bar{t}$  (semi-leptonic and dileptonic decay modes) plus  $W(l\nu)$ +jets (where  $l = e, \mu, \tau$ ). The trigger used in this analysis was the logical OR of the 4j50 multi-jet, the e22i single electron and the mu20 single muon triggers [7].

A control sample defined by  $\text{HT2} < 300$  GeV was used to estimate the shape of the  $E_T^{\text{miss}}$  significance. The assumption is that this shape is independent of HT2 so it can be used to predict the shape of the  $E_T^{\text{miss}}$

Figure 9: Missing  $E_T$  distribution in “lepton+jet”  $t\bar{t}$  events with  $M_T > 100$  GeV at Monte Carlo “truth” level. Left: as a function of truth leading-jet  $p_T$ . Right: as a function of truth second-leading jet  $p_T$ .

Table 10: Predicted and actual background levels as a function of  $E_T^{\text{miss}}$  significance cut for an integrated luminosity of  $1 \text{ fb}^{-1}$  in the HT2 analysis. A rough equivalent  $E_T^{\text{miss}}$  cut is listed, but the  $E_T^{\text{miss}}$  cut is not sharp.

$E_T^{\text{miss}}$ sig. cut	Rough equivalent $E_T^{\text{miss}}$ cut [GeV]	Predicted BG	Actual BG
14	180	$57.3 \pm 5.5$	$60.6 \pm 3.2$
16	200	$34.8 \pm 4.5$	$39.2 \pm 2.6$
18	220	$19.1 \pm 3.1$	$23.6 \pm 2.0$
20	240	$10.1 \pm 2.1$	$15.1 \pm 1.5$
22	260	$6.2 \pm 1.8$	$9.8 \pm 1.2$
24	280	$3.8 \pm 1.5$	$6.2 \pm 0.9$
26	300	$1.3 \pm 0.7$	$3.5 \pm 0.6$

significance in the signal “band” defined by  $\text{HT2} > 300$  GeV. The normalization of the prediction in the signal band was obtained by the number of events with  $\text{HT2} > 300$  GeV, but at low  $E_T^{\text{miss}}$ , specifically  $8 < E_T^{\text{miss}}$  significance  $< 14$ . A comparison of this predicted background with the correct background is shown in Figure 10 (left). The agreement between the predicted background and the actual background in Fig. 10 is reasonable, indicating that the correlation between  $\text{HT2}$  and  $E_T^{\text{miss}}$  significance is small. A numerical comparison of predicted and actual background levels can be seen in Table 10. For each value of the  $E_T^{\text{miss}}$  significance cut, a rough equivalent in  $E_T^{\text{miss}}$  is listed as a guide, but it should be emphasized that the cut in  $E_T^{\text{miss}}$  is not sharp. The number of events is for  $\text{HT2} > 300$  GeV, which corresponds approximately to a cut on the effective mass of  $M_{\text{eff}} > 600$  GeV.

The ratio of observed to predicted backgrounds for a  $E_T^{\text{miss}}$  significance cut of 14 is  $1.06 \pm 0.12$ ; while the ratio is consistent with unity, we take the uncertainty on the ratio (12%) as a systematic uncertainty due to possible correlations between  $\text{HT2}$  and  $E_T^{\text{miss}}$  significance. Monte Carlo samples with larger numbers of events would provide one possible way to further study the potential for correlations.

The distribution of the “orthogonal” variable, namely  $\text{HT2}$ , was predicted in a similar way. The  $\text{HT2}$  distribution was measured in a control region defined by  $8 < E_T^{\text{miss}}$  significance  $< 14$ . This distribution was then normalized to the number of events at large  $E_T^{\text{miss}}$  significance and low  $\text{HT2}$ , specifically,  $E_T^{\text{miss}}$  significance  $> 14$ , and  $150 \text{ GeV} < \text{HT2} < 300 \text{ GeV}$ . The results are shown in Fig. 10 (right).

The near independence of  $\text{HT2}$  and  $E_T^{\text{miss}}$  significance should provide an important tool in understanding jet energy and  $E_T^{\text{miss}}$  performance in the complex events that make up the background to SUSY searches. After all the SUSY selection cuts have been applied, the jet energy performance can be studied

Figure 10: Left: Points: Predicted  $E_T^{\text{miss}}$  significance distribution in a  $t\bar{t}$  plus  $W$  + jets sample. Histogram: actual  $E_T^{\text{miss}}$  significance distribution. Right: Predicted HT2 distribution in the same sample. Histogram: actual HT2 distribution.

Table 11: Predicted and actual background levels (for  $1 \text{ fb}^{-1}$ , HT2 method) for  $E_T^{\text{miss}}$  significance  $> 14$  as a function of systematic effects applied to the reconstructed objects.

Modification	Predicted BG	Actual BG	Actual/predicted
Baseline	$57.3 \pm 5.5$	$60.6 \pm 3.2$	$1.05 \pm 0.12$
Energy scaled up	$64.1 \pm 5.5$	$79.3 \pm 3.7$	$1.24 \pm 0.12$
Energy scaled down	$45.5 \pm 4.5$	$47.3 \pm 2.7$	$1.04 \pm 0.12$
Jet resolution smearing	$55.5 \pm 5.1$	$65.3 \pm 3.4$	$1.18 \pm 0.12$

by looking at the HT2 distribution for low  $E_T^{\text{miss}}$  events; conversely, the  $E_T^{\text{miss}}$  distribution can be studied by selecting events with low HT2. Events in the tails of these distributions can be examined for signs of detector problems.

**Systematic uncertainties due to detector miscalibrations** The results of systematic uncertainties due to detector performance are summarized in Table 11. The energy scale variations change the background level by about 30% while the worsening jet energy resolution results in about a 10% increase in background. However the predictions tend to change in the same direction as the actual backgrounds, and generally continue to provide reasonable determinations. We assign a 20% systematic uncertainty due to detector effects.

**Systematic uncertainties due to event generation parameters** The systematic uncertainties in the method due to changes in Monte Carlo event generation parameters were studied with ALPGEN. The parton  $p_T$  cut in ALPGEN was changed from 40 to 15 GeV and the renormalization scale was reduced by a factor of 2. The results of the studies are summarized in Table 12. We assign a 20% systematic uncertainty due to event generation uncertainties.

**Background estimation in the presence of SUSY** In this section, we repeat the background estimation in the presence of SUSY signal. Figure 11 (left) shows the  $E_T^{\text{miss}}$  significance distributions for the true background, true signal, and the estimated background, as well as the observed distribution of signal plus

Table 12: Predicted and actual background levels (for  $1 \text{ fb}^{-1}$ , HT2 method) for  $E_T^{\text{miss}}$  significance  $> 14$  as a function of changes in the Monte Carlo generation parameters.

Modification		Predicted BG	Actual BG	Actual/predicted
$t\bar{t}$	$W + \text{jets}$

Figure 11: Left: Histogram: observed  $E_T^{\text{miss}}$  significance distribution for the sum of  $t\bar{t}$  plus  $W + \text{jets}$  background plus SUSY signal. Open circles: SUSY signal. Blue triangles: true  $t\bar{t}$  plus  $W + \text{jets}$  background. Black filled circles: estimated background. The SUSY signal shown here is the “1 TeV SUSY” point (see text). Right: Open circles: true SUSY signal as a function of  $E_T^{\text{miss}}$  significance. Black: estimated SUSY yield, obtained from the difference of the observed  $E_T^{\text{miss}}$  significance distribution minus the estimated background distribution.

background. The SUSY signal here is the so-called “1 TeV SUSY” point ( $m_0 = m_{\frac{1}{2}} = 400 \text{ GeV}$ ,  $\tan \beta = 10$ ,  $A=0$ ,  $\mu > 0$ ).

Because of the signal contamination in the control region, the background level is overestimated, leading to an underestimation in the excess of signal over background. Nevertheless, it is clear that by cutting harder on  $E_T^{\text{miss}}$  significance, for example, the signal can still be clearly seen over the estimated background. A comparison of the estimated signal yield to the true signal is shown in Figure 11 (right).

The results for all the tested SUSY points are summarized in Table 13.

### 2.3.5 Top background estimation with top rede decay simulation

**Introduction** It is possible to isolate a pure biased sample of fully-leptonic  $t\bar{t}$  events by selecting low  $E_T^{\text{miss}}$  (to reduce SUSY signal) opposite sign dilepton events where one and only one pair of invariant mass combinations  $m_{\ell j}$  between the two leptons and two hardest jets ( $b$  jets if tagging available) gives values below the expected endpoint from  $t \rightarrow Wb \rightarrow \ell \nu b$  decays:  $m_{\ell j}^{\text{max}} = \sqrt{m_t^2 - m_W^2}$  (neglecting  $m_b$ ).

A possible use of such a sample is to estimate the background of fully-leptonic  $t\bar{t}$  events to SUSY searches. One can reconstruct the kinematics of the decaying particles ( $W$ 's or top quarks), remove their inferred decay products from the reconstructed event (including the event  $E_T^{\text{miss}}$ ), rede decay the reconstructed  $W$ 's or top quarks using an event generator (e.g. PYTHIA) and then merge the simulated re-decay products back into the parent (‘seed’) event. By rede decaying particles earlier in the decay chain (i.e. the top rather than the  $W$ ) the kinematic bias obtained from the event selection can be minimised.

Table 13: True and estimated background and signal, using the HT2 method, when the background estimation is performed in the presence of SUSY signal. The numbers are for an integrated luminosity of  $1 \text{ fb}^{-1}$  except for the SU4 point where  $100 \text{ pb}^{-1}$  is used.

This technique has a number of advantages over conventional Monte Carlo techniques. In particular the event generator is used purely for modelling relatively well-understood decay and hadronisation processes – initially poorly understood aspects of process generation, such as parton distributions and the underlying event model, are effectively obtained from the data. In principle this technique is applicable also to other background processes such as  $Z \rightarrow \tau^+ \tau^-$ , which could be modelled by replacing identified electrons or muons in  $Z \rightarrow \ell^+ \ell^-$  control sample events with redecaied taus.

It should be noted that this technique is at best an approximation, assuming as it does the factorisation of each  $t\bar{t}$  event into two independent tops, and hence neglecting effects such as colour connection and spin correlations between the tops and other partons in the event. It is therefore unlikely to be competitive with a detailed Monte Carlo study using a fully tuned generator and validated parton distribution functions. In the early days of data-taking however it potentially provides a route to a rapid direct estimate of  $t\bar{t}$  background from data complementary to, and independent from, more conventional estimates.

**Seed event selection** Seed events were selected from the ‘data’ with cuts designed to maximise the number of fully leptonic  $t\bar{t}$  ( $2\ell\text{-}t\bar{t}$ ) events while minimising the number of Standard Model backgrounds or SUSY signal events. Events were required to pass the  $j45_{\text{jet}} + E_T^{\text{miss}}$  trigger [7]. Single and dilepton triggers were not included in this study, but are planned to be added in future analyses. Subsequently, the following criteria were applied:  $N_{\text{jet}} \geq 2$ ,  $p_T(\text{jet}_2) > 20 \text{ GeV}$ , two Opposite Sign (OS) isolated leptons should be present,  $p_T(\ell_2) > 10 \text{ GeV}$ , if the two leptons are of the same flavour  $|m_{\ell\ell} - m_Z| > 15 \text{ GeV}$  and  $m_{\ell\ell} > 10 \text{ GeV}$  is required,  $|m_{\tau\tau} - m_Z| > 15 \text{ GeV}$ , where  $m_{\tau\tau}$  is calculated assuming the neutrinos travel parallel to their parents, and  $E_T^{\text{miss}} < \frac{1}{2}(p_T(\ell_1) + p_T(\ell_2))$ . The upper limit on  $E_T^{\text{miss}}$  as a function of lepton  $p_T$  rejects SUSY signal events. For the purposes of this early-data study  $b$ -tagging was assumed to be either not available or not well-understood.

Figure 12: Distributions of  $m_{\ell j}$  values for various different Standard Model backgrounds and SUSY signal. The histograms show distributions of ‘data’ events selected with the  $2\ell$ - $t\bar{t}$  selection. The data-points show the equivalent distribution estimated with redeca simulation, normalised to the peak.

**Kinematic Reconstruction and Redecay Simulation** The  $m_{\ell j}$  distribution of selected events (the histogram in Figure 12) contains a prominent edge at the expected position  $m_{\ell j}^{\max} = 155.4$  GeV ( $m_t = 175$  GeV). Events were further selected in which one and only one of the two possible pairs of  $\ell j$  combinations obtained from the two leptons and two hardest jets gave  $m_{\ell j}$  values which were both less than  $m_{\ell j}^{\max}$ .

For  $2\ell$ - $t\bar{t}$  signal events the two ( $b$ ) jets, two leptons and  $E_T^{\text{miss}}$  components satisfy the constraints of Eq. 3 given in section 2.3.3. These constraints, assuming massless neutrinos, leptons and jets, may be solved for the 8 unknown 4-momentum components of the neutrinos. The constraints together give a quartic equation which can be solved with standard analytical techniques. If no solution was obtained then to maximise statistics the real part of the least imaginary solution was taken. If multiple solutions were obtained the solution with the smallest mean  $|p_z|$  of the reconstructed top was used.

This selection results in 2207 dileptonic  $t\bar{t}$  events for  $1 \text{ fb}^{-1}$ . The contamination by other Standard Model processes and SUSY signal events was 912 events, dominated by semileptonic  $t\bar{t}$  events, as shown in Figure 12. The SUSY contamination in the sample is small, due to the tight selection cuts.

Four-vectors of the two reconstructed top quarks from each event were passed to a modified version of PYTHIA 6.4 [10]. 1000 redecaied tops were produced from each reconstructed seed top, with each  $W$  forced to decay to  $e$ ,  $\mu$  or  $\tau$ . This ‘recycling’ of seed events increases the statistics of decay resimulated events for the final  $E_T^{\text{miss}}$  estimation process but leads to correlations between resimulated events derived from the same seed event. These correlations were taken into account in the final uncertainties quoted below. Decay products were passed to the ATLAS fast simulation program, and then merged back into their parent seed events.

As a cross-check of the estimation procedure redecaied events were passed through the same selection as their parent seed events and the distribution of  $m_{\ell j}$  constructed and normalised to the seed  $m_{\ell j}$  distribution. This is shown in Fig. 12 and indicates good agreement below  $m_{\ell j}^{\max}$ .

**Use in one-lepton search background estimate** Decay resimulated events were subjected to the standard one-lepton SUSY search selection described in section 2.1, with one modification:  $M_T(\ell, E_T^{\text{miss}}) > 150$  GeV.

Figure 13:  $E_T^{\text{miss}}$  (left) and  $M_{\text{eff}}$  (right) distributions of events passing the basic one-lepton SUSY selection cuts described in the text. Note that  $Z + \text{jet}$  and  $W + \text{jet}$  backgrounds are under-represented in these plots for  $E_T^{\text{miss}} < 80$  GeV or  $M_{\text{eff}} < 350$  GeV due to filter requirements applied to the respective Monte Carlo samples.

The remaining background at high  $E_T^{\text{miss}}$  following such cuts is dominated by semi-leptonic  $t\bar{t}$  events, and to a lesser extent leptonic  $W + \text{jets}$ ,  $Z + \text{jets}$ , single-top and di-boson events. For all these backgrounds one expects primarily a Jacobian peak in the event  $M_T(\ell, E_T^{\text{miss}})$  distribution near  $M_W$  ( $M_Z$  for  $Z + \text{jets}$ ). This  $1\ell$ -Jacobian background was estimated with the  $E_T^{\text{miss}}$  distribution of events selected with the same cuts, with the exception of the  $M_T(\ell, E_T^{\text{miss}})$  cut, which was reversed to require  $M_T(\ell, E_T^{\text{miss}}) < 100$  GeV.

The  $1\ell$ -Jacobian and the  $2\ell$ - $t\bar{t}$  background estimates were compared to ‘data’ events subjected to the one-lepton selection criteria described above. The two estimates were simultaneously normalised to the ‘data’  $E_T^{\text{miss}}$  distribution in two bins:  $40 < E_T^{\text{miss}} < 100$  GeV and  $100 < E_T^{\text{miss}} < 140$  GeV. The total ( $2\ell$ - $t\bar{t}$  +  $1\ell$ -Jacobian) normalised estimate is plotted in Fig. 13(left) together with the ‘data’  $E_T^{\text{miss}}$  distribution. For  $E_T^{\text{miss}} > 200$  GeV the agreement between the estimate and the ‘data’ is good:  $30.7 \pm 9.8$  (30%) estimated, versus 39 ‘observed’.

In Fig. 13(right), the  $M_{\text{eff}}$  distribution is shown, with the estimate normalised with the same factors as used in Fig. 13(left). The semi-leptonic  $t\bar{t}$  forms a larger fraction of the background at large  $M_{\text{eff}}$  compared to at large  $E_T^{\text{miss}}$  because it produces a larger number of jets than fully-leptonic  $t\bar{t}$ .

**SUSY contamination** The shape of the estimated distribution is effectively insensitive to the presence of SUSY signal, primarily due to the low  $E_T^{\text{miss}}$  requirement in the  $2\ell$ - $t\bar{t}$  selection.

However, there may be SUSY signal in the normalisation region. The bias in the estimate will be proportional to the amount of SUSY in the normalization region, which is largest for the samples with the highest SUSY cross-section: SU3 and SU4. The effect of admixture of SU3 or SU4 signal events is shown in Table 14. In case of SU3, the background estimate is 60% higher, in case of SU4 as large as a factor 15. For both samples, however, the excess of signal events is still significant.

In principle the contamination effect could be reduced by normalization to more signal-free regions. The  $2\ell$ - $t\bar{t}$  and  $1\ell$ -Jacobian estimates could be normalized for example to the tail and peak of the  $M_T(\ell, E_T^{\text{miss}})$  distribution at low  $E_T^{\text{miss}}$ .

### 2.3.6 Combined fit method

The fit-based method for measuring the background, as described in this section, aims to improve upon the plain  $M_T$  sideband subtraction method for the one-lepton SUSY search mode. By analysing data in a L-shaped region at both low- $E_T^{\text{miss}}$  in the full  $M_T$  range and at low  $M_T$  in the full  $E_T^{\text{miss}}$  range, and

Table 14: Estimated and true background with the redecaay method, in case of no SUSY signal, or presence of SU3 or SU4 SUSY signals. For the latter, also the amount of observed signal plus background events is shown, proving that although the background is overestimated, the excess is still present.

Sample	Estimated BG	True BG	Observed signal + BG
No SUSY	$30.7 \pm 9.8$	39	39
SU3	$50.8 \pm 13.6$	39	392
SU4	$456 \pm 102$	39	1230

performing a two-dimensional extrapolation into the SUSY signal region we hope to enhance the background estimation. In a fit, correlations between  $E_T^{\text{miss}}$  and  $M_T$  can be taken into account. Furthermore, an explicit assumption can be put in that there is a finite SUSY contamination in the control sample.

For our purposes, we define in this analysis a sideband (SB) region and a SUSY signal (SIG) region. For both regions, we apply the standard SUSY one-lepton selection cuts defined in section 2.1, with the exception of the cut on  $M_T$ . The SB region is defined by the following additional cut:  $E_T^{\text{miss}} < 200$  GeV or  $M_T < 150$  GeV. In this analysis, the SIG region is defined by:  $E_T^{\text{miss}} > 200$  GeV and  $M_T > 150$  GeV. This classification assumes that the mass scale of SUSY is much higher than 200 GeV, which is true for all SUSY points considered in this note except SU4.

The analysis described here has been applied to electron + jets events only, but we expect the muon + jets analysis to be completely analogous.

The main Standard Model backgrounds we expect are single-leptonic  $t\bar{t}$  decays, double-leptonic  $t\bar{t}$  decays, and  $W$  + jets events. Other backgrounds, such as  $Z$  + jets, diboson production or single top are negligible for  $1 \text{ fb}^{-1}$ . The trigger used was an OR of the e22i single electron trigger, and the 4j50 multi-jet trigger [7].

**Shape of the backgrounds** We will try to fit the contributions of the backgrounds in three observables:  $M_T$ ,  $E_T^{\text{miss}}$  and  $m_{\text{top}}$ . Here  $m_{\text{top}}$  is the invariant mass of the three jets in the event with the largest vector-summed  $p_T$  [11].

We construct probability density functions (p.d.f.'s) that model the major contributing processes in the three observables after the event selection. We have done this both with and without explicitly taking into account correlations between the three observables. Most of these correlations are in any case consistent with zero.

Figure 14 shows the distribution of the three observables for each type of background we consider, as well as for one SUSY signal sample (SU3). The empirical model that we use to describe each background type is overlaid on the data. This comparison of shapes demonstrates that there is sufficient information in these three observables to be able to measure each of them in a combined fit.

We perform the procedure of constructing an empirical model from Monte Carlo for multiple SUSY data points. A striking feature of a comparison of  $E_T^{\text{miss}}$  and  $M_T$  distributions of these SUSY points *in the SB region* is that, with the exception of lower mass SUSY point SU4, they are all quite similar in shape. We can thus construct a model-independent 'Ansatz' shape to describe the SUSY contamination at low energy.

To validate this procedure, we perform fits to a "data" sample consisting of either background only, or background plus SU3 SUSY signal. The yields we find in a fit to  $1 \text{ fb}^{-1}$  are listed in Table 15 and are in agreement within errors with the truth values of the fitted event mix. If, in contrast, a SU3 SUSY signal would be present in data, but the fit would not allow for SUSY (see table), the fit would overestimate dileptonic  $t\bar{t}$  and  $W$  + jets, and underestimate semileptonic  $t\bar{t}$ . This is as expected, as the SUSY signal has a long tail in  $M_T$ , but no substantial peak in the top mass.

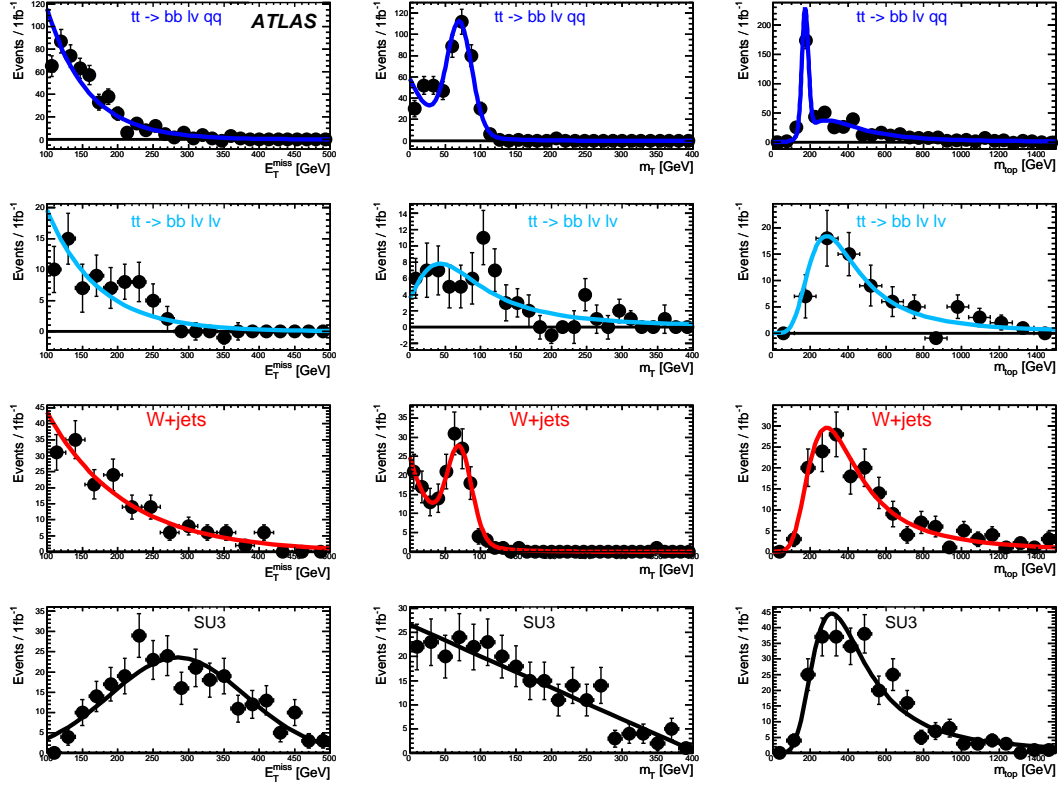

Figure 14: Distributions in missing  $E_T$  (left),  $M_T$  (middle) and  $m_{top}$  (right) of single lepton  $t\bar{t}$  (top row), double lepton  $t\bar{t}$  (second row),  $W$  + jet events (third row) and SUSY SU3 (last row). Each distribution is overlaid with a projection of the three-dimensional model that is fitted to that sample.

The same table also lists the yields obtained from a fit in which all components are taken as a simple uncorrelated product of three one-dimensional p.d.f.'s. The yields and their uncertainties are very similar to those from the fit with models that include correlations and indicates that the effect of correlations in the description of the background components is minor.

**Fitting the data** The fit with fixed shapes relies on simulated events to determine the shapes of the various background components, while all yields are fitted from the data. The next step is to release as many of the shape parameters in the fit to the data; in total there are 15 of these parameters. In the limit that all parameters can be floated, with the exception of the SUSY ansatz shape, the method becomes almost independent on simulation input and fully data driven. It turns out that on a  $1 \text{ fb}^{-1}$  sample we can float all but two of the  $W$  + jets and 1-lepton  $t\bar{t}$  shape parameters. These two are the fraction of events that give the correct top quark mass in  $m_{top}$  for single lepton  $t\bar{t}$  and the fraction of events with a correctly constructed  $W$  boson in  $M_T$  in single lepton  $t\bar{t}$ .

Floating the 2-lepton  $t\bar{t}$  shape parameters in addition causes the fit to become unstable because the shapes of the dilepton component and that of the SUSY ansatz model are very similar. We are currently investigating the possibility of introducing additional constraints on the shape of the di-lepton  $t\bar{t}$  events in order to solve this.

The result of the  $1 \text{ fb}^{-1}$  fit with floating parameters is shown in Figure 15.

The final step in the analysis is to extrapolate the yields of the standard model background components from the sideband region to the signal region. Table 16 shows the yields from the combined fit with

Table 15: Yields from the combined fit with fixed shapes for the various modeled physics processes. The leftmost column lists the yield fitted with models that include correlations in the model structure. The middle column shows these yields for models in which correlation terms have been disabled. The rightmost column gives the true yields in the fitted event mix.

**Effect of SUSY signal** While table 16 shows the results of the fit for the various backgrounds and the SUSY signal in the case of the SU3 sample, Table 17 shows results, for fits with floating shapes, for other SUSY signal samples.

As has been noted earlier, SU4 is a special case. It is too close to the background for the Ansatz of the shape to be valid, and it can not be fitted very well.

Figure 15: Distribution of missing  $E_T$  (left),  $M_T$  (center) and  $m_{top}$  (right) of a  $1 \text{ fb}^{-1}$  mix of  $t\bar{t}$ ,  $W$  + jets standard model events and SUSY SU3 events overlaid with projections of the combined model on these observables that was fitted to this mix of events with floating yield parameters and floating shaped parameters. For each projection the contributions of the 1-lepton  $t\bar{t}$   $t\bar{t}$ bar contribution (dark blue), 2-lepton  $t\bar{t}$   $t\bar{t}$ bar contribution (light blue),  $W$  + jet contribution (red) and ansatz SUSY contribution (black) are shown.

Table 17: Yields from the combined fit with floating shapes in the sideband region extrapolated to the full parameter space, the truth yields in full parameter space, the extrapolated yields into the signal region and the truth yields in the signal region, for various SUSY samples.

**Systematics** Table 18 summarizes the results of a series of systematic studies. These studies are quantified in terms of relative variations of the measured SUSY cross-section, which we define as the counted number of events in the data in the SIG region minus the fitted and extrapolated number of SM model events expected in that same region, and divided by the efficiency for the selection of SUSY events, including the SIG region cuts, as measured from a pure sample of simulated SU3 SUSY events.

The second column of Table 18 lists the relative variation under the influence of each systematic variation if no extrapolation is applied in the fit and the analysis is performed without the SIG region cut. This column thus quantifies the effect on the shape fit stability only. The third columns shows the effect of each systematic study on the fitted yield in the signal region using extrapolation. Most effects are here of the order of 5-7%. The uncertainties due to Monte Carlo statistics are explicitly listed in the table.

Table 18: List of studied systematic uncertainties for the combined-fit method.

Systematic variation	w/o extrapolation $\pm$ MC-error [%]	in SIG $\pm$ MC-error [%]
Jet energy scale	$1.9 \pm 0.7$	$3.1 \pm 1.1$

Electron energy scale	$4.8 \pm 0.6$	$5.6 \pm 1.4$
Electron energy resolution	$9.0 \pm 1.2$	$7.2 \pm 1.4$
Electron identification efficiency	$0.5 \pm 0.2$	$3.6 \pm 2.3$
Soft $E_T^{\text{miss}}$ scale	$8.1 \pm 1.8$	$7.4 \pm 3.4$

### 3 No-lepton search mode

#### 3.1 Selection

In the no-lepton search mode, we veto all events with an identified electron or muon with a  $p_T$  of more than 20 GeV. We demand at least 4 jets with  $|\eta| < 2.5$  and  $p_T > 50$  GeV, one of which must have  $p_T > 100$  GeV. The transverse sphericity  $S_T$  should be larger than 0.2, and the missing transverse energy  $E_T^{\text{miss}}$  should be larger than 100 GeV and larger than  $0.2 M_{\text{eff}}$ , where  $M_{\text{eff}}$  is the effective mass. We add one more cut against the QCD background: the minimum value of the difference in azimuthal angle between the  $E_T^{\text{miss}}$  vector and the three highest- $p_T$  jets should be larger than 0.2. This cut is further discussed in a dedicated note on QCD background estimation [3].

#### 3.2 Backgrounds in Monte Carlo

Figure 16 shows the distributions of  $E_T^{\text{miss}}$  and  $M_{\text{eff}}$  after all the selections are applied.

#### 3.3 Data-driven estimation strategies

In this section we discuss data-driven estimation strategies for the no-lepton search mode. The strategies we have studied are:

1. estimation of  $Z (\rightarrow \nu\bar{\nu})$  plus jets from  $Z (\rightarrow \ell^+\ell^-)$  plus jets, purely from data (replace method, section 3.3.1);
2. estimation of  $Z$  and  $W$  in an analogous way, but also helped by Monte Carlo (section 3.3.2);
3. estimation of  $W$  and  $t\bar{t}$  background from a one-lepton control sample derived by reversing one of the selection cuts (on  $M_T$ ) (section 3.3.3);
4. estimation of the cross-section of the  $t\bar{t} \rightarrow b\bar{b}q\bar{q}'\tau\nu$  process with hadronic tau decay (section 3.3.4).

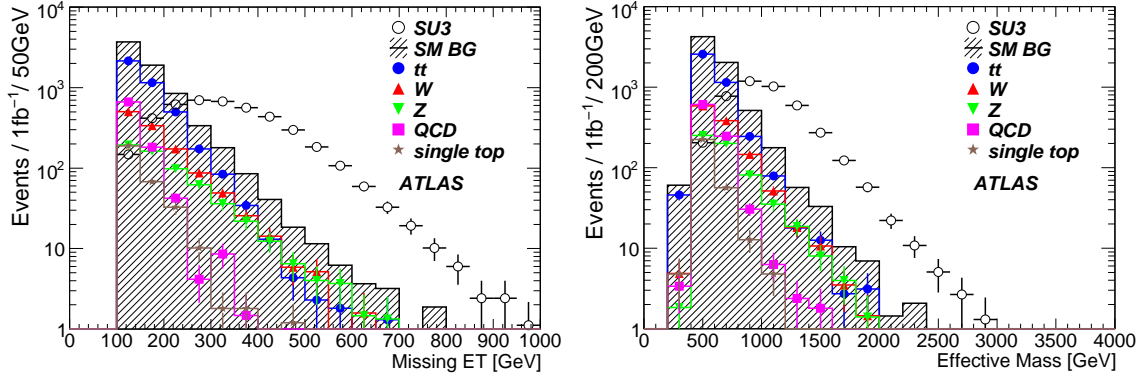

Figure 16: The  $E_T^{\text{miss}}$  and effective mass distributions of the SUSY signal and background processes for the no-lepton mode with an integrated luminosity of  $1 \text{ fb}^{-1}$ . The open circles show the SUSY signal (SU3 point). The shaded histogram shows the sum of all Standard Model backgrounds; different symbols show the various components.

### 3.3.1 Replace method: $Z \rightarrow \nu\bar{\nu}$ from $Z \rightarrow \ell^+\ell^-$

**Introduction** The  $Z \rightarrow \nu\bar{\nu}$  background is one of the main background process in the no-lepton channel. In order to estimate and reproduce the number of expected background events, as well as the shape of the  $E_T^{\text{miss}}$  and  $M_{\text{eff}}$  distributions,  $Z \rightarrow \ell^+\ell^-$  events are selected, and the charged leptons are replaced by neutrinos. However, as the ratio of branching-ratios  $\text{Br}(Z \rightarrow \ell^+\ell^-)/\text{Br}(Z \rightarrow \nu\bar{\nu})$  is small, statistical uncertainties will tend to be relatively large. Two solutions are proposed :

1. Taking the distribution shape from  $Z \rightarrow \ell^+\ell^-$  data but constraining it via a fit plus the assumption of a smooth evolution of the fitting parameters when relaxing the cuts. This is the method described in this section.
2. Taking the distribution shape from Monte Carlo simulation as described in the next section ( Section 3.3.2).

The Monte Carlo method is more sensitive to generator-level and detector systematic uncertainties, but does not suffer from the larger statistical uncertainties, whereas the replace method precision is limited by the number of events in the control sample, but less sensitive to systematic uncertainties from the detector. Both methods have to account for the fact that the detected charged lepton pairs will not cover the full phase space of the neutrinos.

**Control Sample Selection** The control sample selection is identical to the no-lepton SUSY search selection, except that two electrons or two muons are required, and that the missing  $E_T$  ( $E_T^{\text{miss}}$ ) is replaced by  $p_T(\ell^+\ell^-) \simeq p_T(Z)$ . Thus it is assumed that neutrinos are the main contribution to  $E_T^{\text{miss}}$  when the  $Z$  boson decays into two neutrinos, such that  $E_T^{\text{miss}}$  is roughly equivalent to  $p_T(Z)$  for this physics process. The  $E_T^{\text{miss}}$  resolution of ATLAS is sufficient for this to be a good approximation. In addition to pairs of isolated charged leptons, a sample composed of  $Z \rightarrow e^\pm X$  is added, where  $X$  is a non-isolated electron or an electron-like object with very loose cuts. This additional sample is used to increase the statistics and measure the electron identification efficiency via the “tag-and-probe” method. The goal of the tag-and-probe method is to select on one side a good electron (tag) and look at the other side to the nature of the object (the probe) which matches the constraint on the  $Z$  mass. Two cuts are added to reject the

remaining backgrounds :  $81 < M_Z(\ell^+\ell^-) < 101$  GeV, and Missing  $E_T < 30$  GeV. After all cuts the number of selected events is summarized in Table 19. In particular, Table 19 shows the effect of an upper cut on  $E_T^{\text{miss}}$  in order to reject  $t\bar{t}$  background in the  $Z \rightarrow e^\pm X$  channel. It has been verified that the efficiencies measured with the tag-and-probe method agree with efficiencies obtained directly from Monte Carlo, confirming that  $X$  is indeed dominated by electrons rather than hadronic jets.

Table 19: Number of selected  $Z \rightarrow \ell^+\ell^- + \geq 4$  jets events in  $1 \text{ fb}^{-1}$  in the replace-method analysis.

Process	No $E_T^{\text{miss}}$ cut	$E_T^{\text{miss}} < 30 \text{ GeV}$
$Z \rightarrow e^+e^- + \text{n jets}$	18.2	14.1
$Z \rightarrow e^\pm X + \text{n jets}$	25.6	19.6
$Z \rightarrow \mu^+\mu^- + \text{n jets}$	33.2	26.1
$Z \rightarrow \tau^+\tau^- + \text{n jets}$	1.6	0.
$t\bar{t} \rightarrow b\bar{b}\ell\nu\ell\nu + \text{n jets}$	56.2	0.3
$t\bar{t} \rightarrow b\bar{b}\ell\nu q\bar{q} + \text{n jets}$	506.6	2.5

**Lepton identification and acceptance corrections** A number of correlations must be applied in order to derive  $Z \rightarrow \nu\bar{\nu}$  distributions from  $Z \rightarrow \ell^+\ell^-$ : (1) a fiducial correction, since we cannot detect  $e$  and  $\mu$  leptons beyond  $|\eta| = 2.5$ ; (2) a kinematics correction for the additional cuts used to select  $Z \rightarrow \ell^+\ell^-$ , including the  $Z$  invariant-mass window, the  $p_T$  cut on the leptons, and the  $E_T^{\text{miss}}$  cut; and (3) a correction for the lepton identification efficiency. The first two effects have to be computed from simulation whereas the lepton identification efficiency can be measured from collision data using the tag-and-probe method.

After all corrections, the distribution can be summarized by the following formula:

$$N_{Z \rightarrow \nu\bar{\nu}}(E_T^{\text{miss}}) = N_{Z \rightarrow \ell^+\ell^-}(p_T(\ell^+\ell^-)) \times c_{\text{Kin}}(p_T(Z)) \times c_{\text{Fidu}}(p_T(Z)) \times \frac{\text{Br}(Z \rightarrow \nu\bar{\nu})}{\text{Br}(Z \rightarrow \ell^+\ell^-)}, \quad (5)$$

where  $N_{Z \rightarrow \nu\bar{\nu}}(E_T^{\text{miss}})$  is the corrected number of events per bin of missing  $E_T$ ,  $N_{Z \rightarrow \ell^+\ell^-}(p_T(\ell^+\ell^-))$  is the raw number of control sample events as a function of  $p_T(Z)$ ,  $c_{\text{Kin}}$  and  $c_{\text{Fidu}}$  are the kinematic and fiducial corrections. The  $E_T^{\text{miss}}$  and  $M_{\text{eff}}$  distributions of  $Z \rightarrow e^+e^- + e^\pm X$  and  $Z \rightarrow \mu^+\mu^-$  events after all corrections are compared to  $Z \rightarrow \nu\bar{\nu}$  distributions in Figure 17.

For very high values of  $E_T^{\text{miss}}$  and  $M_{\text{eff}}$ , statistics is low. In order to present a smooth prediction of the background, for example as a function of  $M_{\text{eff}}$ , a fit of the shape has been performed. Of course, the fit is also affected by the low statistics in the tail, but by relaxing the jet  $p_T$  and  $E_T^{\text{miss}}$  cuts and observing how the fit parameters evolve with the cuts, a smooth prediction can be made.

**Systematic uncertainties** The effects of various Monte Carlo generator and detector systematic uncertainties are summarized in Table 20. The main generator systematic uncertainty is due to the variation of the renormalization scale and affects the acceptance correction, whereas the principal detector systematic uncertainty is related to the soft part of the missing transverse energy which is not taken into account when replacing neutrinos by charged leptons.

**SUSY contamination in the control sample** Due to the tight control sample selection cuts, in particular  $E_T^{\text{miss}} < 30$  GeV, the SUSY contamination in the control sample in  $1 \text{ fb}^{-1}$  is negligible: 0.1 events for SU1, 0.4 events for SU2, 0.9 events for SU3, and  $< 0.07$  events for SU6.

Figure 17: (Left)  $E_T^{\text{miss}}$  distribution after all corrections for  $Z \rightarrow \nu\bar{\nu}$ ,  $Z \rightarrow e^+e^- + e^\pm X$  and  $Z \rightarrow \mu^+\mu^-$  processes. The number of events corresponds to an integrated luminosity of  $1 \text{ fb}^{-1}$ . (Right)  $M_{\text{eff}}$  distribution for the same physics processes.

Table 20: Summary of systematic uncertainties for the replace method.

Description	Relative uncertainty $\Delta N/N$ [%]
MC generator systematics	
ALPGEN parameter variation	6.3

### 3.3.2 $Z$ and $W$ background estimates from $Z \rightarrow \ell^+\ell^-$ plus Monte Carlo shape

A modification of the method of the previous section is described here. Denoted the “MC method”, it uses only the number of events in the  $Z(\rightarrow \ell^+\ell^-) + \text{jets}$  control sample for normalization, but otherwise relies on Monte Carlo simulation of kinematical distributions of events. The same normalization factor is used for both the  $Z(\rightarrow \nu\bar{\nu})$  background and the  $W(\rightarrow \ell\nu)$  background since the production mechanism is very similar.

**Control sample** The event selection of the control sample demands: two opposite-sign same-flavour leptons with  $p_T > 20 \text{ GeV}$ ;  $E_T^{\text{miss}} < 40 \text{ GeV}$ ; a di-lepton mass  $M_{\ell\ell}$  within  $\pm 10 \text{ GeV}$  of  $m_Z$ . Subsequently, the standard no-lepton SUSY cuts are applied after replacing  $\ell^+\ell^-$  with  $\nu\bar{\nu}$ .

The number of events selected with  $1 \text{ fb}^{-1}$  is summarized in Table 21. The contamination from  $t\bar{t}$  events is about  $10^{-2}$  and therefore not significant. The number of events estimated by a full simulation sample (with event filter  $p_T^Z > 80 \text{ GeV}$ ) is  $72 \pm 3$  for  $1 \text{ fb}^{-1}$ , which leads to a statistical uncertainty on the estimation of 12%.

The method has been tested with a pseudo data sample prepared with Monte Carlo parameters set

Table 21: Number of events in the MC method control sample (for  $1 \text{ fb}^{-1}$ ).

process	$\mu$ mode	e mode	$\mu + e$ (sum)
$Z(\rightarrow \ell^+ \ell^-)$	$51 \pm 1$	$34 \pm 1$	$85 \pm 1$
$Z(\rightarrow \tau^+ \tau^-)$	$< 0.1$	$< 0.1$	$< 0.1$
$t\bar{t}$	$1.0 \pm 0.3$	$0.5 \pm 0.2$	$1.5 \pm 0.4$

Table 22: Systematic uncertainty from variation of Monte Carlo generator parameters (ALPGEN) for the MC method. The pseudo data sample is discussed in the text.

$Z(\rightarrow \nu \bar{\nu})$	$E_T^{\text{miss}} > 300 \text{ GeV}$	$M_{\text{eff}} > 800 \text{ GeV}$
pseudo data sample	5%	3%
half renormalization scale	2%	0%
lower parton $p_T$	9%	4%
$W(\rightarrow \ell \nu)$	$E_T^{\text{miss}} > 300 \text{ GeV}$	$M_{\text{eff}} > 800 \text{ GeV}$
pseudo data sample	16%	7%
half renormalization scale	4%	2%
lower parton $p_T$	12%	15%

Table 23: Systematic uncertainty from detector performance in the MC method.

	$E_T^{\text{miss}} > 300 \text{ GeV}$	$M_{\text{eff}} > 800 \text{ GeV}$
Jet energy scale	6%	6%
Jet energy resolution	1%	1%
$E_T^{\text{miss}}$ soft component scale	1%	$< 1\%$
Lepton energy scale	$< 1\%$	$< 1\%$
Lepton identification efficiency	2%	2%

differently from the standard Monte Carlo sample<sup>4</sup>. In this pseudo data sample, the shape of  $E_T^{\text{miss}}$  and  $M_{\text{eff}}$  distributions is not affected; only the normalization changes significantly. The MC method is able to recover such a change and predict the background correctly.

**Systematic uncertainty** The MC method relies on Monte Carlo for the shapes of the background distributions. The systematic uncertainty from the Monte Carlo is estimated by using samples with different Monte Carlo parameters (pseudo real data, half renormalization scale sample, lower parton threshold sample). The results are summarized in Table 22; the deviation of the samples is 16% at most.

Other potential sources of systematic error in the background estimation from uncertainties in detector performance are summarized in Table 23. Since Monte Carlo is used, an uncertainty in the experimental jet energy scale affects the MC method prediction significantly more than for the replace method (Section 3.3.1).

**SUSY contamination of the control sample** The tight selection cuts of the control sample makes any SUSY contamination negligible (as was also the case for the replace method discussed in Section 3.3.1).

<sup>4</sup>renormalisation and factorisation scale 0.8 times the default, a minimum parton  $p_T$  of 30 GeV (rather than 40 GeV), and separation between partons  $\Delta R_{jj} = 0.6$  (rather than 0.7).

### 3.3.3 Control sample constructed from an $M_T$ -selected one-lepton sample

**$W$  and top backgrounds** The  $t\bar{t}$  and  $W^\pm + \text{jets}$  processes contribute to the background in the no-lepton mode, when the lepton emitted in the  $W^\pm \rightarrow \ell\nu$  process is not identified. The reasons why the emitted lepton is missed are summarized in Table 24. Hadronic decay of  $\tau$ 's and the lepton being out of acceptance (the  $p_T$  of the lepton is required to be larger than 20 GeV) are the dominant reasons, and similar reasons/ratio's are observed in both  $t\bar{t}$  and  $W^\pm + \text{jets}$  processes.

Table 24: Numbers of events in which leptons are missed for various reasons in the semi-leptonic and leptonic decays of top and  $W^\pm$ . The numbers are normalized to  $1 \text{ fb}^{-1}$  and listed after the SUSY no-lepton selection is applied.

	$t\bar{t}$	$W^\pm + \text{jets}$
$W^\pm \rightarrow \tau \rightarrow \text{hadron}$	1993 (43%)	773 (42%)
Out of acceptance	1805 (39%)	762 (41%)
Isolation (close to jet)	807 (18%)	322 (17%)

The production processes  $t\bar{t}$  and  $W^\pm$  with  $W^\pm \rightarrow \ell\nu$  where the lepton is identified constitute good control samples from which to estimate these background processes in the no-lepton mode, since similar kinematic distributions are expected except for the presence of the lepton. For the control sample, the same kinematic selections as for the signal in the no-lepton mode are applied. In addition, exactly one isolated lepton (e or  $\mu$  with  $p_T$  larger than 20 GeV) is required and the transverse mass between this lepton and the  $E_T^{\text{miss}}$  is required to be smaller than 100 GeV to enhance the  $t\bar{t}$  and  $W^\pm$  processes. After these selections, this identified lepton is treated as if had been missed and all kinematic variables are recalculated.

The distributions of  $t\bar{t}$  and  $W^\pm + \text{jets}$  events differ after the SUSY selections are applied. The  $E_T^{\text{miss}}$  for  $W^\pm$  tends to be larger than for  $t\bar{t}$  events, since the boost factor of the  $W^\pm$  is larger for  $W^\pm + \text{jets}$  after several high  $p_T$  jets are required. Therefore the reproduced distributions are sensitive to the mixture of the  $t\bar{t}$  and  $W^\pm + \text{jets}$  events in the control sample. The fractions of the  $t\bar{t}$  and  $W^\pm + \text{jets}$  processes in the control sample are 81% and 19%, respectively, close to the actual backgrounds in the signal region, which are 73% and 27% respectively. The systematic errors due to the uncertainties in the cross-section of  $t\bar{t}$  and  $W^\pm + \text{jets}$  will be discussed later.

The estimated distribution is normalized with the data at  $100 \text{ GeV} < E_T^{\text{miss}} < 200 \text{ GeV}$ , where the contribution of the SUSY signal is expected to be small. The estimated distributions are slightly harder than the true distributions of the background processes, but similar distributions are obtained. The number of estimated background events is summarized in the two top rows in Table 25. Reasonable agreement is observed at high  $E_T^{\text{miss}}$ .

**QCD,  $W$  and top background without and with SUSY signal** In a dedicated note within this volume [3] various methods for the estimation of QCD background from data are discussed.

In this section, we include QCD background, and estimate it as follows. It has been shown that after the removal of events with mismeasured  $E_T^{\text{miss}}$  (e.g. noisy or dead calorimeter cells), as discussed elsewhere in this volume [12], semi-leptonic heavy quark ( $b, c$ ) decays are the dominant contribution to large  $E_T^{\text{miss}}$  in the QCD background. A function is derived to represent the momentum fraction taken by the neutrino in  $b$  and  $c$  quark decays. This function is then applied to a control sample taken from data (at least four jets with  $p_T$  larger than 50 GeV,  $p_T$  of the leading jet larger than 100 GeV,  $E_T^{\text{miss}}$  smaller than 100 GeV) dominated by light-quark QCD events. The resulting distributions are normalized

to data in the region of  $\Delta\phi_{\min} < 0.2$ , where  $\Delta\phi_{\min}$  is the minimum value of the difference in azimuthal angle between the  $E_T^{\text{miss}}$  vector and any of the three highest  $p_T$  jets, as discussed in section 3.1 and the dedicated note [3].

The  $W^\pm$  and  $t\bar{t}$  background processes can also be estimated from the data, as discussed in the previous paragraph. Since all these processes are present in the data simultaneously, the background estimations should be done together. The same holds true for the presence of SUSY signal, which would contaminate the control samples.

Figure 18 (top row) shows the estimated and true distributions of  $E_T^{\text{miss}}$  and the effective mass for the combined background processes, without SUSY signal. The background distributions are reproduced well and the correct normalizations are obtained for all the background processes. The numbers of events are also summarized in Table 25.

Table 25: Number of true and estimated (MT method) background events in the no-lepton mode, for  $t\bar{t}$ ,  $W^\pm$  and QCD processes without SUSY signal, normalized to  $1 \text{ fb}^{-1}$ .

	$E_T^{\text{miss}} > 100 \text{ GeV}$	$E_T^{\text{miss}} > 300 \text{ GeV}$
$t\bar{t}$ and $W^\pm$ only		
True BG (top and $W^\pm$ )	$6894 \pm 83$	$276 \pm 17$
estimated BG (top and $W^\pm$ )	$7018 \pm 269$	$311 \pm 28$
QCD, $t\bar{t}$ and $W^\pm$		
True BG (QCD, top and $W^\pm$ )	$8077 \pm 90$	$300 \pm 17$
Estimated BG	$8158 \pm 273$	$327 \pm 28$
Ratio(Est./True)	$1.01 \pm 0.04$	$1.09 \pm 0.11$

If SUSY exists, SUSY signal can contaminate the background estimations. This is illustrated in Figure 18 (middle row) and Table 26. In the figure, the SUSY SU3 signal point is used; the table shows the variation over a number of SUSY samples. The figure and the table show that SUSY contamination causes a decrease of SUSY event excess by typically 30%, but that the considered points, with the exception of SU2, are still observable with  $1 \text{ fb}^{-1}$ .

Table 26: Number of background events and estimated (MT method) numbers for  $t\bar{t}$ ,  $W^\pm$  and QCD processes, as well as various SUSY signals, in the no-lepton mode, normalized to  $1 \text{ fb}^{-1}$ .

	$E_T^{\text{miss}} > 100 \text{ GeV}$	$E_T^{\text{miss}} > 300 \text{ GeV}$	$E_T^{\text{miss}} > 100 \text{ GeV}$	$E_T^{\text{miss}} > 300 \text{ GeV}$
True BG (QCD,top and $W^\pm$ )	$8077 \pm 90$	$300 \pm 17$	$8077 \pm 90$	$300 \pm 17$
Estimated BG True BG + SUSY signal	SU1		SU4	
	$8493 \pm 283$	$510 \pm 39$	$27527 \pm 588$	$1409 \pm 83$
	$9152 \pm 96$	$1078 \pm 33$	$34209 \pm 185$	$3535 \pm 59$
Estimated BG True BG + SUSY signal	SU2		SU6	
	$8198 \pm 274$	$329 \pm 30$	$8362 \pm 279$	$431 \pm 35$
	$8193 \pm 91$	$351 \pm 19$	$8930 \pm 95$	$924 \pm 30$
Estimated BG True BG + SUSY signal	SU3			
	$9188 \pm 299$	$633 \pm 44$		
	$11333 \pm 106$	$2113 \pm 46$		

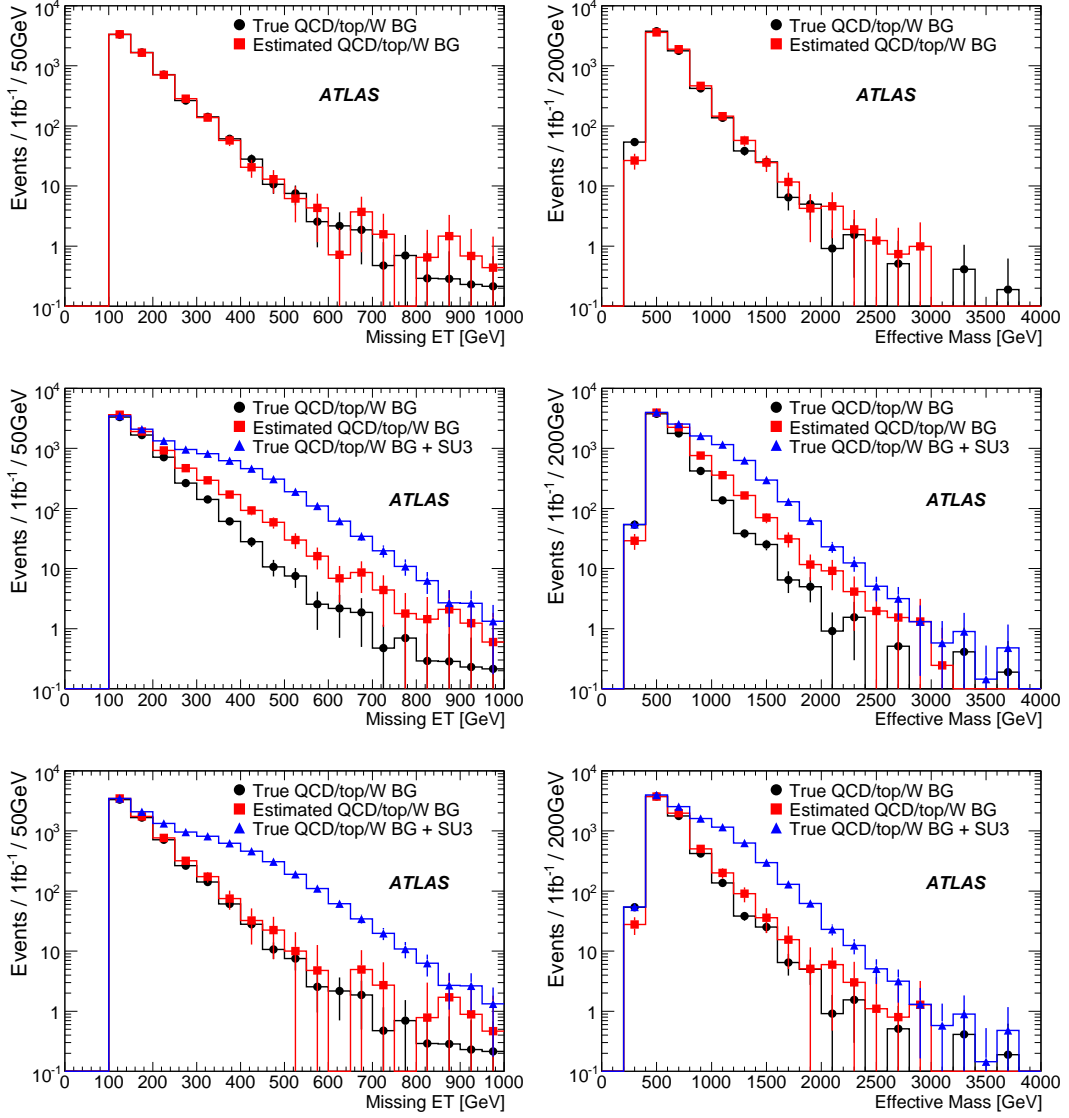

Figure 18: The estimated distributions of  $E_T^{\text{miss}}$  and the effective mass of the  $t\bar{t}$ ,  $W^\pm$  and QCD backgrounds in the no-lepton mode with a luminosity of  $1 \text{ fb}^{-1}$ . In the plots in the top row, no SUSY signal is present in the data, and black/red histograms show the true/estimated (MT method) background distributions. In the plots in the middle and bottom rows, a SUSY SU3 signal is present in the data, and the blue histograms show the background plus the SUSY signal. In the two plots in the middle row, no correction was applied. In the two bottom plots, a correction with the “new MT method” was performed.

**New MT method** The “new MT method”, discussed in section 2.3.1, provides a first rough method to correct for the presence of SUSY signal in the control sample, once a SUSY excess has been observed in data. With this method, the distributions shown in the bottom row of Figure 18 are obtained. The figure shows the estimated background distributions with the new MT method, compared to the true background distributions, when SU3 SUSY signal is present in data.

**Systematic uncertainties** The systematic errors of this method are summarized in Table 27. The ALPGEN parameter variation includes a variation of the relative fraction of  $t\bar{t}$  and  $W$  + jets in the sample. Although the actual number of background events varies with jet energy scale and Monte Carlo generator parameters by some 25%, the data-driven MT method is able to predict the background in the signal region to within an assigned systematic error of 15%.

Table 27: Systematic uncertainties of the MT-method background estimations in the no-lepton mode without SUSY signal. Also changes of the absolute background numbers are listed. Numbers are normalized to  $1 \text{ fb}^{-1}$ .

	Syst. error	Change in background level
Jet energy scale	$< 5\%$	25%
Lepton energy scale	$< 5\%$	0%
Lepton Efficiency	$< 5\%$	$< 1\%$
MC@NLO vs ALPGEN	$< 5\%$	16%
ALPGEN parameter variation	$< 5\%$	8%

### 3.3.4 Top pairs with $\tau$ decay

**Introduction** The precise determination of the cross-section for the process of top-pair production with one tau that decays hadronically,  $t\bar{t} \rightarrow W(q\bar{q}')W(\tau_{\text{had}}\nu_\tau)b\bar{b}$ , is relevant because it constitutes an important background to SUSY searches with no leptons and significant  $E_{\text{T}}^{\text{miss}}$ . In fact, if no tau veto is applied, about 65% of the total  $t\bar{t}$  background in the no-lepton mode corresponds to events containing one tau.

**Event reconstruction and selection** The topology of  $t\bar{t} \rightarrow W(q\bar{q}')W(\tau_{\text{had}}\nu)b\bar{b}$  events consists of two light-quark jets, one tau, and two  $b$  jets.

The control of the tau fake rate is very important in a busy environment like  $t\bar{t}$  where the purity of the reconstructed tau sample is low due to the large jet multiplicity. A high tau purity is needed in order to reduce the internal combinatorial background and the background from the semileptonic ( $t\bar{t} \rightarrow W(\ell\nu_\ell)W(q\bar{q}')b\bar{b}$  where  $\ell \in \{e, \mu\}$ ) decays of  $t\bar{t}$ . In this analysis, we use a calorimeter-based tau reconstruction algorithm [1], and require a minimum visible  $p_T$  of the identified tau of 25 GeV.

The event is built independently on the hadronic side and the leptonic side, and topology variables useful to identify  $t\bar{t}$  events and reject QCD and  $W$  + jet background are extracted. On the hadronic side, a hadronic  $W$  invariant mass is built choosing, among all the combinatorial possibilities of di-jets, the pair of jets with closest invariant mass to its PDG value. The hadronic top is built combining this hadronic  $W$  with the closest identified  $b$  jet in  $\Delta R$ . The  $b$ -jet identification is loose, with a 75% efficiency for  $b$  jets from top decay.

The  $E_{\text{T}}^{\text{miss}}$  is combined with the identified tau in order to build a leptonic  $W$  transverse mass. We assume a collinear approximation for the decay of the tau (the visible products of the hadronic decay of the tau and the associated  $\bar{\nu}_\tau$  are collinear), and determine the invariant transverse mass of the leptonic  $W$ . The resulting leptonic  $W$  is then combined with the closest (in  $\Delta R$ )  $b$  jet to constitute the leptonic top.

For each event, a reconstructed tau will build a leptonic  $W$  (and top) in combination with  $E_{\text{T}}^{\text{miss}}$ , and will have an associated hadronic  $W$  (and top). If there is more than one reconstructed tau we select the one that is associated with the jet pair that gives the hadronic  $W$  invariant mass closest to its PDG value.

Once the event is built, topology variables suitable for  $t\bar{t}$  selection are computed and selection cuts are applied:  $E_{\text{T}}^{\text{miss}} > 35 \text{ GeV}$ , no identified electron or muon with  $p_T > 15 \text{ GeV}$  should be present in the event, the angle  $\Delta\phi$  between the two reconstructed top quarks should be larger than 2.5, the ratio between the

transverse momentum of the two reconstructed top quarks should be smaller than 2, the angular distance ( $\Delta R$ ) between the reconstructed  $b$  jets should be larger than 1, and the angle  $\Delta\phi$  between the missing momentum vector and the hadronic  $b$  jet should be larger than 0.5.

Figure 19: Missing  $E_T$  of  $t\bar{t}$  events with  $(q\bar{q}', \tau_{\text{had}})$  for (circles)  $t\bar{t}$  selection as in this analysis (control sample) and (squares) for the SUSY no-lepton mode selection.

With the loose  $b$  tagging used here, 2910  $t\bar{t}(q\bar{q}', \tau_{\text{had}})$  events are selected for  $1 \text{ fb}^{-1}$ . The background consists of QCD and  $W + \text{jets}$ , for which 110 and 100 events respectively are selected. Therefore, with loose  $b$  tagging a good signal-to-background ratio can already be reached, although the uncertainty on the QCD background number is large. If one were to use tighter  $b$  tagging (60% efficiency), 1650  $t\bar{t}(q\bar{q}', \tau_{\text{had}})$  events would be selected, against 2 QCD events and no  $W + \text{jet}$  events.

In the presence of SUSY, the numbers of SUSY signal events that would pass the event selection with the loose  $b$  tag for  $1 \text{ fb}^{-1}$  are given in Table 28. They are generally small, with the exception of the SU4 point.

Table 28: The number of SUSY events remaining after  $t\bar{t}(q\bar{q}', \tau_{\text{had}})$  selection for different SUSY points, for  $1 \text{ fb}^{-1}$ .

	SU1	SU2	SU3	SU4	SU6	SU8
$N_{\text{evt}}$	$22 \pm 1$	$5 \pm 1$	$155 \pm 5$	$1700 \pm 60$	$70 \pm 4$	$45 \pm 3$

**Estimation of the  $t\bar{t}$  with  $(q\bar{q}', \tau_{\text{had}})$  background to SUSY.** Figure 19 shows that the selection applied in order to identify the  $t\bar{t}$  events with  $(q\bar{q}', \tau_{\text{had}})$  introduces little bias in the  $E_T^{\text{miss}}$  distribution, as compared to the SUSY no-lepton mode selection.

Applying the SUSY no-lepton mode cuts, we estimate 210  $t\bar{t}(q\bar{q}', \tau_{\text{had}})$  events as remaining background to the SUSY no-lepton mode for  $1 \text{ fb}^{-1}$ .

**Systematic uncertainties** In the data-driven analysis of  $t\bar{t}$  decays in the  $(q\bar{q}', \tau_{\text{had}})$  final state, the most relevant contributions to the detector uncertainties are the jet and  $E_{\text{T}}^{\text{miss}}$  energy scale,  $b$ -tagging efficiency and  $\tau$  identification efficiency.

Table 29: Systematic variation of the  $t\bar{t}(q\bar{q}', \tau_{\text{had}})$  cross-section due to detector-related uncertainties.

Systematic variation	Cross-section variation [%]
Jet energy scale	2.5
$b$ -tagging efficiency	7.5
Light quark rejection in $b$ -tag	1.3
$\tau$ -identification efficiency	3.4
Light quark rejection in $\tau$ -identification	4.5

The  $b$ -tagging efficiency plays an important role in the  $t\bar{t}(q\bar{q}', \tau_{\text{had}})$  reconstruction, since one of the selection criteria is that the two  $b$  jets expected in the final state should be reconstructed and correctly identified<sup>5</sup>.

The systematic contribution to the measurement of the  $t\bar{t}(q\bar{q}', \tau_{\text{had}})$  cross-section due to the  $\tau$  identification efficiency has been estimated by varying the  $\tau$  identification efficiency and the light quark rejection factor by 10%.

The uncertainty on the QCD background in the  $t\bar{t}(q\bar{q}, \tau_{\text{had}})$  sample is large due to the limited number of Monte Carlo events which could be generated. Probably tight  $b$  tagging is required in this analysis. Further study is needed on this topic.

## 4 Multi-lepton and tau search modes

As well as the one-lepton and no-lepton search modes described earlier, there is considerable SUSY discovery potential in the multi-lepton and tau search modes, as discussed elsewhere in this volume [2,4].

The data-driven estimation of backgrounds in these modes, particularly the opposite-sign dilepton and the tau modes, can use the methods that have been described earlier in the context of the one-lepton search mode have also proven to be useful. These include the MT method, the HT2 method, the kinematic reconstruction method and the redecaay method. Furthermore, for the same-sign dilepton mode, a technique based on lepton isolation, as described in the note on QCD backgrounds [3] could be further developed.

## 5 Discussion

The methods presented in this note represent a number of ideas on how top,  $W$  and  $Z$  backgrounds to SUSY searches can be extracted from the data, with appropriately chosen control samples. The results indicate that we expect, with  $1 \text{ fb}^{-1}$ , to be able to measure in the no-lepton mode:

- the  $Z \rightarrow \nu\bar{\nu}$  background with two different methods to 8–13% stat. error, 10–15% syst. error;
- the  $t\bar{t}$  background with hadronic tau decay to  $< 6\%$  stat. error, 10–15% syst. error (but with a caveat for the QCD background);
- and the sum of top,  $W$  and QCD backgrounds with the MT method to 4–8% stat. error, and 15% syst. error.

---

<sup>5</sup>This is in fact the only analysis in this note where  $b$  tagging is used.

In the one-lepton mode:

- the MT method gives the sum of  $t\bar{t}$  and  $W$  background to 4–8% stat. error, 15% syst. error;
- the semileptonic  $t\bar{t}$  background can be estimated to 5% stat. error, 22% syst. error;
- we can determine the fully leptonic  $t\bar{t}$  background to 10% stat. error, 20% syst. error in at least three independent ways;
- and we have a combined fit method to extract all components.

These methods can also be applied to the multi-lepton and tau search modes.

The results obtained with the MT method in this note are stable with respect to systematic variations in detector performance and Monte Carlo parameters and cross-sections to the 15% level. However, the MT method measures a sum of semileptonic and fully leptonic  $t\bar{t}$  and  $W/Z + \text{jets}$  background; it relies on a control sample with different composition than the signal sample, and there is a subtle interplay between the  $t\bar{t}$  and  $W/Z + \text{jets}$  components of the background. More work is needed to understand possible systematic effects. It is desirable to understand the individual components of the backgrounds as well, and the various other methods discussed in this note appear to succeed in this.

The presence of SUSY signal would affect the background estimates, at a level that depends on the SUSY signal properties, as well as on the method. Methods with very tight control samples (replace method, topbox method) see almost no effect. For the other methods, the background is overestimated by typically 20–30% for samples like SU1, SU2, SU3 and SU6. If a SUSY excess is nevertheless observed (which is possible with  $1 \text{ fb}^{-1}$ ), a correction for the background overestimation can be applied. First ideas have been presented in this note, using the MT method, and the combined fit method. More work is needed in this area. The SU4 benchmark point is a special case because of its light spectrum. It produces events with kinematics which are similar to the Standard Model backgrounds and its cross-section is high, so many methods would struggle to provide background predictions. It would, however, not be missed [11].

# Estimation of QCD Backgrounds to Searches for Supersymmetry

## Abstract

This note deals with techniques for estimating QCD multijet backgrounds to inclusive jets +  $E_T^{\text{miss}}$  + leptons searches for Supersymmetry. The note documents how the backgrounds may be estimated using a data set with an integrated luminosity of  $1 \text{ fb}^{-1}$  or less. The likely systematic and statistical uncertainties in such estimates are also discussed. Data-driven approaches discussed include jet smearing with functions derived from data and techniques for background estimation using control samples. Monte Carlo based techniques using a variety of generators and simulation tools are also discussed with a view to establishing their likely precisions and hence the optimum simulation strategy.

## 1 Introduction

In searches for supersymmetry in events containing jets and missing transverse energy ( $E_T^{\text{miss}}$ ) the biggest background-determination challenge will be in understanding QCD jet events. Although fast simulation studies [1] indicate that such backgrounds should be sub-dominant in the high  $E_T^{\text{miss}}$  and large jet multiplicity region, the situation with real data is still uncertain, and likely to be less favourable for SUSY searches. In particular non-Gaussian tails to the detector jet response function, which can be caused by dead material, jet punch-through, pile-up of machine backgrounds and other effects, can dramatically increase the cross-section of high  $E_T^{\text{miss}}$  QCD background. QCD jet events in which such processes have occurred shall be referred to in this note as “fake”  $E_T^{\text{miss}}$  events in what follows, since in such events the net  $p_T$  of non-interacting particles measured in a perfect detector is inherently small. Events in which the  $E_T^{\text{miss}}$  vector is dominated by contributions from non-interacting particles such as neutrinos or the Lightest Supersymmetric Particle (in the case of SUSY signal) shall be referred to as “real”  $E_T^{\text{miss}}$  events.

Accurate estimation of QCD jet backgrounds is difficult for a number of reasons. Processes generating fake  $E_T^{\text{miss}}$  from event mis-measurement are expected to be poorly modeled in current GEANT4 [2] simulations – this situation will improve once validation has been performed with real data. Furthermore theoretical and experimental uncertainties will conspire to decrease further the systematic precision of Monte Carlo estimates while the large QCD cross-section will limit statistical precision by rendering production of unbiased GEANT4 samples corresponding to more than a few  $\text{pb}^{-1}$  unfeasible. This note addresses these problems, assessing the relative magnitudes of some of the uncertainties, identifying techniques for minimising the contribution of such backgrounds in the SUSY signal region and studying novel Monte Carlo- and data-driven approaches to accurate background estimation. It should be understood that the background estimates presented here are not intended to be definitive; rather the focus is on developing and evaluating the performance of tools for future use. This note should be read in conjunction with the notes outlining ATLAS  $E_T^{\text{miss}}$  performance [3], data-driven estimation strategies for  $W$ ,  $Z$  and top backgrounds [4] and inclusive SUSY searches [5]. The main variables sensitive to the presence of SUSY signal which have been considered in this note are  $E_T^{\text{miss}}$  and the ‘effective mass’ defined by  $M_{\text{eff}} = \sum_{i=1}^4 |p_T(j_i)| + E_T^{\text{miss}}$  [5], where the sum runs over the four leading jets satisfying the conditions described below.

Wherever possible events appearing in  $E_T^{\text{miss}}$  or  $M_{\text{eff}}$  distributions have been selected with a standard jet selection requiring at least four jets with  $p_T > 50 \text{ GeV}$  and  $|\eta| < 2.5$ , at least one of which must have

$p_T > 100$  GeV. In some sections describing studies of new simulation techniques with limited available simulation statistics these cuts have been relaxed – these cases are highlighted in the text. In addition the performance of the different background estimation techniques has been compared by assessing the uncertainties of the background estimates for events passing a standard baseline set of cuts for the jets +  $E_T^{\text{miss}}$  + 0-lepton (1-lepton for Section 5.2) channel described elsewhere in this volume [5].

## 2 Fake $E_T^{\text{miss}}$ rejection

### 2.1 Jet fiducialisation in $\eta$

In QCD multijet events the generation of large fake  $E_T^{\text{miss}}$  from jets falling in poorly instrumented regions of the detector is a significant mechanism by which such events mimic SUSY signal. Conversely the large number of such events means they can provide a useful in-situ probe of the the ability of the detector to measure  $E_T^{\text{miss}}$ . Here we consider the use of such events for defining non-fiducial regions where jets may be expected to be poorly measured and hence capable of generating significant fake  $E_T^{\text{miss}}$ .

The  $E_T^{\text{miss}}$  resolution of the ATLAS detector is known to scale with  $\sqrt{\Sigma E_T}$  [6], where  $\Sigma E_T$  is the scalar sum over the transverse energies of all calorimeter objects. For this reason the  $E_T^{\text{miss}}$ -significance defined by  $S = E_T^{\text{miss}} / \sqrt{\Sigma E_T}$  is frequently used to distinguish real  $E_T^{\text{miss}}$  from fake  $E_T^{\text{miss}}$ . Because QCD multijet events typically have little energy in invisible particles the value of  $\langle S \rangle$  is determined by the  $E_T^{\text{miss}}$  resolution of the detector. Much of the variance in  $S$  is due to intrinsic shower fluctuations, but because the reconstructed  $E_T^{\text{miss}}$  is dominated by the transverse energy near the highest- $p_T$  jets, some is due to the non-uniformity in energy resolution of the detector. A measurement of  $\langle S \rangle$  in a sample of events in which one of the highest- $p_T$  jets points into a particular region of the calorimeter can therefore be used as a measure of the relative performance of that region.

In this study, the  $E_T^{\text{miss}}$ -significance of QCD jet events was used to calculate  $\langle S \rangle$  in  $\eta$  bins across the calorimeter. Each event  $S$  value was used in two  $\eta$  bins – one for each of the two highest- $p_T$  jets. The same techniques could be used generate a full  $(\eta, \phi)$  map of the calorimeter. A sample of PYTHIA [7] simulated QCD jet events with  $p_T > 280$  GeV and corresponding to an integrated luminosity of  $23.8 \text{ pb}^{-1}$  was used for the study [8]. Events were required to pass the 160 GeV high-level single-jet trigger [9] and to possess at least two high- $p_T$  jets with  $p_T(j_1) > 100$  GeV and  $p_T(j_2) > 50$  GeV. These two jets were required to be back-to-back in the transverse plane such that  $\pi - |\Delta\phi(j_1, j_2)| < 0.4$ . Events were vetoed if they contained an isolated lepton with  $p_T > 10$  GeV and  $|\eta| < 2.5$  or if  $E_T^{\text{miss}}$  was greater than 80 GeV. The  $\Delta\phi$  and  $E_T^{\text{miss}}$  cuts eliminate contamination from events with significant true  $E_T^{\text{miss}}$ , eg.  $Z (\rightarrow \nu\bar{\nu}) + \text{jets}$  and heavy quark jets. While the  $E_T^{\text{miss}}$  cut does, in principle, prohibit the identification of catastrophically unresponsive regions with this method, regions with consistently poor response would be readily identifiable via the relative deficiency of events with jets pointing into them.

The resulting calorimeter map is shown in Fig. 1. The degraded response in the tile barrel and tile barrel-extended barrel gaps ( $\eta \sim 0$  and  $0.6 < |\eta| < 0.8$ ) and the LAr barrel-endcap and hadronic LAr-forward calorimeter transition regions ( $1.3 < |\eta| < 1.5$  and  $3.1 < |\eta| < 3.3$ ) are all clearly visible. The principal application of these data is to define non-fiducial regions of the detector, such that events with jets pointing into these regions can be rejected. Defining a cut value  $\langle S \rangle_{\text{min}}$  on  $\langle S \rangle$ , a region is defined to be non-fiducial if  $\langle S \rangle > \langle S \rangle_{\text{min}}$  in all of the corresponding bins in the calorimeter map (Fig. 1) and if  $\langle S \rangle - \langle S \rangle_{\text{min}} > 3\varepsilon$  in at least one of those bins, where  $\varepsilon$  is the uncertainty on the mean  $\langle S \rangle$ . Fig.1 also shows the non-fiducial regions obtained in this way with  $\langle S \rangle_{\text{min}} = 0.95$ .

The jet fiducialisation process has been tested on the QCD jet sample which was used to define the regions and also on SUSY events from model point SU3 [10]. Events were required to satisfy the jet cuts listed in Section 1 and events with a jet with  $p_T > 40$  GeV pointing into one of the non-fiducial regions depicted in Fig.1 were rejected. The efficiency of these cuts for the QCD and SUSY samples was

Figure 1:  $\langle E_T^{\text{miss}} / \sqrt{\Sigma E_T} \rangle$  vs.  $\eta_j$ , where  $j$  is the first or second highest- $p_T$  jet in each event (points). The non-fiducial regions selected with a cut at 0.95 (dashed line) are also shown (shaded areas; see text). These regions correspond to the LAr barrel-endcap and HEC-forward transition regions.

$(74.8 \pm 0.4)\%$  and  $(75.4 \pm 0.6)\%$  respectively for  $E_T^{\text{miss}} > 0$  GeV, and  $(67.5 \pm 3.7)\%$  and  $(75.5 \pm 0.7)\%$  for  $E_T^{\text{miss}} > 100$  GeV. The effect of these cuts on the simulated data-samples is clearly small however they may be of more use with real data acquired with an imperfect detector, and the technique could be used as an on-line monitor of calorimeter performance.

## 2.2 Jet- $E_T^{\text{miss}}$ $\phi$ correlations

One of the main methods used to reduce the QCD multijet background in  $E_T^{\text{miss}}$  + jets inclusive SUSY searches at the Tevatron has been the elimination of events in which the  $E_T^{\text{miss}}$  is closely associated with one of the leading jets in the transverse plane [11, 12]. This section provides a brief exploration of this method of background elimination in ATLAS.

Figure 2: The  $|\Delta\phi(j_1, E_T^{\text{miss}})| - |\Delta\phi(j_2, E_T^{\text{miss}})|$  plane for QCD multijet (left) and SUSY SU3 events (right) passing SUSY jet cuts and  $E_T^{\text{miss}} > 100$  GeV.

Fig. 2 shows the  $|\Delta\phi(j_1, E_T^{\text{miss}})| - |\Delta\phi(j_2, E_T^{\text{miss}})|$  plane for events from the QCD multijet sample described in Section 2.1 which pass the jet cuts described in Section 1 and possess  $E_T^{\text{miss}} > 100$  GeV (note that this sample has at least one jet with  $p_T > 280$  GeV – significantly higher than the SUSY leading-jet  $p_T$  requirement of 100 GeV). Almost all events are confined to small regions around  $(\pi, 0)$  and  $(0, \pi)$ , with a small number of events in which the  $E_T^{\text{miss}}$  is not associated with one of the two highest- $p_T$  (reconstructed) jets lying outside these regions. For comparison, the  $|\Delta\phi(j_1, E_T^{\text{miss}})| - |\Delta\phi(j_2, E_T^{\text{miss}})|$  plane for events from a SUSY (SU3 model) sample [8] passing the above cuts is shown in Fig. 2. No such correlation with  $E_T^{\text{miss}}$  is observed for this SUSY benchmark point.

Figure 3: The  $\Delta\phi_{\min}$  distribution for QCD multijet (solid line) and SU3 SUSY (dashed line) events passing the SUSY jet cuts and with  $E_T^{\text{miss}} > 100$  GeV, as described in the text. Good discrimination is achieved with a cut at  $\Delta\phi_{\min} = 0.2$  (vertical dotted line).

For the purposes of background reduction, this technique can be generalised by considering three correlations between the  $E_T^{\text{miss}}$  vector and the leading three jets by defining  $\Delta\phi_{\min}$  as:

$$\Delta\phi_{\min} = \min(\Delta\phi(j_1, E_T^{\text{miss}}), \Delta\phi(j_2, E_T^{\text{miss}}), \Delta\phi(j_3, E_T^{\text{miss}})). \quad (1)$$

The  $\Delta\phi_{\min}$  distribution for the QCD and SUSY samples passing the SUSY jet cuts and with  $E_T^{\text{miss}} > 100$  GeV are shown in Fig. 3. Also shown is the position of a cut at  $\Delta\phi_{\min} > 0.2$  used in Ref. [5].

### 2.3 Calorimeter and tracking cuts

Events in which jet reconstruction problems lead to fake  $E_T^{\text{miss}}$  can be identified with several variables [3]. Cuts on the fraction of the total energy of the jet ( $E_{\text{Total}}$ ) deposited in the outermost layers of the tile calorimeter  $E_{\text{Tile2}}$  and in the hadronic endcap calorimeter  $E_{\text{HEC}}$  can be defined to veto events with likely problems in jet containment. Additional cuts on the fraction of the jet energy deposited in the cryostat between the tile and the liquid argon ( $E_{\text{Cryo}}$  – estimated from the energy in the closest calorimeter layers) and in the gap and crack scintillators ( $E_{\text{Gap}}$ ) can be used to reject events with large depositions in dead material. It is also possible to identify events in which there have been problems reconstructing the missing transverse momentum by comparing the value calculated from charged tracks ( $E_{T,\text{Trk}}^{\text{miss}}$ ) with the usual calorimetric  $E_T^{\text{miss}}$ .

Table 1: Cross-section of SUSY SU3 signal and QCD jet backgrounds before and after application of the selection and cleaning cuts proposed in the text. Quoted statistical uncertainties in cross-sections after cuts derive from statistics of the Monte Carlo samples used.

Sample	No cuts [pb]	Selection cuts [pb]	Cleaning cuts [pb]
SUSY SU3	27.51	$9.654 \pm 0.019$	$6.792 \pm 0.016$
QCD ( $280 \text{ GeV} < p_T < 560 \text{ GeV}$ )	$1.25 \times 10^4$	$17.2 \pm 1.3$	$9.7 \pm 1.0$
QCD ( $560 \text{ GeV} < p_T < 1120 \text{ GeV}$ )	360.0	$4.22 \pm 0.13$	$1.805 \pm 0.082$
QCD ( $1120 \text{ GeV} < p_T < 2240 \text{ GeV}$ )	5.71	$0.434 \pm 0.003$	$0.130 \pm 0.002$

Table 1 shows the cross-section of SU3 signal and multijet background following application of the SUSY jet cuts described in Section 1 together with a cut requiring  $E_T^{\text{miss}} > 100$  GeV, and in addition

applying the fake  $E_T^{\text{miss}}$  cleaning cuts discussed above. The latter cuts were applied to jets with  $p_T > 150$  GeV with the following acceptance criteria :  $E_{\text{Tile2}}/E_{\text{Total}} < 0.1$ ,  $E_{\text{Cryo}}/E_{\text{Total}} < 0.2$ ,  $E_{\text{Gap}}/E_{\text{Total}} < 0.2$ ,  $E_{\text{HEC}}/E_{\text{Total}} < 0.5$  and  $E_{T,\text{Trk}}^{\text{miss}} - E_T^{\text{miss}} < 50$  GeV. Note that the specific cut values are analysis dependent and should be adapted for other cases. The table shows that the cleaning cuts are effective at removing between 40% (low  $p_T$ ) and 70% (high  $p_T$ ) of the multijet background, while rejecting  $\sim 30\%$  of the remaining signal after selection cuts.

## 2.4 Cosmic backgrounds and rejection cuts

Searches for supersymmetry must contend with backgrounds in which fake  $E_T^{\text{miss}}$  arises from a variety of sources. Examples in which the fake  $E_T^{\text{miss}}$  is generated independently from a hard scatter include dead or noisy calorimeter channels, accelerator-related background and cosmic rays in which a muon undergoes a hard bremsstrahlung. A range of data-cleaning tools is being prepared to reject fake  $E_T^{\text{miss}}$  in ATLAS; here we focus on timing information from the hadronic tile calorimeter (TileCal). As one gains a better understanding of the first data, this will be combined with information from other subdetectors.

Calorimeter timing can be a powerful tool to remove fake  $E_T^{\text{miss}}$  backgrounds from cosmic rays [13]. Timing in ATLAS is defined such that particles from the nominal interaction point ( $x = 0, y = 0, z = 0$ ) will arrive in the calorimeter cells at time  $t = 0$ . Cosmic ray events, however, will arrive at random times with no correlation to the LHC beam structure. One of the methods to reject cosmic rays is to calculate the “up-minus-down” time, in which one divides the TileCal into two segments, an upper segment, with  $\phi > 0$  and a lower segment with  $\phi < 0$ , where  $\phi$  is the angle in the transverse plane. One then calculates the average time of cells in each segment, weighted by the energy of each cell  $i$ :

$$t_{\text{up(down)}} = \sum_i (E_i^{\text{up(down)}} \times t_i) / \sum_i E_i^{\text{up(down)}}. \quad (2)$$

The difference between the two quantities  $t_{\text{up}}$  and  $t_{\text{down}}$ , should reflect the average time-of-flight. The resulting “up-minus-down” time should be centered at  $t = 0$  for particles from the interaction point, as demonstrated in Fig. 4. In this figure, the “up-minus-down” time is calculated for a simulated Monte Carlo QCD dijet sample. As expected, the signal distribution peaks near zero. Note that the simulation includes electronic noise, and so the timing distribution has a spread of several ns.

Depending on their trajectory, cosmic ray muons traveling from the top to the bottom of ATLAS at near the speed of light will have a time-of-flight of typically 18-20 ns over their travel distance of approximately 6-7 m [14] in the TileCal. This is demonstrated in Fig. 5 for a simulated Monte Carlo sample of cosmic ray muons. In this case, the distribution peaks near -18 ns (the time of flight is negative as expected for a particle traveling from the top to the bottom). The width of the simulated distribution is 3 ns, allowing for a good separation of the background from the signal peaking at  $t = 0$ . Further details of calorimeter timing studies with cosmic rays in ATLAS can be found in Ref. [14].

## 3 Monte Carlo systematics

### 3.1 Generator systematics: proton PDF and underlying event

In this section, uncertainties on the Monte Carlo generation of QCD events arising from proton parton distribution functions (PDFs) and modeling of the underlying event are briefly investigated. These uncertainties provide a limit to the precision with which the novel detector simulation strategies described in Sections 4.1 and 4.2 can model QCD backgrounds to SUSY. Due to the large number of Monte Carlo samples required for this study, each with different PDF or underlying event parameters, it was unfeasible to work with GEANT4 detector simulation samples. Therefore dedicated samples of events were generated in the same  $p_T$  ranges as the GEANT4 samples used elsewhere in this note [8] and passed through

Figure 4: “Up-minus-down” timing distribution in TileCal for a simulated Monte Carlo di-jet sample. As expected, the distribution peaks near 0.

Figure 5: “Up-minus-down” timing distribution in TileCal for a simulated Monte Carlo cosmic ray sample. As expected, the distribution peaks near -18 ns.

the ATLAS fast detector simulation [15]. For all distributions shown in this section, QCD events were selected with the common jet cuts described in Section 1.

Figure 6: The  $M_{\text{eff}}$  distribution for simulated QCD events satisfying SUSY jet cuts described in Section 1. The left plot shows the number of events per bin, scaled to  $1\text{fb}^{-1}$  and the right plot shows the fractional difference with respect to CTEQ6.1M. In each case, the solid histogram and shaded band shows the results from the CTEQ6.1M proton PDF. The dashed and dotted histograms show the results from the MRST2004 and CTEQ6L1 PDFs, respectively. The error bars reflect the Monte Carlo statistics.

**Proton Parton Distribution Functions** All calculations of cross-sections at the LHC rely on a knowledge of the proton parton distribution functions (PDFs). High- $p_T$  QCD events will be particularly sensitive to the gluon PDF at large  $x$  which, in current global fits [16–19], is relatively poorly known. In this section, the impact of the PDF uncertainties on distributions of observables sensitive to the presence of SUSY signal is estimated.

Events were generated using PYTHIA 6.403 [7], with the following PDFs: CTEQ6L1 [20], CTEQ6.1M [17]

and MRST2004nlo [21]. Note that CTEQ6L1 is a leading order (LO) PDF, while CTEQ6.1M and MRST2004nlo sets are both next-to-leading-order (NLO) sets. CTEQ6.1M provides a set of error PDFs ( $S_i^\pm$ ), corresponding to the  $N$  eigenvector directions. Note that the  $S_i^\pm$  only reflect the experimental uncertainties on the data, and do not include any information on theoretical assumptions used in the fit. The total PDF uncertainty arising from experimental sources, on a given observable,  $\Sigma$ , can then be constructed according to:

$$\Delta\Sigma^\pm = \sqrt{\sum_{i=1}^N \left( \max \left( \pm\Sigma(S_i^\pm) \mp \Sigma(S_0), \Sigma(\pm S_i^\pm) \mp \Sigma(S_0), 0 \right) \right)^2}; \quad (3)$$

where  $\Delta\Sigma^+$  ( $\Delta\Sigma^-$ ) are the upper (lower) uncertainties on the observable and  $S_0$  represents the central (best fit) PDF value. For CTEQ6.1M, there are 40 error PDF sets,  $S_i^\pm$ , corresponding to  $N = 20$  eigenvector directions. Since the uncertainty band obtained from CTEQ6.1M only reflects the uncertainties of the experimental data, the predictions of this PDF are also compared here to those from MRST2004nlo (an alternative, independent NLO PDF) and to CTEQ6L1<sup>1</sup>.

The distribution of  $M_{\text{eff}}$  for the different PDFs considered, and the fractional uncertainty with respect to the central prediction of CTEQ6.1M, is shown in Fig. 6. The CTEQ6.1M uncertainty band ranges from  $\sim 20 - 50\%$ , as  $M_{\text{eff}}$  increases. The largest contribution to this band comes from eigenvector 15, which is mainly sensitive to the gluon at large  $x$ . The results from MRST2004nlo lie well within the CTEQ6.1M uncertainty band across the whole range of the distribution. The prediction from CTEQ6L1, a LO PDF, lies below those of the NLO PDFs. For  $M_{\text{eff}} \gtrsim 1$  TeV, the difference is approximately constant and at the level of  $\sim 20\%$ . The validity of using NLO versus LO PDFs, with LO matrix-element generators, is discussed in a recent publication [22]. However, these results indicate that the difference between the results from LO and NLO PDFs is smaller than the CTEQ6.1M uncertainty band.

Figure 7: The  $M_{\text{eff}}$  distribution for simulated QCD events satisfying SUSY jet cuts described in Section 1. The left plot shows the number of events per bin and the right plot shows the fractional uncertainty with respect to the “PYTHIA – ATLAS default” model for the underlying event. In each plot, the solid histogram shows the results from the “PYTHIA – ATLAS default”, the dotted histogram shows “PYTHIA – Tune A”, the dashed histogram shows “PYTHIA – no MPI” and the dot-dashed histogram shows “JIMMY – ATLAS default”. The error bars reflect the Monte Carlo statistics.

<sup>1</sup>Note that the PYTHIA parameters used by default within ATLAS are tuned to the CTEQ6L1 proton PDF. Strictly, if a different PDF is used, a retuning of the Monte Carlo parameters to data should be performed. This has not been done in the current study, and this should be borne in mind when interpreting the results.

**Underlying Event** Monte Carlo generation of QCD events is also sensitive to the underlying event. Multi-parton interactions are modelled in several Monte Carlo generators. For this study, the PYTHIA 6.403 [7], and HERWIG 6.507 [23] (used in conjunction with JIMMY v4 [24]) are used. Further details of the underlying-event models compared are summarised below. Note that, unless otherwise stated, CTEQ6L1 is used as the proton PDF.

The underlying event models considered are briefly summarised below:

- “PYTHIA – ATLAS default” : the ATLAS default underlying-event tune for PYTHIA 6.4 [8].
- “PYTHIA – Tune A” : a model based on the “PYTHIA-TuneA” [25] to Tevatron data. Note that since underlying-event tunes also depend on the PDFs, CTEQ5L [26], appropriate to Tune A, has been used here.
- “PYTHIA – no MPI” : a model in which multi-parton interactions have been switched off. All other parameters were left at the PYTHIA 6.403 defaults. This model does not describe the Tevatron data, but is included for comparison.
- “JIMMY – ATLAS default” - the ATLAS default underlying event tune for HERWIG 6.5 + JIMMY 4 [8].

The distribution of  $M_{\text{eff}}$  is shown in Fig. 7. The left plot shows the number of events per bin (scaled to  $1 \text{ fb}^{-1}$ ) while the right plot shows the fractional ratio with respect to “PYTHIA – ATLAS default”. As expected, the model with no underlying event contribution, “PYTHIA – no MPI”, lies below the predictions of all other PYTHIA models. The highest model prediction is given by the “PYTHIA – Tune A” model, based on “PYTHIA-TuneA” to Tevatron data. The ATLAS default tunes, “PYTHIA – ATLAS default” and “JIMMY – ATLAS default”, show differences of  $\sim 20\%$ . However, some of this difference may come from the different normalisations of PYTHIA and HERWIG and not totally due to the underlying event model. The overall spread in predictions from these models, is  $\sim 40\%$  and is approximately constant across the range of  $M_{\text{eff}}$  shown.

### 3.2 Jet energy scale uncertainty

A significant source of irreducible experimental uncertainty in Monte Carlo QCD background estimates will arise from the uncertainty in the jet-energy-scale (JES). In this section, a simple estimate of the impact of the JES uncertainty is performed. For each event, the energy and momentum of each jet has been scaled by a constant factor, corresponding to a 10%, 5%, 3% and 1% uncertainty on the JES. The  $E_{\text{T}}^{\text{miss}}$  has also been adjusted accordingly, by an amount corresponding to the change in the sum of the jet momenta in the  $x$  and  $y$  directions. All such scaling is performed prior to any selection cuts. For this study, the QCD dijet events generated with PYTHIA have been used, with a fake  $E_{\text{T}}^{\text{miss}}$  filter applied to enhance the rate of potentially mismeasured events [3, 8].

Figure 8 shows the resulting  $M_{\text{eff}}$  distribution. The shaded bands show the uncertainties on the distribution for the four different values of the JES uncertainty considered. For a 10% value, the uncertainty on the  $M_{\text{eff}}$  distribution ranges from  $\sim 50 - 150\%$ . An improved understanding of the JES to a level of 5% reduces the uncertainty on  $M_{\text{eff}}$  by more than a factor of two, while a 3% value shows an improved uncertainty on  $M_{\text{eff}}$  of between  $\sim 10 - 30\%$ . If the challenging goal of a 1% JES uncertainty is achievable, the results indicate that the uncertainty on high- $p_{\text{T}}$  events could be much reduced, to a level of  $\sim 5 - 10\%$ .

### 3.3 Generator comparison: PS vs. ALPGEN

The recent development of event generators in which regions of phase-space populated by a multi-parton matrix-element calculation are matched to those populated by a parton shower algorithm offer

Figure 8: The  $M_{\text{eff}}$  distribution for simulated QCD events satisfying SUSY jet cuts described in Section 1. The left plot shows the number of events per bin and the right plot shows the fractional uncertainty with respect to the central prediction. The shaded bands show the estimated uncertainty on the observable for assumed JES uncertainties of 10% (light), 5% (medium-light), 3% (medium) and 1% (dark).

the prospect of improved simulation of high  $p_T$  QCD jet events. In this section we compare the physics performance of such a generator, namely the leading-order ALPGEN [27] code, with that of a conventional stand-alone parton-shower generator (PYTHIA 6.403 [7]).

Multijet QCD events were generated with ALPGEN 2.05+JIMMY and with PYTHIA 6.403 and the resulting distributions of observables sensitive to SUSY signal events compared using fast simulation [15]. PYTHIA events were generated in different  $p_T$  ranges of the two leading partons to study the high energy tails with sufficient statistics (see Ref. [8]). Such sliced-sample production is also possible in ALPGEN. Only events satisfying the standard SUSY jet cuts described in Section 1 were studied. The number of PYTHIA events passing the jet selection cuts is 2.1 times larger than the number of ALPGEN events for the same integrated luminosity<sup>2</sup>. To facilitate comparison of the two samples, they were both normalized to  $1 \text{ fb}^{-1}$  and ALPGEN samples were further multiplied by a factor of 2.1. Error bars on each histogram below are based on the Monte Carlo statistics used in this study.

Figure 9 shows the  $p_T$  distribution of the leading four jets for ALPGEN and PYTHIA events. The new parton shower scheme available in PYTHIA 6.403 can produce hard subleading jets with similar  $p_T$  to those produced by ALPGEN while the two leading jets are somewhat softer. Even though PYTHIA also generates  $2 \rightarrow 2$  scattering using matrix-element calculations, the two highest- $p_T$  jets are softer because additional partons are emitted from the leading partons using splitting functions.

The use of fast detector simulation for the comparison of event generators described in this section prevents accurate study of the impact of generator differences on ‘fake’  $E_T^{\text{miss}}$  distributions. Nevertheless, ‘real’  $E_T^{\text{miss}}$  events in which heavy quark decays generate neutrinos can potentially dominate in the tail of the  $E_T^{\text{miss}}$  distribution following application of the cuts described in Section 2 and Ref. [3]. Fast detector simulation can legitimately be used to study this background permitting comparison of PYTHIA and ALPGEN predictions of  $E_T^{\text{miss}}$  and  $M_{\text{eff}}$  distributions. Figure 10(a) shows the  $E_T^{\text{miss}}$  distributions obtained from PYTHIA and ALPGEN while Figure 10(a) shows the relative difference between the distributions of the  $E_T^{\text{miss}}$ .

<sup>2</sup>No  $b\bar{b}$  or  $c\bar{c}$  pair production events where the heavy quark pair is produced in the hard scatter rather than through gluon splitting were generated in PYTHIA. This contribution is 10 % of the total  $b\bar{b}$  cross-section and negligible compared to the total multi-jet cross-section.

Figure 9: The  $p_T$  distributions of the four highest- $p_T$  jets; (a) the leading, (b) the second (c) the third and (d) the fourth jet for PYTHIA (open circles) and ALPGEN (open histogram) events.

PYTHIA predicts somewhat larger  $E_T^{\text{miss}}$  than ALPGEN, although limited Monte Carlo statistics prevent firm conclusions from being drawn at large  $E_T^{\text{miss}}$ . This effect likely originates from the fact that multi-jet events containing gluon splitting are not fully included in ALPGEN because of the requirements of matrix element – parton shower matching.<sup>3</sup> The equivalent  $M_{\text{eff}}$  distributions and the relative differences between generators are shown in Figure 11. The  $M_{\text{eff}}$  distribution of ALPGEN events is harder than that of PYTHIA events, as expected from Figure 9(a) and (b).

## 4 Monte Carlo estimates

### 4.1 Jet smearing with Transfer Function

**Introduction** In this section, a Monte Carlo based detector simulation technique is described which models the response function of the ATLAS calorimeter to jets as a function of energy and  $\eta$  using Monte Carlo “truth” information, and then uses this response function to smear the energies of jets and other objects in Monte Carlo QCD jet events. The truth-derived response function used here is referred to as the particle-jet transfer function (PJTF) and in principle may be measured also from data using techniques such as those described in Section 5.1.

<sup>3</sup>To avoid double counting of partons generated by the matrix element calculation and parton shower algorithm, the MLM matching scheme employed by ALPGEN requires that matrix element partons satisfy cuts on  $p_T$  ( $>40$  GeV) and  $\Delta R$  between partons ( $>0.7$ ). As a result of these requirements, processes such as  $ggb\bar{b}$  generating multiple partons with  $\Delta R_{b\bar{b}} < 0.7$  are rejected during matching. Events with gluon splitting generated in the parton shower algorithm are however kept.

Figure 10: (a) ATLFAST  $E_T^{\text{miss}}$  distribution for PYTHIA(circles) and ALPGEN (histogram) and (b) the relative difference  $(N_{\text{PYTHIA}} - N_{\text{ALPGEN}}) / N_{\text{ALPGEN}}$  of the  $E_T^{\text{miss}}$  distributions. The shaded band is the Monte Carlo statistical error.

Figure 11: (a) ATLFAST  $M_{\text{eff}}$  distribution for PYTHIA(circles) and ALPGEN (histogram) and (b) the relative difference  $(N_{\text{PYTHIA}} - N_{\text{ALPGEN}}) / N_{\text{ALPGEN}}$  of the  $M_{\text{eff}}$  distributions. The shaded band is the Monte Carlo statistical error.

**Modeling jets – reconstruction of the PJTF** In this section we use the following terminology for two different types of jets formed from Monte Carlo events – “particle jets”, made from all the generated particles in the event except muons and neutrinos, and “calorimeter jets” formed from topological clusters in the calorimeter.

In general there is a high efficiency for reconstructing jets in the calorimeter, even though their energy can potentially be mis-measured by a large amount. Jet fragmentation to particles of different types and the response of the detector material to these particles in different  $\eta$  regions can produce tails in the PJTF. It is possible for there not to be a one-to-one match between generator-level jets and calorimeter jets even though the same jet clustering algorithms are used.

To reconstruct the PJTF it is necessary to measure the response of the calorimeter to generator-level jets. This is accomplished by matching these to calorimeter jets, and requiring a good jet isolation in both jets (separation from nearest jet  $\Delta R > 0.8$ ), to ensure that accidental jet overlaps do not contribute

to the tails in the PJTF. Jet energy responses are modeled with double Gaussians. The ratio of the 1st and 2nd Gaussian components is empirically known to follow the ratio of energy deposits in the electromagnetic and hadron calorimeter and hence the 1st/2nd Gaussian ratio is fixed to the mean value of  $E_{\text{had}}/(E_{\text{em}} + E_{\text{had}})$  with a fitting procedure. GEANT4 simulated PYTHIA dijet samples with  $p_T > 17$  GeV [8] are used to estimate the PJTF. Reconstructed jet energies are corrected with an energy-density based weighting scheme [28]. The fits are performed before the jet energy corrections have been applied, i.e. the PJTF is obtained at the calorimeter cell energy calibration level. To use the PJTF on reconstructed jets, cell-to-jet energy corrections are applied after the PJTF. For the  $E_T^{\text{miss}}$  calculation the cell-level correction is used directly to retain consistency with full GEANT4 simulation  $E_T^{\text{miss}}$ .

**Modeling  $E_T^{\text{miss}}$**  All truth jets (formed from stable truth particles expected to shower in the calorimeter) with energy greater than 10 GeV are smeared with the PJTF. This avoids double counting of interacting particles (electron, photon, tau) due to the potentially different treatment of merging and splitting of objects, for example when the photon is close to a jet. This simplification of reconstructing jets from all stable showering particles mis-measures the energy scale of isolated electrons, photons and taus by a small amount, however the ATLAS procedure of identifying and calibrating electromagnetic and hadronic showers separately ensures that the resulting bias is minimised. This study is additionally focussed on QCD jet events and hence any such bias is still less important. Muons in the event are simulated with the ATLFAST fast simulation code [15] due to the prohibitive time overhead associated with full simulation of the ATLAS tracking systems. Finally in order to account for the potentially large fluctuation in the underlying event, we vectorially sum all the particles that are not part of jets above 10 GeV to form a “soft jet”. This soft jet is added to the above jet sum to compensate for the contribution from soft particles outside of the jet cones. Once all the objects in the event are defined, the  $E_T^{\text{miss}}$  in the event is calculated by summing their four-vectors, enabling comparison of the performance of the PJTF technique with full GEANT4 simulation.

**Performance** The performance of the PJTF technique was assessed by comparing PJTF predictions with those obtained from full GEANT4 simulation using the  $p_T > 17$  GeV dijet samples described above. The event-by-event comparison was performed using both ATLFAST and fully reconstructed objects in the GEANT4 simulation samples.

The jet multiplicity difference between full GEANT4 simulation and PJTF, and between full GEANT4 simulation and ATLFAST are shown in Fig. 12. Only jets with  $p_T > 50$  GeV and  $|\eta| < 2.5$  were used, but no event selection based on the jet multiplicity was performed.

Figure 12: Event by event difference in number of jets between full GEANT4 simulation and PJTF (blue,solid) and between full GEANT4 simulation and ATLFAST (red,dashed). The left plot is for  $140 \text{ GeV} < p_T < 280 \text{ GeV}$  events, and the right one is for  $560 \text{ GeV} < p_T < 1120 \text{ GeV}$  events.

There is good agreement in jet multiplicity between the full GEANT4 simulation and the PJTF events. The ATLFAST events have a somewhat higher multiplicity due to the simplified calorimeter map used for jet reconstruction. For the PJTF technique to be effective, it is important that the multiplicity at reconstruction level is not biased. This is clearly demonstrated in Fig. 12. Good agreement was found for jet  $p_T > 40$  GeV, which can be explained as follows. The topological clustering jet algorithm has a  $\sim 100\%$  efficiency so if the transfer function is correctly scaling and smearing the energy the jet multiplicity could only be biased by jets splitting and/or merging.

Another performance check is the comparison of the scalar  $p_T$  sum of the four leading jets obtained from full GEANT4 simulation, PJTF, and ATLFAST events. Events passing the typical SUSY jet cuts listed in Section 1 are used. Fig. 13 shows the comparisons for  $140 \text{ GeV} < p_T < 280 \text{ GeV}$  and  $560 \text{ GeV} < p_T < 1120 \text{ GeV}$  events. Good agreement is observed between the full GEANT4 simulation and PJTF events, while ATLFAST events have significant deviations for the same reasons as for Fig. 12.

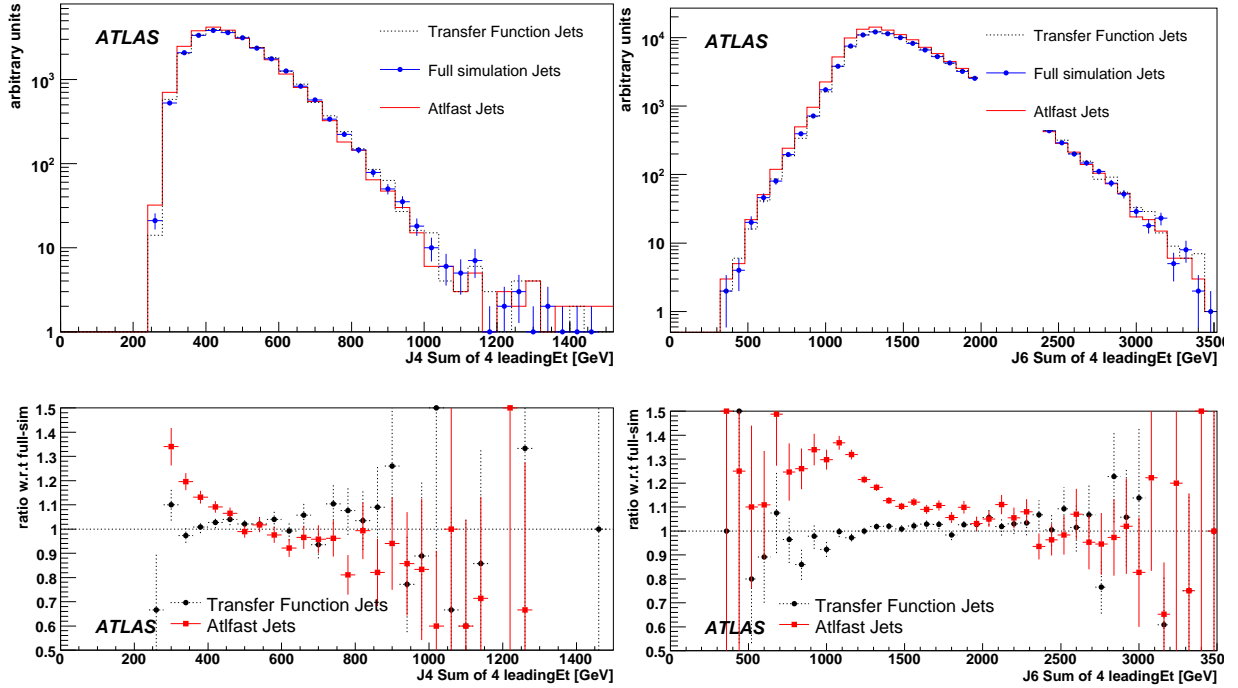

Figure 13: Top: distributions of the scalar  $p_T$  sum of the four leading jets in PJTF (black, solid), ATLFAST (red, solid) and fully GEANT4 simulated jets (blue, points). The left plot is for  $140 \text{ GeV} < p_T < 280 \text{ GeV}$  events, and the right plot is for  $560 \text{ GeV} < p_T < 1120 \text{ GeV}$ . Bottom: the ratio with respect to the fully GEANT4 simulated jets.

In order to check the performance of  $E_T^{\text{miss}}$  modeling the typical SUSY jet cuts described in Section 1 were applied, with no  $E_T^{\text{miss}}$  cut applied initially. We define fake  $E_T^{\text{miss}}$  as follows:

$$E_T^{\text{miss,fake}} = |\mathbf{p}_T^{\text{miss,reco}}| - |\mathbf{p}_T^{\text{miss,true}}|$$

where  $\mathbf{p}_T^{\text{miss,reco}}$  is the missing transverse momentum vector reconstructed using either the PJTF technique, GEANT4 simulation, or ATLFAST, and  $\mathbf{p}_T^{\text{miss,true}}$  is the transverse vector of the sum of the neutrino momenta.

Fig. 14 shows the fake  $E_T^{\text{miss}}$  distribution obtained from the PJTF technique and from full GEANT4 simulation. Also shown are the ATLFAST results, and the PJTF results without the soft-jet corrections.

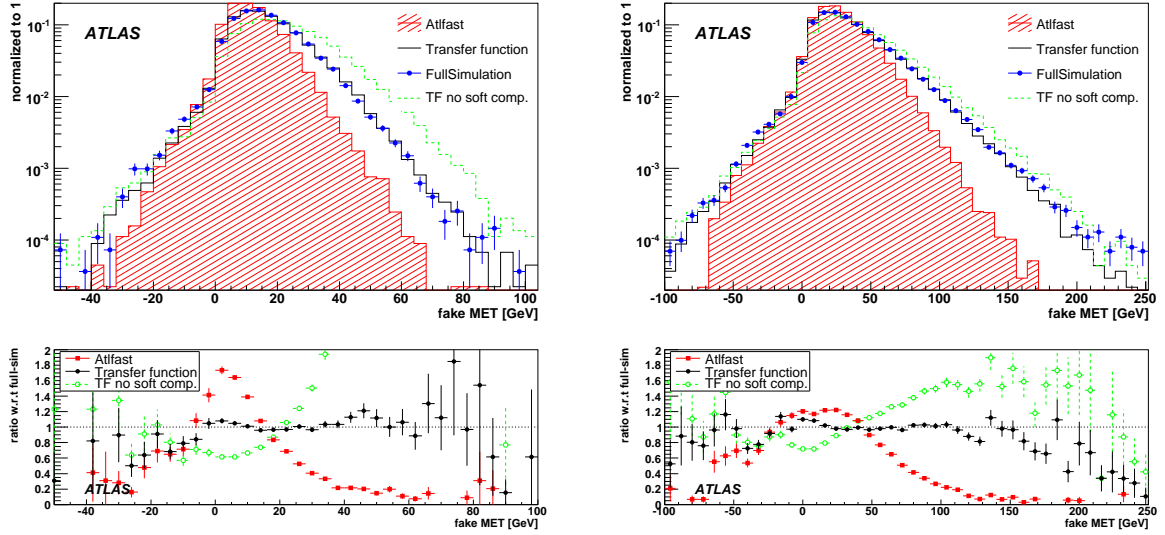

Figure 14: Fake  $E_T^{\text{miss}}$  distributions from ATLFAST (red hatched), PJTF technique (black, solid) and full GEANT4 simulation (blue, points). Also shown with the dashed green line is the PJTF distribution without soft-jet correction. The left plot is for  $140 \text{ GeV} < p_T < 280 \text{ GeV}$  events, and right plot is for  $560 \text{ GeV} < p_T < 1120 \text{ GeV}$ . Bottom plots are the ratio of each distribution with respect to the full GEANT4 simulation.

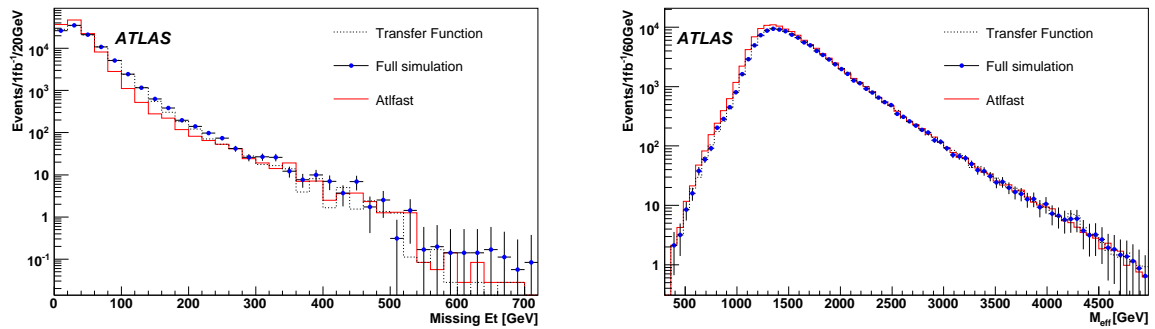

Figure 15:  $E_T^{\text{miss}}$  (left) and  $M_{\text{eff}}$  (right) distributions of  $560 < p_T < 2240 \text{ GeV}$  PYTHIA QCD jet events simulated with ATLFAST (light/red solid), the PJTF technique (dark/black, solid) and full GEANT4 simulation (points). Events were required to pass the SUSY jet cuts described in Section 1.

Table 2: Numbers of  $560 < p_T < 2240$  GeV PYTHIA QCD jet events passing cuts for  $1 \text{ fb}^{-1}$  data, starting from an original total of  $3.5 \times 10^5$  events. Errors are also normalized to  $1 \text{ fb}^{-1}$ . The cut definitions are described in the text.

Method	Cut 1	Cut 2	Cut 3
Full simulation	$(103.8 \pm 0.3) \times 10^3$	$(65.7 \pm 0.3) \times 10^3$	$4.3 \pm 2.1$
PJTF technique	$(104.9 \pm 0.3) \times 10^3$	$(62.3 \pm 0.2) \times 10^3$	$2.2 \pm 1.5$
ATLFAST	$(120.0 \pm 0.3) \times 10^3$	$(86.1 \pm 0.3) \times 10^3$	$2.1 \pm 1.5$

It can be seen from the figure that  $E_T^{\text{miss}}$  estimated with the PJTF technique and with full GEANT4 simulation agree at the 20% level for fake  $E_T^{\text{miss}} < 80$  GeV (200 GeV) for 140–280 GeV (560–1120 GeV) dijet events. The figures highlight the improvement in performance relative to the naive ATLFAST estimate of  $E_T^{\text{miss}}$ , with the agreement between PJTF and full GEANT4 simulation persisting down into the tail region a factor  $10^{-3}$  below the peak.

Fig. 15 shows the performance of the PJTF technique for estimating QCD backgrounds to the  $E_T^{\text{miss}}$  and  $M_{\text{eff}}$  distributions obtained following application of the SUSY jet cuts described in Section 1. In these plots the event-weights and errors are normalized to  $1 \text{ fb}^{-1}$ . Good agreement is seen between the PJTF distributions and the full simulation distributions over the full  $p_T$  range, while the naive ATLFAST distributions show larger deviations from the full simulation results.

Additional cuts equivalent to the full SUSY cuts described in Section 1 were applied to assess further the consistency between the PJTF results and those obtained with full GEANT4 simulation. In Table 2 the remaining numbers of events after each stage in the event selection are shown. Cut 1 is the standard SUSY jet cut applied above. Cut 2 adds the requirement  $\Delta\phi_{\min} > 0.2$  (see Section 2.2) while Cut 3 requires additionally  $E_T^{\text{miss}} > \max(100 \text{ GeV}, 0.2M_{\text{eff}})$  and  $M_{\text{eff}} > 800$  GeV. Despite limited statistics the results show that the PJTF approach provides reduced event selection bias in comparison with the naive ATLFAST simulation.

## 4.2 Fast GEANT4 simulation

**Introduction** The simulation of the ATLAS detector is currently based on GEANT4 v.4.8.3 [2]. GEANT4 simulation is very time consuming however and so its use for QCD background simulation at moderate or low  $p_T$  is not viable. The fully GEANT4-based approach (referred to as full simulation in the following) is especially slow in the simulation of electromagnetic cascades in the calorimeters due to their complicated geometry. A fast simulation tool (ATLFAST [15]) based on Gaussian smearing is also available, and is used for studies of systematic uncertainties elsewhere in this note, but it does not reproduce with sufficient accuracy the tails of distributions interesting for SUSY analysis, i.e.  $E_T^{\text{miss}}$  or  $M_{\text{eff}}$ . For this reason, an intermediate approach to the simulation of the ATLAS detector, based on the parameterisation of the calorimeters’ response, is under study [29]. In the so-called ‘fast’ GEANT4 simulation, electrons entering the calorimeters may receive different treatments according to their energy. For high energy particles a shower parameterisation is used while for medium energy particles (below 1 GeV) the detector response is taken from a shower library (“frozen showers”), and low energy particles (below 10 MeV) are “killed” by depositing their energy in a single spot in the calorimeter.

**Performance** We tested fast GEANT4 simulation algorithms by simulating PYTHIA [7] dijet events with moderate transverse momentum ( $280 \text{ GeV} < p_T < 560 \text{ GeV}$ ). The fast GEANT4 simulation can be performed using different options, which differ in the treatment applied to electromagnetic particles (shower parameterization, frozen showers or “killing”) in different parts of the calorimeters (for more details,

see [29]). In the following, the fast GEANT4 options are numbered from 1 to 3, the first one being the most conservative option, i.e., the closest to full simulation, and the third one the fastest option currently available. The measured fast GEANT4 simulation time is  $\sim 60\%$  lower than that required for full simulation. The three fast GEANT4 options differ among themselves by only a few percent of the full simulation time. To study the effect of the fast GEANT4 simulation algorithms in SUSY searches, we compared the distributions of typical quantities, i.e. the jet multiplicity and transverse momentum,  $E_T^{\text{miss}}$ , transverse sphericity, and effective mass in 5000 fast GEANT4 simulated events with the ones obtained from full simulation (see Figs. 16, 17 and 18). We reconstructed jets with  $p_T > 50$  GeV and  $|\eta| < 2.5$ . Due to the limited number of Monte Carlo events, no requirement was applied to the jet multiplicity, except in the  $E_T^{\text{miss}}$  and  $M_{\text{eff}}$  distributions, where the standard SUSY jet cuts described in Section 1 were applied. Transverse sphericity and effective mass quantities were calculated only for events with at least 2 jets.

Whilst the largest jet transverse momentum is well reproduced in the fast simulated samples, the average jet multiplicity is lower than that of the fully simulated sample by 1-2%. The most conservative sample (option 1) is in agreement with the full simulation distribution inside the statistical uncertainty. The width of the jet  $p_T$  resolution is consistent across the samples, however the jet energy scale is too low by 1-2% (see Fig. 17). Due to the limited number of events available only a qualitative comparison is possible in regions of interest for SUSY searches for  $E_T^{\text{miss}}$  (higher than 100 GeV) and transverse sphericity (larger than 0.2). Within the statistical precision possible the fast simulated distributions agree well with those obtained from full GEANT4 simulation. The size of the available samples preclude a full assessment of performance for the baseline SUSY cuts described in the introduction, since no events pass all cuts when using any of the three options. Similarly, from an equivalent number of GEANT4-simulated events, none pass all the cuts.

Figure 16: Reconstructed jet multiplicity (left) and highest jet  $p_T$  (right) for PYTHIA dijet samples simulated with different options. The statistical uncertainty only is shown for the full simulation sample.

Overall, the fast GEANT4 simulation has been shown to be a promising faster alternative to the full GEANT4 based simulation. The reconstructed quantities in fast GEANT4 simulated samples are in good agreement with full simulation. Work is on-going to further reduce the simulation time, and to improve the modeling of the jet energy scale.

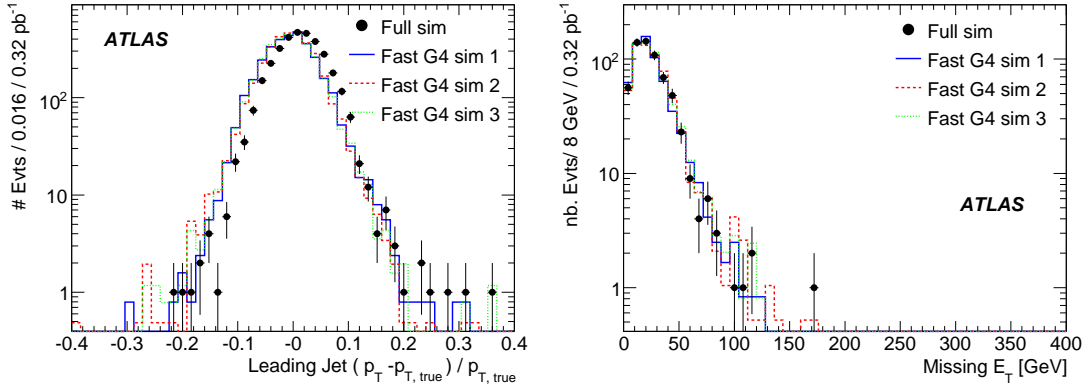

Figure 17: Leading jet  $p_T$  resolution (left) and  $E_T^{\text{miss}}$  (right) for PYTHIA dijet samples simulated with different options. The statistical uncertainty only is shown for the full simulation sample.

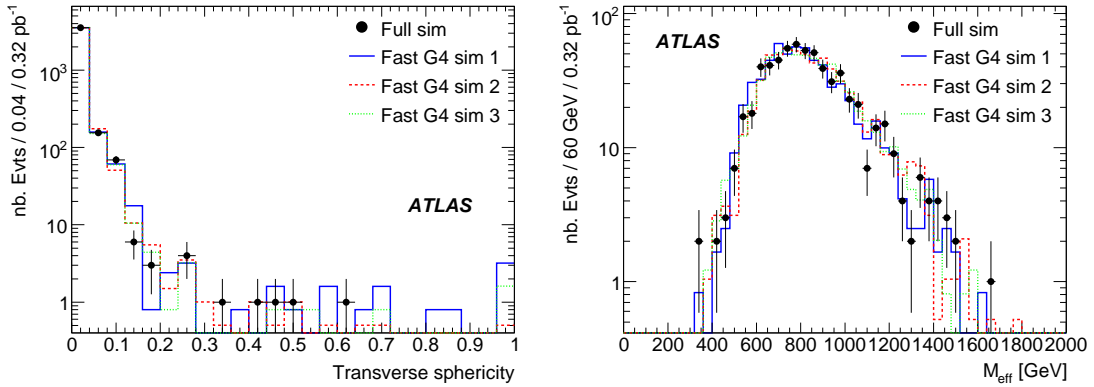

Figure 18: Transverse sphericity (left) and  $M_{\text{eff}}$  (right) for PYTHIA dijet samples simulated with different options. The statistical uncertainty only is shown for the full simulation sample.

## 5 Data-driven estimates

### 5.1 Jet smearing in the zero-lepton mode

**Introduction** The inherent systematic and statistical uncertainties in Monte Carlo based QCD background estimates will limit their use until sufficient data have been acquired to understand both the ATLAS detector and the underlying physics of QCD processes at 14 TeV. For this reason data-driven background estimates with minimal reliance on Monte Carlo simulation will be a priority for the early phase of data-taking.

The method described in this section reduces dependence on Monte Carlo simulation by smearing jet transverse momenta in low  $E_T^{\text{miss}}$  QCD multijet data with a data-measured jet response function  $R$  defined as the distribution of event-by-event ratios of measured jet  $p_T$  to true jet  $p_T$ . This response function could potentially be used inter-changeably with the Monte Carlo-truth derived Particle Jet Transfer Function (PJTF) discussed in Section 4.1. Consequently the method described below provides a route to practical realisation of the PJTF technique for use with real data. The technique can be broken down into three distinct parts which are outlined below.

**Step 1: Gaussian response function measurement** The “ $E_T^{\text{miss}}$  projection method” [30] applied to  $\gamma$  + jet events allows a measurement of the Gaussian response  $R^G$  of the ATLAS calorimeters to jets. The limited number of events prevent the measurement of the non-Gaussian tail with this technique (see Step 2). The method uses transverse momentum conservation to constrain the  $p_T$  of all activity associated with a reconstructed jet with the  $p_T$  of a hard photon.  $R^G$  is obtained from the distribution of the photon-jet  $p_T$  balance  $R_1$ :

$$R_1 = 1 + \frac{\mathbf{p}_T^{\text{miss}} \cdot \mathbf{p}_T(\gamma)}{|\mathbf{p}_T(\gamma)|^2}, \quad (4)$$

where  $\mathbf{p}_T(\gamma)$  is the photon transverse momentum, and  $\mathbf{p}_T^{\text{miss}}$  is the missing-transverse-momentum two-vector.

A GEANT4-simulated PYTHIA [7] sample equivalent to  $23.8 \text{ pb}^{-1}$  of  $\gamma$  + jets events was used, with events required to pass a 60 GeV single-photon trigger [9]. With the additional requirement that events should contain one and only one reconstructed jet, the jet response was measured with the distribution of  $R_1$  values defined above. The  $R_1$  distribution was measured in a number of photon  $p_T$  bins, and each was fitted with a Gaussian function. The standard deviations from these fits to the response distributions are shown in Fig. 19 with the statistical error bars derived from the fit errors. The  $p_T$  dependence of the widths of the  $R_1$  distributions was fitted with the parametric form

$$\sigma_R = A + \frac{B}{\sqrt{p_T}} + \frac{C}{p_T}, \quad (5)$$

shown in the figure to describe well the GEANT4 simulated data. The sampling ( $A$ ) and stochastic ( $B$ ) terms in the above formula were used to calculate the width of  $R^G$  as a function of jet  $p_T$ , while the constant term ( $C$ ) was used to estimate the additional smearing of  $E_T^{\text{miss}}$  not associated with jets (see Step 3 below).

Figure 19: Standard deviations of Gaussian fits to measured response distributions vs.  $p_T^\gamma$ . The fit is of the functional form  $\sigma_R(p_T) = A + Bp_T^{-1/2} + Cp_T^{-1}$ .

**Step 2: Full (Gaussian + non-Gaussian) response function measurement** In order to reproduce the tail of the QCD multijet  $E_T^{\text{miss}}$  distribution it is necessary to characterise the non-Gaussian response of the calorimeters to jets. The next stage in the technique therefore uses events in which the  $E_T^{\text{miss}}$  vector can be unambiguously associated in  $\phi$  with a single jet  $J$  to measure that response. The response of the

ATLAS calorimeters to jet  $J$  if its  $p_T$  lies in the non-Gaussian tail can be obtained from

$$R_2 = \frac{\mathbf{p}_T(J) \cdot \mathbf{p}_T(J, \text{true})}{|\mathbf{p}_T(J, \text{true})|^2}, \quad (6)$$

where  $\mathbf{p}_T(J)$  denotes the reconstructed transverse momentum of jet  $J$ . If it is assumed that the  $E_T^{\text{miss}}$  in these events is dominated by fluctuations in  $\mathbf{p}_T(J)$  then  $\mathbf{p}_T(J, \text{true})$  can be approximated by

$$\mathbf{p}_T(J, \text{true}) \simeq \mathbf{p}_T(J) + \mathbf{p}_T^{\text{miss}}. \quad (7)$$

The non-Gaussian response of ATLAS,  $R^{NG}$ , is measured with the distribution of event  $R_2$  values.

QCD jet events from the sample described in Section 2.1 were required to pass one of the high- $p_T$  multijet or  $E_T^{\text{miss}}$  triggers [9], and required to contain at least three jets with  $p_T > 250, 50$  and  $25$  GeV, respectively. Events were also required to possess  $E_T^{\text{miss}} > 60$  GeV. Events were further required to contain a jet unambiguously associated with the  $E_T^{\text{miss}}$  vector - i.e. events with one and only one jet parallel or anti-parallel to the  $E_T^{\text{miss}}$  vector. Of the remaining jets in each event, the two with the highest  $p_T$  were required to have  $p_T > 250, 50$  GeV. In this way, the selected events predominantly had a ‘Mercedes’ type configuration, with  $E_T^{\text{miss}}$  parallel or anti-parallel to the  $p_T$  of one of the jets. The  $p_T$  of this jet was used in Eqn. 6 to measure  $R_2$ . The estimate of the jet response non-Gaussian tail  $R^{NG}$  obtained from the distribution of  $R_2$  values is plotted as the histogram in Fig. 20(right) with a normalisation obtained with the procedure described below. Although not considered in detail here, the  $W(\rightarrow \tau\nu) + 2$  jet background could have been removed with a cut on the multiplicity of inner detector tracks per jet.

Next we combine the Gaussian and non-Gaussian components of the jet response  $R$  measured previously. The relative normalisation of the Gaussian ( $R^G$ ) and non-Gaussian ( $R^{NG}$ ) components can be measured using the balance of transverse momenta of jets in dijet events. The relative normalisation can be obtained from the ratio of the numbers of dijet events with respectively one and zero jets with  $p_T$  lying in the non-Gaussian tail of the jet response function. We therefore need to define a variable which can classify dijet events according to the number of jets with  $p_T$  lying in the non-Gaussian tail. A suitable variable is provided by  $R_3(j)$ , defined as the projection of the transverse momentum of each jet  $j'$  in the event onto the event  $E_T^{\text{miss}}$ :

$$R_3(j) = 1 + \frac{\mathbf{p}_T^{\text{miss}} \cdot \mathbf{p}_T(j')}{|\mathbf{p}_T(j')|^2}, \quad (8)$$

which measures the response to the other jet  $j$  in the event (cf. Eqn. 4). If  $R_3(j)$  lies below some threshold then jet  $j$  can be considered to lie in the non-Gaussian tail.

Events were selected from the QCD jet event sample used above with the requirement that they passed a 160 GeV single-jet trigger requirement [9] and contained two and only two jets, back-to-back in the transverse plane. The distribution of  $R_3(j)$  for these events is plotted as data-points in Fig. 20(right). The ratio of the integral of the low tail of the  $R_3(j)$  distribution to the integral of a Gaussian function fitted to the peak is used to obtain the relative normalisation of the non-Gaussian and Gaussian components of the jet response function. The full jet response function including normalised Gaussian and non-Gaussian components is plotted in Fig. 20 (left).

As a ‘closure test’ of the reconstruction of the full response function, jets in a subset of the selected dijet events with low  $E_T^{\text{miss}}$ -significance (see Section 2.1) were smeared to reproduce the  $R_3(j)$  distribution. The resulting distribution is shown in Fig. 20 (right) for comparison with ‘data’.

**Step 3: Seed event selection and jet  $p_T$  smearing** In order to estimate the  $E_T^{\text{miss}}$  and  $M_{\text{eff}}$  distributions of QCD multijet events the jet response function  $R$  measured in Step 2 was used to smear jet transverse momenta in multijet events with low  $E_T^{\text{miss}}$  (referred to below as ‘seed events’). Seed events were

Figure 20: Left – smearing function for a jet of 250 GeV (thick line), with Gaussian and non-Gaussian components (right and left facing hatches respectively) shown separately. Right – dijet balance distribution (points) compared with the equivalent estimated distribution obtained from the jet response function to provide a ‘closure test’ of the technique. Also shown are a Gaussian fit to the region  $0.8 < R_3(j) < 1.15$  (thick line), and the non-Gaussian tail distribution (dashed histogram) measured with ‘Mercedes’ events normalised to the tail of the dijet balance distribution.

selected from the same PYTHIA jet sample used in Step 2. Seed event candidates were required to pass one of the ATLAS high- $p_T$  jet triggers [9] together with the standard SUSY jet selection cuts described in Section 1 with a reduced jet  $p_T$  threshold ( $p_T(j_i) > 45$  GeV for  $i = 2, 3, 4$ ) in order to avoid biasing the final estimate after smearing. Both the  $E_T^{\text{miss}}$  significance (see Section 2.1) and the equivalent quantity constructed from  $E_T^{\text{miss}}$  derived only from in-cone jet energy were required to be less than  $0.5 \text{ GeV}^{1/2}$  and  $0.7 \text{ GeV}^{1/2}$ , respectively. The latter of these two cuts ensures that the hadronic activity in the selected seed events is well contained in the jets that will be smeared.

Smeared events were constructed from each selected seed event by smearing the transverse momenta of their constituent jets with the jet response function  $R$  determined in Step 2. The  $E_T^{\text{miss}}$  of smeared events was calculated by replacing the contribution to the  $E_T^{\text{miss}}$  from the  $p_T$  of seed jets with a contribution from the  $p_T$  of the equivalent smeared jets. An additional contribution  $\mathbf{p}_{T,C}^{\text{miss}}$  to  $\mathbf{p}_T^{\text{miss}}$  generated by the constant term measured in Step 1 was also taken into account. The smeared  $E_T^{\text{miss}}$  was therefore given by the magnitude of

$$\mathbf{p}_T^{\text{miss}'} = \mathbf{p}_{T,C}^{\text{miss}} - \sum_i \mathbf{p}_T'(j_i) + \sum_i \mathbf{p}_T(j_i), \quad (9)$$

where primed quantities are smeared.

Fig. 21 shows the  $E_T^{\text{miss}}$  and  $M_{\text{eff}}$  distributions for  $23.8 \text{ pb}^{-1}$  of GEANT4 simulated ‘data’ and smeared seed events passing the SUSY jet cuts listed in Section 1. The estimate was normalised to GEANT4 simulated PYTHIA QCD jet events (‘data’) with  $E_T^{\text{miss}} < 50$  GeV and somewhat tighter jet cuts ( $p_T(j_4) > 60$  GeV) imposed to ensure a reasonable sample of ‘data’ events obtained with the multi-jet triggers [9].

The dominant sources of systematic uncertainty in the estimate were  $p_T$  bias in the selection of events and finite statistics in the non-Gaussian tail measurement. Uncertainties on the  $A$ ,  $B$ , and  $C$  parameters in Eqn. 5 and the relative normalisation of the Gaussian and non-Gaussian parts of the jet response function were also considered.

Good agreement can be seen between the estimated and GEANT4 ‘data’  $E_T^{\text{miss}}$  and  $M_{\text{eff}}$  distributions. Applying the full SUSY cuts described in Section 1,  $2.36 \pm 0.09$  (stat)  $\pm 1.44$  (syst) events are estimated versus 1 ‘observed’. The uncertainty in the estimate is therefore  $\sim 60\%$  for  $23.8 \text{ pb}^{-1}$ . If these figures

Figure 21:  $E_T^{\text{miss}}$  (left) and  $M_{\text{eff}}$  (right) distributions for smeared events and GEANT4 ‘data’ passing 0-lepton SUSY jet cuts. Also included for comparison are 23.8 pb<sup>-1</sup> of SUSY (SU3) and the summed contribution from  $Z \rightarrow \nu\bar{\nu} + \text{jets}$ ,  $W \rightarrow \ell\nu + \text{jets}$  and  $t\bar{t} + \text{jets}$ .

are extrapolated to 1 fb<sup>-1</sup> then the equivalent calculated uncertainties are  $\sim 0.6\%$  (stat.) and 12.6% (syst.), with the systematic uncertainty reduced through access to increased statistics at step 2. However, residual Standard Model (e.g.  $W(\rightarrow \tau\nu) + 2 \text{ jets}$ ) contamination of the ‘Mercedes’ control sample has not been included in these uncertainty estimates and therefore we conservatively assume the same 60% systematic uncertainty for 1 fb<sup>-1</sup> of data. Systematic bias in the background estimate caused by the presence of SUSY signal is expected to be small – in particular the fractional contribution of SUSY events to the  $E_T^{\text{miss}}$  normalisation region is  $\lesssim 10^{-4}$ .

## 5.2 Lepton isolation in the one-lepton mode

**Introduction** Although QCD multijet background is not expected to be significant after application of SUSY signal cuts in the 1-lepton mode [5], it still must be estimated. This will be particularly important when preparing control samples for data-driven background estimates of other backgrounds; it is important to ensure that such samples (which will have looser cuts than the final SUSY selection) are not significantly contaminated by QCD background. The technique studied here is also relevant for QCD backgrounds in other lepton+jets channels, such as  $W(\rightarrow l\nu) + \text{jets}$  or  $t\bar{t}$  in the semileptonic channel, although the kinematic cuts used in searches for Supersymmetry (e.g. lepton +  $E_T^{\text{miss}}$  transverse mass,  $M_T > 100 \text{ GeV}$ ) might select different background mechanisms.

The method, which has been used at the Tevatron, relies on the (near) independence of  $E_T^{\text{miss}}$  and lepton isolation. The shape of the  $E_T^{\text{miss}}$  distribution is estimated from multijet events containing a non-isolated lepton. This distribution is then normalized to the number of events containing an isolated lepton, but with low  $E_T^{\text{miss}}$ . The method, if valid, would be complementary to the jet-smearing technique described in Section 5.1 applied to one-lepton events, thereby allowing an important crosscheck of the systematic uncertainties of the two methods.

In evaluating this method, it is important to understand potential correlations between isolation and  $E_T^{\text{miss}}$ . One possible mechanism can arise when there are multiple sources of leptons in QCD multijet events; if the sources each have a different  $E_T^{\text{miss}}$  shape, and the relative mixture of the sources changes with lepton isolation, this will appear as a correlation between  $E_T^{\text{miss}}$  and isolation. A possible example involves electrons arising from jet mis-identification and electrons from heavy-flavour decay. Another example might involve leptons from charm versus leptons from bottom quark decays. Another possible

source of correlation arises from the kinematics of the heavy quark itself; the  $p_T$  of the lepton, the associated neutrino, and the remainder of the heavy quark fragmentation (which will be related to the isolation) are all coupled.

Preliminary indications from studies of GEANT4 simulated QCD dijet samples suggest that the primary source of electrons is a jet faking an electron, while the muon case is dominated by the decay of  $B$  hadrons. Thus the issue of multiple background sources alluded to above is not a serious concern according to these Monte Carlo studies, but should be kept in mind for real data.

We first study the applicability of the lepton isolation technique in a pure sample of  $b\bar{b}$  + jets. We then move to a more realistic sample containing a mixture of  $t\bar{t}$  and  $W$  + jets events in addition to the  $b\bar{b}$  + jets sample, focussing on the muon channel. The dominant systematic is found to be contamination of control samples by  $t\bar{t}$  events.

Figure 22: Points:  $E_T^{\text{miss}}$  distribution for the non-isolated lepton sample. Histogram:  $E_T^{\text{miss}}$  distribution for the isolated lepton sample. The two distributions have been normalized to the same area in the region  $E_T^{\text{miss}} = [10, 20]$  GeV.

**Lepton isolation versus  $E_T^{\text{miss}}$  for  $b\bar{b}$  + jets** The dependence of  $E_T^{\text{miss}}$  on lepton (e,  $\mu$ ) isolation was studied with a sample of  $b\bar{b}$  + jets events generated with ALPGEN [27], corresponding to an integrated luminosity of about  $200 \text{ pb}^{-1}$ . At the event generator level, one of the  $b$  quarks was forced to undergo semileptonic decay to  $e$  or  $\mu$ ; also applied at the event generator level were filters requiring true  $E_T^{\text{miss}} > 30 \text{ GeV}$ , four or more truth jets with  $p_T > 40 \text{ GeV}$ , a leading truth jet with  $p_T > 80 \text{ GeV}$  and truth lepton with  $p_T > 10 \text{ GeV}$ . In the offline analysis, the events were required to satisfy the SUSY jet cuts described in Section 1. The events were required to have one and only one lepton with  $p_T$  greater than  $20 \text{ GeV}$ , where the lepton could be either an electron or muon. Events with additional leptons (with  $p_T > 10 \text{ GeV}$ ) were rejected.

A (non-isolated) control sample was defined by the requirement  $E_T^{\text{cone}} = [10, 20] \text{ GeV}$ , where  $E_T^{\text{cone}}$  is the  $E_T$  inside an  $\eta - \phi$  cone of radius  $0.2$  centered around the lepton, excluding the lepton  $p_T$ . The (isolated) signal sample was defined as  $E_T^{\text{cone}} < 10 \text{ GeV}$ . The  $E_T^{\text{miss}}$  distribution of the control sample was normalized in the region  $E_T^{\text{miss}} = [10, 20] \text{ GeV}$  to the signal sample. This normalized  $E_T^{\text{miss}}$  distribution was used to estimate the  $E_T^{\text{miss}}$  distribution for isolated leptons. Fig. 22 shows the  $E_T^{\text{miss}}$  distribution for the isolated and non-isolated samples. The agreement is good, suggesting that the correlation between  $E_T^{\text{miss}}$  and lepton isolation in  $b\bar{b}$  + jets events is small.

It is also apparent from Fig. 22 that the absolute level of background is low, even though typical SUSY selection cuts on  $E_T^{\text{miss}}$ , transverse mass and effective mass (typically  $E_T^{\text{miss}} > 100$  GeV,  $M_T > 100$  GeV, and  $M_{\text{eff}} > 800$  GeV) have not yet been applied. We will return to this point later. The  $M_{\text{eff}}$  distribution after the jet and lepton selection cuts is shown in Fig. 23(left). Ideally, one would like to demonstrate that the lack of correlation between lepton isolation and  $E_T^{\text{miss}}$  still holds even after the other SUSY selection cuts, such as those on  $M_T$  and  $M_{\text{eff}}$ , have been applied. This was not possible in this study with fully simulated data due to the limited number of events available.

Figure 23: Left: distribution of the effective mass in the  $b\bar{b}$  +jets sample after the jet and lepton selection cuts. Right:  $E_T^{\text{miss}}$  distributions for  $t\bar{t}$  isolated muon sample (black filled circle),  $t\bar{t}$  non-isolated muon sample (red filled square),  $W$  + jets isolated muon sample (black open circle),  $W$  + jets non-isolated muon sample (black open square),  $b\bar{b}$  isolated muon sample (blue open triangle),  $b\bar{b}$  non-isolated muon sample (magenta filled triangle).

**Contamination from  $W$  + jets and  $t\bar{t}$**  An important systematic effect comes from the contamination of the control samples by  $W$  + jets and  $t\bar{t}$  events. This was studied with fast simulation samples which had no generator-level cuts. The sample sizes corresponded to integrated luminosities of approximately  $200 \text{ pb}^{-1}$ ,  $6 \text{ fb}^{-1}$  and  $3 \text{ fb}^{-1}$  for  $b\bar{b}$  + jets,  $t\bar{t}$  and  $W$  + jets, respectively. The  $E_T^{\text{miss}}$  distribution, after the event selection cuts described above is shown in Fig. 23(right) for the  $b\bar{b}$ ,  $t\bar{t}$  and  $W$  + jets samples for isolated and non-isolated muons defined as above. Looking first just at the  $b\bar{b}$  events, there is good agreement in the shape of the  $E_T^{\text{miss}}$  distribution for the isolated and non-isolated samples; this reinforces the findings from the GEANT4-simulated  $b\bar{b}$  + jets samples on the independence of muon isolation and  $E_T^{\text{miss}}$ . It is also clear that the non-isolated sample is dominated by  $b\bar{b}$  at low  $E_T^{\text{miss}}$ . However, the  $E_T^{\text{miss}}$  tail is dominated by  $t\bar{t}$  and  $W$  + jets events, even in the non-isolated sample.<sup>4</sup> This implies that the shape of the  $E_T^{\text{miss}}$  distribution in the control sample will be distorted by the high  $E_T^{\text{miss}}$  tail. It is possible to increase the number of  $b\bar{b}$  events in the control sample by further loosening the isolation requirement, however this has the disadvantage of extrapolating into the isolated signal region over a large range, which could be susceptible to correlations between isolation and  $E_T^{\text{miss}}$ . Furthermore, even if the isolation requirement in the control sample were successfully loosened, there is the problem of normalization. In the isolated sample,  $t\bar{t}$  and  $W$  + jets completely dominate, even at very low  $E_T^{\text{miss}}$ ; this means that the normalization of the  $E_T^{\text{miss}}$  distribution will be distorted when extrapolating from the control to the signal region.

One might consider correcting the event yields in the control regions for the presence of  $t\bar{t}$  and  $W$  + jets events. An early CDF  $t\bar{t}$  cross-section analysis from Run2 [31] made corrections based on an assumed  $t\bar{t}$  cross-section. D0 [32] used the so-called “matrix method” where additional input on the

<sup>4</sup>As an added complication the shape of this tail will change after the application of the  $M_T$  cut which selects primarily dileptonic  $t\bar{t}$  decays.

efficiency for  $t\bar{t}$  and  $b\bar{b}$  events to pass the isolation cuts was used to extract the multijet background. The utility of these methods for the SUSY search could be further studied.

Despite the limitations of the technique in the presence of  $t\bar{t}$  and  $W + \text{jets}$  events background it should be noted that this study also indicates that QCD backgrounds are unlikely to be dominant in the 1-lepton channel. Even with application of just the standard SUSY 4-jet and lepton selection cuts, the QCD multijet background in the 1-lepton channel is significantly smaller than the  $t\bar{t}$  and  $W + \text{jets}$  backgrounds and applying the remaining SUSY selection cuts further suppresses the QCD multijet background. Consequently in the baseline analysis the accuracy of QCD multijet background estimates is less important than that of the estimates other backgrounds described in Ref. [4]. It should be kept in mind however that for some background studies the jet or lepton selection cuts may be further loosened, in which case the the lepton isolation technique might be applicable without the problem of contamination from other backgrounds.

Figure 24: Black circles:  $E_T^{\text{miss}}$  distribution for  $t\bar{t}$  plus  $W + \text{jets}$  samples where the lepton is non-isolated ( $E_T^{\text{cone}} = [10, 20]$  GeV). Histogram:  $E_T^{\text{miss}}$  distribution for  $t\bar{t}$  plus  $W + \text{jets}$  samples with isolated leptons ( $E_T^{\text{cone}} < 10$  GeV).

**Upper limit on  $E_T^{\text{miss}}$  distribution for  $b\bar{b} + \text{jets}$**  If the multijet background is large compared to the background from  $t\bar{t}$  (either because the existing Monte Carlo simulation happens to underestimate the contribution or because the selection cuts were further loosened), then issues of  $t\bar{t}$  contamination will become negligible and the methods described in the previous sections should work well to estimate the multijet background. On the other hand, if the multijet background is small compared to  $t\bar{t}$  as expected, one can obtain the  $E_T^{\text{miss}}$  distribution from the control region ( $E_T^{\text{cone}} = [10, 20]$  GeV) as an upper limit on the multijet background; the (reasonable) assumption here (confirmed in Monte Carlo) is that the  $E_T^{\text{cone}}$  distribution for multijet background is flat (or falling) as  $E_T^{\text{cone}}$  approaches zero. After the  $M_T$  cut, this control region is expected to be dominated by  $t\bar{t}$  and  $W + \text{jets}$  events containing non-isolated leptons with the QCD multijet contribution playing only a very small role. Thus this will be an upper limit on the multijet background, but the number of events so obtained will in any case be many fewer than from the main  $t\bar{t}$  and  $W + \text{jets}$  backgrounds (with isolated leptons) and so are likely to be negligible.

The contribution from  $b\bar{b} + \text{jets}$  has been compared to GEANT4-simulated ALPGEN  $t\bar{t}$  and  $W + \text{jets}$  samples (corresponding to integrated luminosities of about  $3 \text{ fb}^{-1}$ ). In addition to the event selection cuts listed above (jet and lepton selection), the events were required to have  $M_T > 100 \text{ GeV}$  and  $M_{\text{eff}} >$

800 GeV. The  $E_T^{\text{miss}}$  distribution for the sum of  $t\bar{t}$  and  $W + \text{jets}$  samples for events with non-isolated ( $E_T^{\text{cone}} = [10, 20]$  GeV) leptons is shown in Fig. 24; the contribution of  $b\bar{b} + \text{jets}$  cannot be seen compared to that from  $t\bar{t}$  plus  $W + \text{jets}$ . Furthermore, all contributions are negligible compared to the  $t\bar{t}$  plus  $W + \text{jets}$  background with isolated leptons. Counting the number of non-isolated  $t\bar{t}$  plus  $W + \text{jets}$  with  $E_T^{\text{miss}} > 100$  (200) GeV, one would find an upper limit on the multijet background in the lepton channel of  $10 \pm 2$  ( $5 \pm 1$ ) events for an integrated luminosity of  $1 \text{ fb}^{-1}$ . The true number of multijet background events would be estimated to be roughly an order of magnitude lower.

## 6 Summary

This paper has examined a wide range of techniques for estimating QCD backgrounds in searches for Supersymmetry at ATLAS. The focus of the paper has been on outlining the strategies which could be used and assessing the likely uncertainties associated with them. It is important to note that only by comparing uncorrelated results from a number of such independent techniques can a robust QCD background estimate be obtained.

Given the difficulty of obtaining accurate estimates of QCD jet backgrounds generating fake  $E_T^{\text{miss}}$  it will be essential to reduce this source of background using the techniques described in Section 2 and also the more general cuts described in Ref. [3]. The remaining backgrounds can be estimated using Monte Carlo (Section 3 and 4) or data-driven (Section 5) techniques.

All Monte Carlo based estimates will be subject to systematic effects arising from parton distribution and underlying event uncertainties (Section 3.1), likely to be of order 20% in each case for events satisfying the baseline SUSY cuts described in Ref. [5]. A jet energy scale uncertainty of 5% (Section 3.2) will contribute a further  $\sim 30\%$ . While the precision with which Monte Carlo generators model QCD jet physics at 14 TeV is difficult to assess prior to data-taking, the difference (Section 3.3) between a ‘traditional’ parton shower dijet estimate and that obtained from one of the newer matched matrix-element + parton-shower generators for the baseline SUSY cut set is of order 50% if an accurate normalisation to data can be obtained. To these effects must be added luminosity uncertainties ranging from 20–30% at start-up (from machine parameters) reducing to  $< 3\text{--}5\%$  (from total cross-section measurements and  $W/Z$  counting).

In addition to the above systematic effects, Monte Carlo simulation-based estimates will be subject to detector simulation uncertainties – due to the imperfect description of the response of ATLAS to QCD jets, and statistical uncertainties caused by the large QCD cross-section and access to finite computing resources. It is impossible to assess the accuracy of current full (GEANT4) or fast (ATLFAST, ‘fast G4’ – Section 4.2 or PJTF – Section 4.1) detector simulations without recourse to data, however the results of Section 4.1 suggest that uncertainties  $\sim 100\%$  in the understanding of the response of the ATLAS calorimeters to jets may lead to similar uncertainties in the background estimate.

Data-driven background estimates have the advantage that they are less prone to input systematics, and can in some cases benefit from large statistics in control channels used to measure detector performance. However, additional systematic uncertainties have to be considered due to the potential contamination of control samples with non-QCD events, and from relying on Monte Carlo simulation to extrapolate from the control into the signal region. The data-driven estimate for the jets +  $E_T^{\text{miss}}$  + 0-leptons channel described in Section 5.1 could potentially give a combined uncertainty of  $\lesssim 60\%$  for  $1 \text{ fb}^{-1}$  of integrated luminosity and the baseline SUSY cut set, although a precise figure is difficult to obtain without further Monte Carlo data. In the jets +  $E_T^{\text{miss}}$  + 1-lepton channel the QCD jet background is potentially far less significant, in which case the technique described in Section 5.2 is likely to generate a very conservative upper limit on the background a factor  $\sim 10$  above the true background for  $1 \text{ fb}^{-1}$ .

# Prospects for Supersymmetry Discovery Based on Inclusive Searches

## Abstract

This note describes searches for generic SUSY models with  $R$ -parity conservation in the ATLAS detector at the CERN Large Hadron Collider. SUSY particles would be produced in pairs and decay to the lightest SUSY particle,  $\tilde{\chi}_1^0$ , which escapes the detector, giving signatures involving jets, possible leptons, and  $E_T^{\text{miss}}$ . The integrated luminosity simulated is  $1 \text{ fb}^{-1}$ . This article relies on work published elsewhere in this collection, where the Standard Model backgrounds for SUSY are discussed.

## 1 Introduction

This note describes the search for generic SUSY with  $R$  parity, so that SUSY particles are produced in pairs and decay to the lightest SUSY particle,  $\tilde{\chi}_1^0$ , which escapes the detector, giving signatures involving jets, possible leptons and  $E_T^{\text{miss}}$ , an imbalance in the transverse energy measured in the detector. Most of the introductory information necessary to the understanding of this document is given in the introductory SUSY note [1], which should be read before this one. These include a brief description of the theoretical framework, a definition of the SUSY benchmark models SUn studied in the detailed analyses, a description of the Monte Carlo samples used for signal and background. Common identification criteria for jets, taus and leptons have been adopted throughout the analyses in this note, and are also described in [1] as well as the definition of a few global variables relevant for the analysis, such as effective mass ( $M_{\text{eff}}$ ), transverse mass ( $m_{T2}$ ) and transverse sphericity ( $S_T$ ). The background uncertainties used throughout this work are based on Standard Model background studies documented in [2, 3]. Special signatures associated, e.g., with Gauge Mediated SUSY Breaking are treated elsewhere [4].

Two different approaches have been used to develop the inclusive search strategy described here. Firstly, detailed studies have been carried out for various signatures (jets +  $E_T^{\text{miss}}$  + 0 leptons, jets +  $E_T^{\text{miss}}$  + 1 lepton, ...) using data-sets fully simulated with Geant 4 for specific SUSY signal parameters and for the relevant Standard Model backgrounds. These detailed studies are used to develop deeper understanding of how best to reconstruct these relatively complex events and to define strategies for separating the signal from the Standard Model backgrounds. In order to simplify the procedure of combining the results from the different analyses, the various leptonic signatures have been defined so that they are exclusive. For example the 1-lepton signature rejects all events in which more than one lepton is present. However, no attempt is made to combine the different analyses in the present document.

Secondly, the insight gained from studying specific points has been applied to several scans over subsets of the SUSY parameter space. Since large numbers of signal points must be studied, these scans are of necessity based on fast, parameterized simulation. The goal is to verify that the different sets of basic cuts studied on benchmark points provide sensitivity to a broad range of SUSY models. The results shown in this document will be used as a basis for the development of a strategy for SUSY discovery with early ATLAS data.

### 1.1 Trigger

The trigger efficiency for the inclusive SUSY signals at the benchmark points has been studied based on the complete simulation of all three trigger levels of ATLAS. For all the analyses we adopted the trigger thresholds defined for  $2 \times 10^{33} \text{ cm}^{-2} \text{ s}^{-1}$  in the High Level Trigger TDR [5]. These triggers are discussed

further elsewhere [6] in this volume, where a detailed explanation of the naming convention for the trigger menu items appearing in Table 1 can be found.

The jet triggers, denoted by “JETS”, consist of the logical “or” of the following triggers:

- j400: 1 jet with  $p_T > 400$  GeV;
- 3j165: 3 jets with  $p_T > 165$  GeV;
- 4j110: 4 jets with  $p_T > 110$  GeV.

The  $E_T^{\text{miss}}$  trigger “j70\_xE70”, requires  $E_T^{\text{miss}} > 70$  GeV accompanied by a jet with  $p_T > 70$  GeV. The lepton triggers are “e22i”: an isolated electron efficient for  $p_T > 25$  GeV; “2e12i”: two isolated electrons efficient for  $p_T > 15$  GeV, “mu20”: a muon with  $p_T > 20$  GeV and “2mu10”: two muons with  $p_T > 10$  GeV.

Since the goal of this note is to develop a generic SUSY search, only the basic trigger building blocks have been considered. More complex triggers combining different objects can be easily implemented in the trigger menus. Also, only triggers which are not prescaled have been used.

The trigger efficiencies for the signal events passing the the 0, 1, 2, and 3-lepton selections defined in the following sections are listed in Table 1 for different requirements on jet multiplicity. In general the j70\_xE70 is highly efficient, although there is some loss for SU4, the low-mass point with a very large cross-section. The j70\_xE70 trigger is also very efficient for the  $\tau$  and  $b$  modes, described in Sections 6 and 7 below.

The basic performance of the leptonic and j70\_xE70 triggers will be determined from Standard Model events such as  $Z$  and  $t\bar{t}$  using the methods described in [6]. It may be useful to check that performance by comparing (Monte Carlo) samples of SUSY events selected with multiple triggers. For the 0-lepton selection, the efficiency for JETS trigger alone is in the range 30-70%, except for the very low mass point SU4. This provides a useful redundancy in the early phases, as the  $E_T^{\text{miss}}$  trigger may require a longer time than the other triggers to be completely understood, but only j70\_xE70 has an efficiency close to one. For the topologies involving leptons, both the single lepton triggers and j70\_xE70 have typical efficiencies in excess of 80%, so comparing them should be quite effective.

## 1.2 Systematic uncertainties and statistical procedure

To assess the discovery potential of the different analyses it is necessary to take into account systematic uncertainties. SUSY searches will address very complex topologies, typically with many jets in the final state. The prediction of the Standard Model backgrounds to these topologies will require a complex interplay of Monte Carlo and data-driven methods. The development of these methods and the estimate of the corresponding uncertainties are described in detail in [2] and [3]. The approximate uncertainties for an integrated luminosity of  $1 \text{ fb}^{-1}$  are estimated to be:

- 50% for the background from QCD multijet events,
- 20% for the background from  $t\bar{t}$ ,  $W$  + jets,  $Z$  + jets, and  $W/Z$  pairs.

The limited Monte Carlo statistics is also taken into account and all systematic uncertainties are added in quadrature. The background can never be known exactly. Uncertainties on the background are incorporated in the significance by convoluting the Poisson probability that the background fluctuates to the observed signal with a Gaussian background probability density function with mean  $N_b$  and standard deviation  $\delta N_b$  (see e.g. [7, 8] and references therein). Given these assumptions, the probability  $p$  that the background fluctuates by chance to the measured value  $N_{\text{data}}$  or above is given by

$$p = A \int_0^\infty db G(b; N_b, \delta N_b) \sum_{i=N_{\text{data}}}^\infty \frac{e^{-b} b^i}{i!},$$

Table 1: Average event trigger efficiency (in %) for events passing various lepton and jet selection criteria described in detail in the indicated sections.

Trigger	SU1	SU2	SU3	SU4	SU6	SU8.1
	0-lepton, 4-jet selection [Section 2.1]

where  $G(b; N_b, \delta N_b)$  is a Gaussian and the factor

$$A = \left[ \int_0^\infty db G(b; N_b, \delta N_b) \sum_{i=0}^\infty e^{-b} b^i / i! \right]^{-1}$$

ensures that the function is normalised to unity. If the Gaussian probability density function  $G$  is replaced by a Dirac delta function  $\delta(b - N_b)$ , the estimator  $p$  results in a usual Poisson probability.

The probability  $p$  is transformed into “standard-deviations”, denoted in this note by the symbol  $Z_n$ , using the formula

$$Z_n = \sqrt{2} \operatorname{erf}^{-1}(1 - 2p)$$

The Root [9] library provides functions to calculate  $p$  and  $Z_n$ .

If many different data selections are considered, it becomes more likely that statistical fluctuations would be misinterpreted as new phenomena if the number of selections is not considered in the statistical

Table 2: Number of events surviving subsequent selection cuts as defined in the text for 4-jets analysis normalized to  $1\text{fb}^{-1}$  using NLO cross-sections.

procedure. This is known in statistics as the problem of “multiple comparisons”. The probability values are therefore corrected for multiple comparisons via a Monte Carlo method. The effect is the reduction of approximately half a unit of  $Z_n$  for  $Z_n = 3$ , decreasing with increasing  $Z_n$ . In the last section of the note the significance always corresponds to the corrected  $Z_n$ .

## 2 Zero-lepton mode

A SUSY signal at the LHC is typically dominated by the production of squarks and gluinos. In the  $R$ -parity conserving case, at the end of each sparticle decay chain one finds an undetected LSPs, which can together generate large  $E_T^{\text{miss}}$ . The least model-dependent SUSY signature is therefore the search for events with multiple jets and  $E_T^{\text{miss}}$ . Traditionally searches have been performed requiring at least four jets; the high multiplicity helps to reduce the background from QCD and  $W/Z + \text{jets}$ . Both for this topology and for the leptonic topologies in the following sections we adopt very simple sets of cuts, similar to the ones used in the ATLAS Physics TDR [10]. In addition to the four-jet signatures we have also addressed signatures with lower jet multiplicity. These signatures have more backgrounds, but might be favoured in some SUSY models, and should be more cleanly reconstructed in the detector, because of their less-complex topologies. This may be an advantage in the early phases of the experiment.

### 2.1 Four or more jets in final state

The basic selections applied for this channel are:

1. At least four jets with  $p_T > 50$  GeV at least one of which must have  $p_T > 100$  GeV; and  $E_T^{\text{miss}} > 100$  GeV.
2.  $E_T^{\text{miss}} > 0.2M_{\text{eff}}$ .

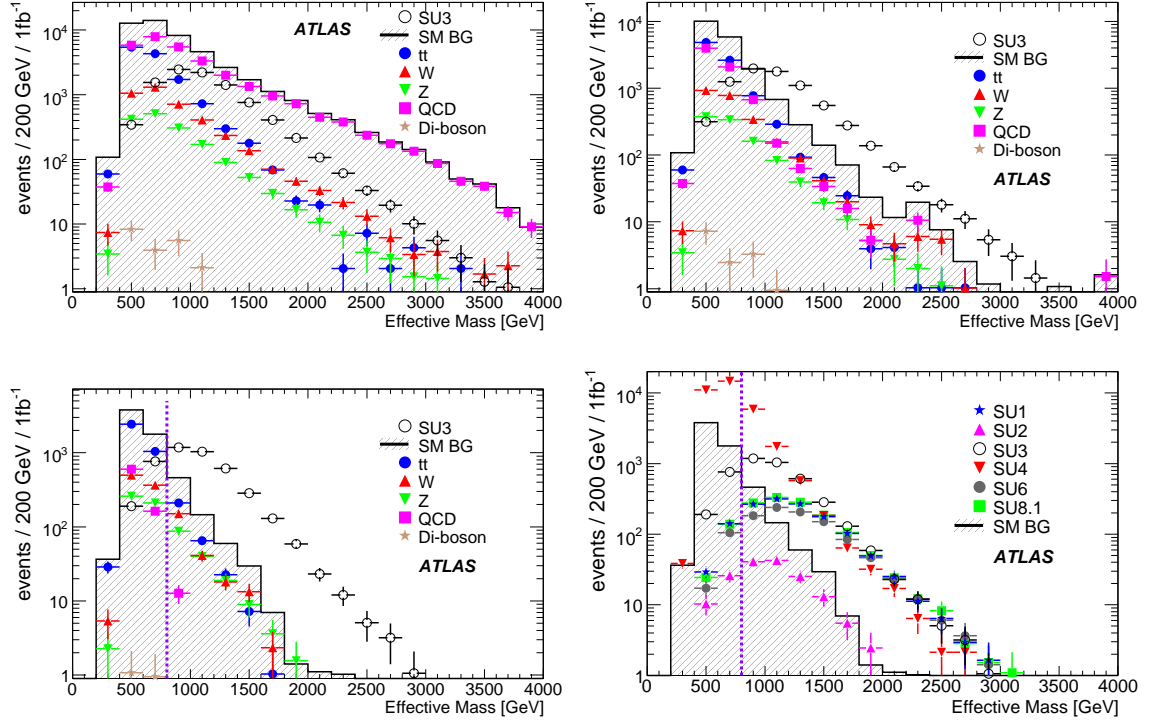

Figure 1:  $M_{\text{eff}}$  distribution for events surviving successive selection cuts: cut 1 (top left), cut 2 (top right), and cuts 3-5 (bottom left). The open circles represent point SU3, and the different background contributions are shown according to the legend. The last plot (bottom right) show all of the SUSY benchmark points and the total Standard Model background after cuts 1-5. Open circles represent the SUSY SU3 signal as predicted by Monte Carlo simulation, while the shaded area shows the total Standard Model background.

3. Transverse sphericity,  $S_T > 0.2$ .
4.  $\Delta\phi(\text{jet}_1 - E_T^{\text{miss}}) > 0.2$ ,  $\Delta\phi(\text{jet}_2 - E_T^{\text{miss}}) > 0.2$ ,  $\Delta\phi(\text{jet}_3 - E_T^{\text{miss}}) > 0.2$ .
5. Reject events with an  $e$  or a  $\mu$ .
6.  $M_{\text{eff}} > 800$  GeV.

Most of the background samples have been filtered at generation level with various requirements on  $E_T^{\text{miss}}$  and jet multiplicity. The first cut in the analysis flow applies harder requirements than any of the ones applied at the filter level to minimise the bias to the study from the use of filtered samples.

The main background at this point from QCD events where  $E_T^{\text{miss}}$  is produced either by a fluctuation in the measurement of the energy of one or more jets, or by a real neutrino from the decay of a  $B$  hadron produced in the fragmentation process. Since the statistical fluctuation on the  $E_T^{\text{miss}}$  measurement grow with increasing  $M_{\text{eff}}$ , the second cut above eliminates the Gaussian part of the  $E_T^{\text{miss}}$  measurement fluctuations. In SUSY events the jets are produced from the decay of heavy particles produced approximately at rest, and are thence distributed isotropically in space, whereas for the QCD events the direction of the two partons from the hard scattering provides a privileged direction. The cut on sphericity is intended to exploit this fact. Both for jet mismeasurement and for  $b$  decays, the  $E_T^{\text{miss}}$  vector will be close the direction of one jets, and so the  $\Delta\phi$  cuts are very efficient in reducing the QCD background. The lepton

veto is applied in order to facilitate the combination with analyses requiring leptons, but it is not expected to significantly modify the signal-to-background ratio.

The number of events surviving each of the cuts for an integrated luminosity of  $1 \text{ fb}^{-1}$  is shown in Table 2 for all of the considered benchmark points and for the backgrounds. The number of events in the last column includes the effect of the j70xE70 trigger, which, as shown in Table 1, has an efficiency in excess of 97% for all considered signal benchmarks.

The distribution of the final selection variable  $M_{\text{eff}}$ , for signal and background, is shown in Fig. 1 for point SU3 at different stages of the analysis. The QCD background is dominant after the first cut but is reduced to a similar level to the backgrounds containing real neutrinos by subsequently requiring  $E_{\text{T}}^{\text{miss}} > 0.2M_{\text{eff}}$  (cut 2). The cuts on event sphericity and  $\Delta\phi$  strongly reduce the QCD background, which becomes concentrated in the region of low  $M_{\text{eff}}$ . After all cuts  $t\bar{t}$  is the dominant background, but there are also significant contributions from  $W + \text{jets}$  and  $Z + \text{jets}$ . The final cut,  $M_{\text{eff}} > 800 \text{ GeV}$ , reduces the background to below the level of the signal for all considered benchmark points except for SU2. For this point to be found in the 0-lepton channel, one would have to select larger values of  $M_{\text{eff}}$  to enhance the signal-to-background ratio, and a greater integrated luminosity would be required.

The statistical significance  $Z_n$  for  $1 \text{ fb}^{-1}$  was calculated using the prescription in Section 1.2 including the systematic uncertainty on the background [2, 3]. The significance for point SU3 after each cut is shown in Table 2. The significances  $Z_n$  after all cuts are 13 for SU3, 6.3 for SU1, 0.9 for SU2, 25 for SU4, 6.3 for SU6, and 6.5 for SU8.1. Evidently only point SU2, for which the cross section is dominated by direct gaugino production (which is investigated elsewhere in this volume [11]), would not be accessible for the assumed set of cuts, integrated luminosity and level of background understanding.

These numbers should be taken as indicative. The uncertainty on the background used in the calculation is the estimate of what one would obtain using complicated procedures for background evaluation based on a combination of data-driven and Monte Carlo methods. The absolute value of the backgrounds used for this study is derived only from Monte Carlo, and the present uncertainty on this value is much higher. An idea of the robustness of the analysis can be obtained by studying the significance for the benchmark points if the background would be increased by a factor 2. In this case the significance for SU3 would drop to 7.8, and the one for SU6 to approximately 3.1. The significance for SU6 would be, in this situation, dominated by the systematic uncertainty on the background evaluation. Therefore an increase in integrated luminosity would result in an increased reach only if it can be used to reduce the uncertainty on the background evaluation.

## 2.2 Inclusive two-jet and three-jet final states

The analyses based on lower jet-multiplicities are based on very similar requirements to the 4-jet analysis above. The differences are: higher  $p_T$  requirements on the remaining jets to cope with the increased QCD background, and a slightly harder  $E_{\text{T}}^{\text{miss}}$  cut. The sphericity cut is less relevant in the case of low jet multiplicities and is dropped. For the two (three)-jet analysis the cuts are respectively:

1. At least two (three) jets, the hardest with  $p_T > 150 \text{ GeV}$  and the second (and third) with  $p_T > 100 \text{ GeV}$ ;  $E_{\text{T}}^{\text{miss}} > 100 \text{ GeV}$
2.  $E_{\text{T}}^{\text{miss}} > 0.3(0.25)M_{\text{eff}}$ .
3.  $\Delta\phi(\text{jet}_1 - E_{\text{T}}^{\text{miss}}) > 0.2$ ,  $\Delta\phi(\text{jet}_2 - E_{\text{T}}^{\text{miss}}) > 0.2$ ,  $(\Delta\phi(\text{jet}_3 - E_{\text{T}}^{\text{miss}}) > 0.2)$
4. Reject events with an  $e$  or a  $\mu$
5.  $M_{\text{eff}} > 800 \text{ GeV}$ .

The  $M_{\text{eff}}$  variable is different from the one defined in [1] in that only the 2(3) highest  $p_T$  jets for the 2–(3–)jet analysis are used.

Since the ALPGEN  $W$  + jets and  $Z$  + jets background samples have a filter at generation level requiring 4 jets, samples produced with the PYTHIA generator were used in this case.

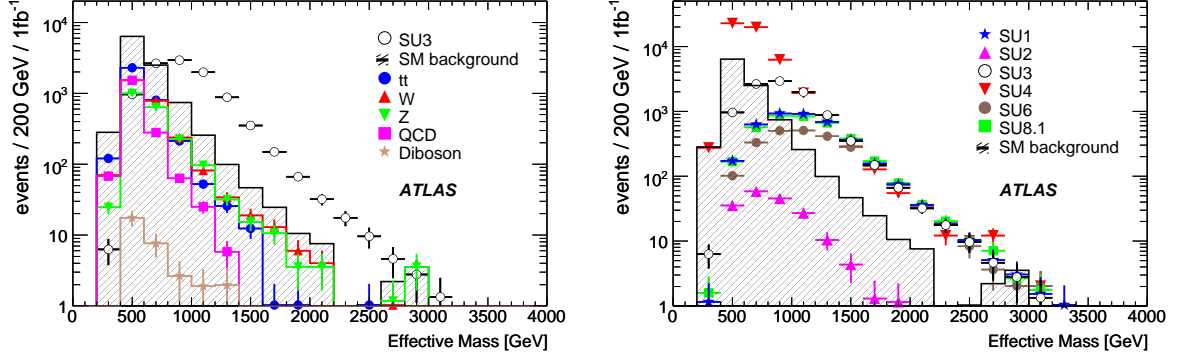

Figure 2:  $M_{\text{eff}}$  distribution for the 0-lepton plus 2-jet analysis, after final cuts. Left: The open circles show the SUSY (SU3) signal Monte Carlo prediction, while the total Standard Model background is shown by the shaded histogram. The individual background contributions are shown by the points, as described in the legend. Right: The points show the distribution of the signal for a number of SUn points.

Table 3: Number of events surviving the selection cuts defined in the text for the 2–jet analysis. Entries are normalized to  $1 \text{ fb}^{-1}$  using next-to-leading-order cross-sections.

Sample	Cut 1	Cut 2	Cut 3	Cut 4	$M_{\text{eff}}$ Cut

SU3 $S/B$	0.12	0.61	0.87	0.97	5.3
SU3 $S/\sqrt{B}$	47.5	87.7	103.2	98.6	185.2
SU3 eff (cum)	67.4%	45.2%	44.1%	36.3%	23.2%
SU3 eff (excl)	67.4%	67.1%	97.6%	82.3%	64.0%

The cut flow for the 2-jet analysis is given in Table 3, and the  $M_{\text{eff}}$  distributions before the  $M_{\text{eff}}$  cut for the different background contributions and for the different signal points are shown in Figure 2. The

number of events after all cuts includes the effect of the  $j70xE70$  trigger, which, as shown in Table 1, has an efficiency in excess of 99% for all considered SUSY benchmark points. After the  $\Delta\phi$  cuts the  $t\bar{t}$ ,  $W + \text{jets}$ ,  $Z + \text{jets}$  and QCD all give comparable contributions to the background. After all cuts the surviving events are approximately doubled both for signal and background, as compared to the 4-jet analysis, except for the low-mass SU4 points for which the harder kinematic cuts reduce the signal efficiency.

Assuming the estimated systematic background errors are the same as for the 4-jet case, the estimated significances are 13.3 for SU3, 8.0 for SU1, 17.2 for SU4, 5.5 for SU6, and 7.7 for SU8.1, for  $1 \text{ fb}^{-1}$  of integrated luminosity. The significance for SU2, for which direct gaugino production is dominant, is less than 1.0. The equivalent numbers for the 3-jet analysis are: 17.0 for SU3, 9.5 for SU1, 25.7 for SU4, 7.3 for SU6 and 9.6 for SU8. Although the signal over background ratio is equivalent or better (for the three-jet topology) than for the 4-jet analysis this is only partially reflected in the significances when the systematic uncertainty is taken into account. This is due to the increased contribution of the QCD background, which has an estimated uncertainty on QCD is of 50%, as compared to 20% for the other backgrounds. Therefore, since the uncertainties of the backgrounds were evaluated for a 4-jet analysis, a dedicated background study would be needed to obtain a correct estimate of the discovery potential in this topology.

The 2-, 3- and 4-jet analyses are based on very similar cuts and therefore have a large overlap in the selected events. About 40% of all 2-jet events are also contained in the 3-jet selection and about 35% in the 4-jet selection. The biggest overlap is for the 3 jet events: about 59% of all 3-jet events are also contained in the 4-jet analysis and about 97% in the 2-jet analysis.

An alternative strategy was explored where cuts 2 and 3 of the  $M_{\text{eff}}$  analysis are dropped, and a cut on the  $m_{T2}$  variable [12, 13],  $m_{T2} > 400 \text{ GeV}$ , is applied as the only discriminating observable. The  $m_{T2}$  variable, has the interesting properties that it takes low values for events where either the visible  $p_T$  or  $E_T^{\text{miss}}$  are small, and in the case of small  $\Delta\phi$ . It can therefore replace these topological cuts. For semi-invisibly decaying particles  $m_{T2}$  is related to the difference in mass between the particles produced in the interactions and their invisible decay products. It can therefore take a larger value for SUSY events than for top or  $W$  events. Taking the estimates of the systematic background errors into account, the significances for the 2-jet  $m_{T2}$  analysis are: 15.6 for SU3, 11.5 for SU1, 10.9 for SU4, 8.3 for SU6, and 11.1 for SU8.1, somewhat better than the equivalent analysis based on  $M_{\text{eff}}$ . The most effective strategy will be ultimately defined by how well the systematic uncertainty on the background evaluation can be controlled in the different approaches.

### 3 One-lepton mode

While the 0-lepton mode with multiple jets plus  $E_T^{\text{miss}}$  is probably the most generic search mode for SUSY with  $R$ -parity conservation, it is sensitive to backgrounds from mismeasured QCD multijet events. Requiring one lepton in addition to multiple jets and  $E_T^{\text{miss}}$  greatly reduces the potential QCD multijet background; the remaining backgrounds are under better control. Even if  $\tau$  decays of gauginos are dominant, leptonic  $\tau$  decays provide a significant 1-lepton rate, at least for high masses. It is not surprising, therefore, that the reach in the 1-lepton and 0-lepton modes are comparable.

The cuts in this analysis are similar to those used in the ATLAS Physics TDR [10] but also include a cut on the transverse mass<sup>1</sup>,  $M_T$ , formed from the lepton and  $E_T^{\text{miss}}$  which has the role of suppressing the  $W + \text{jets}$  and  $t\bar{t}$  backgrounds. The  $S_T$  cut is included for historical reasons, but its effectiveness is questionable:

---

<sup>1</sup>Note the distinction between the transverse mass,  $M_T$ , which is a function of the momentum of one visible particle and the missing transverse momentum and the *stransverse* mass which is a function of the momenta of two visible particles and the missing transverse momentum.

Table 4: Number of events surviving the selection cuts defined in the text for the 1-lepton analysis. Entries are normalized to  $1 \text{ fb}^{-1}$  using NLO cross-sections. The last column reports a simple  $S/\sqrt{B}$  calculation of the corresponding significance of an observation for the SUSY benchmark points (SUn).

Sample	Cuts 1–4	Cut 5	Cut 6	Cut 7	$S/\sqrt{B}$
SU1	571.7	423.0	259.9	232.3	36.0
SU2	86.7	75.6	46.1	39.6	6.1
SU3	995.7	767.9	450.5	363.6	56.4
SU4	7523.6	6260.4	2974.4	895.8	138.9
SU6	342.3	250.9	161.9	147.9	22.9
SU8.1	296.4	214.4	151.4	136.3	21.1
$t\bar{t}$	2028.5	1546.8	131.7	36.0	
$W$	425.2	314.8	9.9	5.4	
$Z$	39.0	27.3	1.7	0.2	
Diboson	7.3	5.1	0.8	0.0	
QCD	0.0	0.0	0.0	0.0	
Standard Model BG	2500.1	1894.0	144.1	41.6	

1. Exactly one isolated lepton with  $p_T > 20 \text{ GeV}$  satisfying the selection criteria described earlier.
2. No additional leptons with  $p_T > 10 \text{ GeV}$ . This ensures no overlap with the 0-lepton, 2-lepton, and 3-lepton analyses.
3. At least four jets with  $p_T > 50 \text{ GeV}$  at least one of which must have  $p_T > 100 \text{ GeV}$ .
4.  $E_T^{\text{miss}} > 100 \text{ GeV}$  and  $E_T^{\text{miss}} > 0.2M_{\text{eff}}$ .
5. Transverse sphericity,  $S_T > 0.2$ .
6. Transverse mass,  $M_T > 100 \text{ GeV}$ .
7.  $M_{\text{eff}} > 800 \text{ GeV}$ .

Cuts 1–2 define the 1-lepton analysis, while Cuts 3–4 both reduce the Standard Model backgrounds and ensure compatibility with the Standard Model filter cuts. Distributions without these four cuts are not meaningful and so are not shown. Cut 5 reduces the  $E_T^{\text{miss}}$  background from mismeasured dijet events; Cut 6 reduces the background from events in which the  $E_T^{\text{miss}}$  comes from  $W \rightarrow \ell\nu$ ; and Cut 7 selects high-mass final states.

The cut flow table for these cuts is shown in Table 4. The number of events after all cuts includes the effect of the j70xE70 trigger, which, as shown in Table 1, has an efficiency of around 99% for all the benchmark points considered other than the low mass SU4 point, for which the efficiency is still above 95%. Note that the QCD background is reduced to a negligible level by the lepton and  $E_T^{\text{miss}}$  cuts as expected. The background after all cuts is dominated by  $t\bar{t}$  and  $W + \text{jets}$ , both of which are expected to be better understood than the QCD background. Therefore, while the 1-lepton mode may not have better reach than the 0-lepton mode given the calculated backgrounds, its reach seems more robust against background uncertainties.

The  $M_{\text{eff}}$  distribution for point SU3 after each cut is shown in Figure 3. The  $E_T^{\text{miss}}$  and  $M_{\text{eff}}$  distributions for all the SUn points after all cuts are shown in Figures 4. It is clear from these figures and from Table 4 that the only significant backgrounds to the 1-lepton mode are from  $t\bar{t}$  and  $W + \text{jets}$ , as one

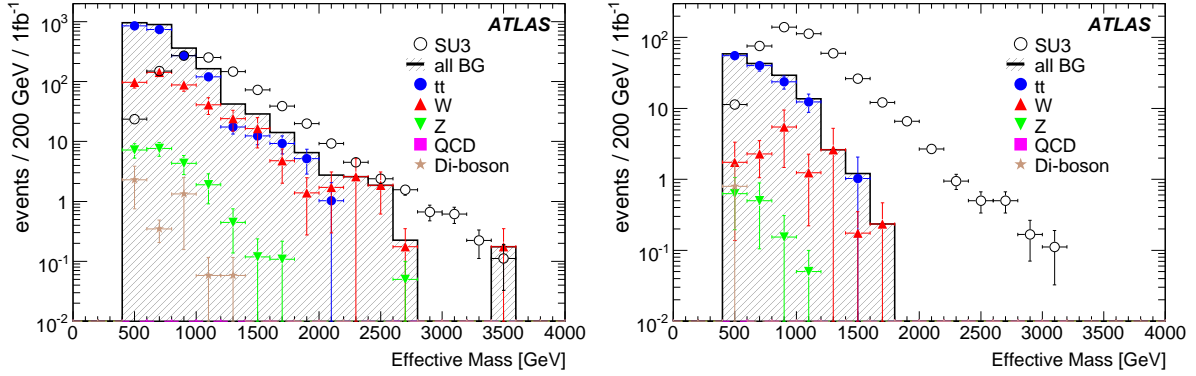

Figure 3: Expected  $M_{\text{eff}}$  distributions after Cuts 1–4 (left), and Cut 6 (right) for the 1-lepton analysis. Compare with Table 4.

Figure 4: The  $M_{\text{eff}}$  distributions for each of the SUn benchmark points, and for the sum of the Standard Model backgrounds with  $1 \text{ fb}^{-1}$  for the 1-lepton analysis. All the cuts except on  $M_{\text{eff}}$  are applied.

would expect. The estimated error on both of these backgrounds using data-driven methods is  $\pm 20\%$  [2]. Given this and the calculated signal and background rates in Table 4, it is evident that all the SUSY points considered except SU2 could be discovered with good significance in the 1-lepton mode. For SU2, the production cross-section is dominated by gaugino pair production, so a different analysis [11] is required.

To make this conclusion more quantitative, the significance  $Z_n$  defined in Section 1.2 was calculated. The central value of each background is taken from the current Monte Carlo simulation; the studies of data-driven background estimation [2, 3] provide estimated errors of  $\pm 50\%$  for QCD multijet backgrounds and  $\pm 20\%$  for  $t\bar{t}$ ,  $W + \text{jets}$ , and all other backgrounds. The results of this calculation are shown in Table 5 for an integrated luminosity of  $1 \text{ fb}^{-1}$ . Each of these points except SU2 would have  $Z_n > 5$  for just  $100 \text{ pb}^{-1}$  if the same 20% background uncertainty could be obtained with that luminosity.

The significances,  $Z_n$ , (Table 5) for  $1 \text{ fb}^{-1}$  are much smaller than the  $S/\sqrt{B}$  values in Table 4. This reflects the fact that, unlike  $S/\sqrt{B}$ , the  $Z_n$  measure of significance includes the estimated systematic uncertainty on the background. Table 5 also indicates that, provided the relative uncertainties in the background determinations did not increase, harder  $M_{\text{eff}}$  cuts would lead to better significances after systematic uncertainties in the background are taken into account.

Table 5: Significance  $Z_n$  for the 1-lepton plus 4-jet analysis with  $1\text{ fb}^{-1}$  including the systematic uncertainty in the background estimation.

SU4	2974	33.7	896	29.4	99	16.6
SU6	162	4.9	148	8.9	76	14.2
SU8.1	151	4.6	136	8.4	66	13.1

 Figure 5:  $M_{\text{eff}}$  distribution for events with one lepton and: 2 jets (left) or 3 jets (right) after all cuts were applied.

Supersymmetry events need not contain large numbers of jets. For example, in mSUGRA the process

$$\begin{aligned} \tilde{q}_L + \tilde{q}_R &\rightarrow \tilde{\chi}_1^\pm q' + \tilde{\chi}_1^0 q \\ &\quad \quad \quad \downarrow \\ &\quad \quad \quad \tilde{\chi}_1^0 \ell^\pm \nu \end{aligned}$$

can have a large rate and gives one lepton and just two hard jets. An alternative 1-lepton analysis has been performed requiring just two or three jets rather than four. Because a 4-jet selection was applied to the Alpgen samples at the generator level, Pythia was used for the  $W + \text{jets}$  backgrounds. The jet cuts employed are harder: 150 GeV for the leading jet and 100 GeV for the others. The missing energy cut is also harder,  $E_T^{\text{miss}} > \max(100\text{ GeV}, 0.3M_{\text{eff}})$  and  $\max(100\text{ GeV}, 0.25M_{\text{eff}})$  for the 2-jet and 3-jet case respectively. The  $M_{\text{eff}}$  distributions after all cuts are shown in Figure 5. Evidently an analysis requiring a smaller number of jets with harder cuts also can be effective.

Table 6: The number of events surviving the selection cuts defined in the text for the opposite-sign dilepton analysis, normalized to  $1\text{fb}^{-1}$  using next-to-leading-order cross-sections. The last two columns give the  $S/B$  ratio and the  $Z_n$  significance, the latter of which includes the systematic uncertainties on the Standard Model backgrounds.

Sample	Cuts 1-3	Cut 4	$S/B$	$Z_n$
SU3	200.8	159.8	1.88	3.55
SU1	91.0	72.6	0.86	1.65

## 4 Two-lepton mode

### 4.1 Opposite sign dileptons

Supersymmetry events with two opposite-sign leptons can arise from neutralino decays, especially  $\chi_2^0 \rightarrow l^\pm l^\mp \chi_1^0$ , either directly or through an intermediate slepton. Such dileptons must have the same flavour to avoid inducing  $\mu \rightarrow e\gamma$  and other lepton-flavour-violating interactions at one loop. By contrast leptons produced from independent decays can give either same-flavour (OSSF) or different-flavour (OSDF) dilepton pairs, again with  $\ell \in \{e, \mu\}$ .

The opposite-sign dilepton analysis uses the following cuts:

1. Two isolated, opposite-sign leptons with  $p_T > 10$  GeV and  $|\eta| < 2.5$  which satisfy the cuts described in the introductory SUSY note [1]. Events containing additional leptons were vetoed.
2. At least four jets with  $p_T > 50$  GeV at least one of which must have  $p_T > 100$  GeV.
3.  $E_T^{\text{miss}} > 100$  GeV and  $E_T^{\text{miss}} > 0.2M_{\text{eff}}$ .
4. Transverse sphericity,  $S_T > 0.2$ .

Cut 1 defines the opposite-sign dilepton sample, while Cuts 2 and 3 both suppress the Standard Model backgrounds and provide consistency with the Monte Carlo generator cuts on those backgrounds. After Cuts 1–3 the dominant background by far is  $t\bar{t}$ , as one would expect. The  $S_T$  cut only increases the  $S/B$  ratio by about 8% while reducing the signal by 20%.

The signals and backgrounds after the cuts, and the corresponding significances, are shown in Table 6. The number of events after all cuts includes the effect of the  $j_{70xE70}$  trigger, which, as shown in Table 1, has an efficiency of around 99% for all considered signal benchmarks, except for the low mass SU4 point, for which the efficiency is above 95%. The benchmark points SU3 and SU4 both have high discovery potential in the dilepton channel. While SU1 has fairly large dilepton branching ratios, many of the leptons are soft because of the small mass gaps between supersymmetric particles. An improved analysis based low- $p_T$  lepton reconstruction algorithms would help greatly for this point.

It is instructive to see how the significances,  $Z_n$ , vary with the cut on the leading jet and on  $E_T^{\text{miss}}$ . This is shown in Figure 6 for each of the points SU1 – SU4. It can be seen that the significance improves with

Figure 6: Significance of signal events for the four benchmark points, as a function of the cut on transverse missing energy (left) and the transverse momentum of the leading jet (right), for an integrated luminosity of  $1 \text{ fb}^{-1}$ .

Table 7: The optimized cuts for each point and corresponding signal, background, and significance. Compare with Table 6.

Sample	$E_T^{\text{miss}}$ cut	Leading jet cut	signal	background	Significance
SU1	100 GeV	320 GeV	37.97	6.30	6.94
SU2	140 GeV	200 GeV	13.74	22.68	1.07
SU3	140 GeV	200 GeV	125.34	22.68	11.45
SU4	110 GeV	100 GeV	772.53	66.80	24.70

harder cuts than those given in the above cut list even for the low-mass point SU4. The optimal cuts for each point and the signal, background and significance are shown in Table 7. Systematic errors of 50% on on all Standard Model backgrounds are included. Of course one should not optimize an analysis for a single point, but the table suggests that, provided the systematic uncertainties on the Standard Model background determinations do not significantly increase, harder cuts would be preferred. Optimization for wider ranges of points is discussed in Section 8.

Observing an non-resonant excess of OSSF dilepton events over OSDF events would be a clear indication of new physics. In SUSY leptonic  $\tilde{\chi}_2^0$  decays can produce this excess, and have a characteristic endpoint set by the masses involved. The significance of the difference, calculated as  $(N_{\text{OSSF}} - N_{\text{OSDF}})/\sqrt{N_{\text{OSSF}} + N_{\text{OSDF}}}$ , is shown in Table 8. This significance calculation assumes that the relative  $e$  and  $\mu$  acceptances are well understood, which is not unreasonable given that all Standard Model processes satisfy  $e/\mu/\tau$  universality. For SU1 the combined branching ratio for  $\tilde{\chi}_2^0 \rightarrow \tilde{\ell}_{L,R}^\pm \ell^\mp$  is 11.7%, but the acceptance is reduced by the small mass gaps. For SU2 gaugino pair production dominates, so the jet cuts suppress the signal.

## 4.2 Same sign dileptons

In the Standard Model the rate for prompt, isolated, same-sign dileptons is small. Of course some leptons from hadronized heavy or light quarks can also pass the isolation cut and contribute like-sign backgrounds. In SUSY, on the other hand, the gluino is a self-conjugate Majorana fermion, so events containing like-sign dileptons can be common. Thus, same-sign dileptons are a good signature for SUSY and a characteristic feature of it.

The cuts used for the same-sign dilepton analysis are:

Table 8: The number of OSSF and OSDF dilepton events passing the optimized cuts and the corresponding statistical significance for  $1\text{fb}^{-1}$ .

Sample	$E_T^{\text{miss}}$ cut	Leading jet cut	$N_{\text{OSSF}}$	$N_{\text{OSDF}}$	Significance
SU1	220 GeV	100 GeV	90.69	58.53	2.63
SU2	140 GeV	100 GeV	31.64	29.95	0.22
SU3	160 GeV	160 GeV	93.75	38.58	4.80
SU4	120 GeV	100 GeV	392.45	281.55	4.27

 Table 9: The number of events surviving the selection cuts (as defined in the text) for the same-sign dileptons analysis, normalized to  $1\text{fb}^{-1}$  using next-to-leading-order cross-sections. No background events pass the final cut; the 90% upper limit for  $t\bar{t}$  background is given.

Process	Cuts 1–3	Cut 4	$Z_n$
SU1	30.1	21.9	7.2
SU2	13.0	6.6	1.9
SU3	37.9	24.9	7.7
SU4	251.8	138.8	19.9
SU6	18.0	13.9	4.5
$t\bar{t}$	2.1	$< 2.3$	
$W + \text{jets}$	0.7	0.0	
$Z + \text{jets}$	0.0	0.0	

1. Exactly 2 same-sign leptons with  $p_T > 20$  GeV satisfying the usual isolation and other cuts [1].
2. At least four jets with  $p_T > 50$  GeV at least one of which must have  $p_T > 100$  GeV.
3. Transverse missing energy  $E_T^{\text{miss}} > 100$  GeV.
4.  $E_T^{\text{miss}} > 0.2M_{\text{eff}}$ .

The first cut defines the same-sign dilepton sample, while Cuts 2-4 suppress the Standard Model backgrounds. Cuts 1 and 2 are used in the Monte Carlo generator filters for some of the backgrounds.

The cut flow table for these cuts is shown in Table 9. The number of events after all cuts includes the effect of the j70xE70 trigger, which, as shown in Table 1, has an efficiency of around 99% for all considered signal benchmarks, except for the low mass SU4 point, for which the efficiency is 84%.

Since the  $W + \text{jets}$  and  $Z + \text{jets}$  backgrounds have been filtered at the generator level, the results for these are biased until after Cut 3, but evidently they are small. A number of other backgrounds were examined and found to be negligible compared to those listed in the table. None of the Monte Carlo events generated for the Standard Model background determination passed all the cuts. A 90% confidence upper limit of 2.3 Monte Carlo events gives the indicated upper limit on the  $t\bar{t}$  background after cut 4. This is used as the estimate of the total background since  $t\bar{t}$  is expected to dominate;  $b$  jets can produce a second lepton of the same sign and that lepton has a non-negligible probability of being well-isolated. The assumption of  $t\bar{t}$  dominance is consistent with the results after Cut 3 in Table 9. Two possible backgrounds,  $W^\pm W^\pm$  and  $t\bar{t}t\bar{t}$ , are probably small but have not been studied.

The  $E_T^{\text{miss}}$  distributions after the other cuts are shown in Figure 7. While the rates are small, the  $S/B$  ratio is good and the signal is distinctive. The  $E_T^{\text{miss}}$  cut was varied and the value in the cuts used here

Figure 7:  $E_T^{\text{miss}}$  in the same sign dilepton events after all cuts except the  $E_T^{\text{miss}}$  cut.

found to be appropriate.

It is clear that the Standard Model same-sign dilepton background is small and is probably dominated by  $t\bar{t}$ . A data-driven analysis of this background has not yet been done. It is expected that it will be possible to measure the background from processes such as  $t \rightarrow \ell^+ X$ ,  $\bar{b} \rightarrow \mu^+ X$  as a function of the isolation cut and to extrapolate to the cut used here. For  $\bar{b} \rightarrow e^+ X$ , where the  $e$  identification cuts impose an implicit isolation cut, it will be necessary to extrapolate from the  $\mu$  result using Monte Carlo techniques. In the absence of such studies the significance for the same-sign dilepton analysis has been calculated using the 90% upper limit for  $t\bar{t}$  given in Table 9 with the standard systematic uncertainty of  $\pm 20\%$ . This gives the  $Z_n$  values listed in the same table. Although the systematic error on the background is uncertain, certainly SU4 and very likely SU1 and SU3 would be observable with a significance greater than  $5\sigma$  with  $1\text{ fb}^{-1}$ .

More work on the same-sign dilepton background, and more generally on estimates of leptons from  $b$  and  $c$  decays passing isolation cuts, is clearly needed.

## 5 Three-lepton mode

The trilepton signal from direct gaugino production [14] is perhaps the best search mode for SUSY at the Tevatron [15, 16]. The corresponding search with ATLAS is described elsewhere in this volume [11]. The analyses discussed here are aimed at trilepton production from all sources, not just from direct production. Two approaches have been followed. The first, the 3-leptons + jet selection makes explicit use of a high- $p_T$  jet, similar to the 1- and 2-lepton analyses described above. The second, the 3-leptons +  $E_T^{\text{miss}}$  selection, relies on track isolation cuts to select prompt leptons and is similar to the exclusive analysis [11]. The LEP trigger typically gives an efficiency of  $\gtrsim 95\%$  for these modes (see Table 1).

### 5.1 Three-lepton + jet analysis

The 3-leptons + jet selection requires:

1. At least three leptons with  $p_T > 10$  GeV satisfying the usual identification and isolation cuts [1].
2. At least one jet with  $p_T > 200$  GeV.

No  $E_T^{\text{miss}}$  cut is made, so this analysis could be used even if detector problems seriously degraded the  $E_T^{\text{miss}}$  performance. The jet cut is sufficient to suppress the  $WZ$  and  $W\gamma^*$  backgrounds, so cuts on the invariant mass of opposite-sign same-family dilepton pairs are also not required.

Table 10: The numbers of surviving SUSY and Standard Model events for the benchmark points SU2, SU3 and SU4, as the “3-leptons+jet” inclusive tripleton selection is applied. All numbers are nomalized to  $1 \text{ fb}^{-1}$  of integrated luminosity.

Sample	Cut 1	Cut 2	$S/B$	$S/\sqrt{B}$	$Z_n$
SU2	35	13	1.1	3.7	2.7
SU3	139	94	7.8	27.1	11.5
SU4	1284	312	26.0	90.0	24.4
$t\bar{t}$	455	11	–	–	–
$ZZ$	59	0	–	–	–
$ZW$	193	1	–	–	–
$WW$	3	0	–	–	–
$Z + \gamma$	9	0	–	–	–
$Zb$	656	0	–	–	–

The cut flow for this selection is shown in Table 10. The number of events after all cuts includes the effect of the 1LEP trigger, which, as shown in Table 1, has an efficiency of around 95% for all of the benchmark points considered. The jet cut (Cut 2) particularly reduces the  $ZW$  and  $Zb$  backgrounds in which the jets tend to be soft. The dominant background after all cuts is  $t\bar{t}$ , but there is also a small remaining background from  $WZ$ . The same table shows the statistical significance  $S/\sqrt{B}$  and the significance  $Z_n$  including a background uncertainty of 20%. As has already been discussed for the same-sign dilepton selection, the key issue for background determination is the estimation of leptons from  $b \rightarrow \ell X$  passing the isolation cut in  $t\bar{t}$  events. We expect that this could be measured as a function of the isolation cut for  $\mu$  and then applied to  $e$  using Monte Carlo simulation. Given the large  $S/B$  in Table 10, even a 100% background uncertainty would yield  $Z_n > 5$  for points SU3 and SU4.

Adding a cut on  $E_T^{\text{miss}}$  to this analysis was investigated. The surviving background events after the tripleton and jet cuts have a wide range of  $E_T^{\text{miss}}$ , so a cut to reduce them would also reduce the already rather small signal.

## 5.2 Three-lepton + $E_T^{\text{miss}}$ analysis

The 3-leptons +  $E_T^{\text{miss}}$  selection does not require (or veto) jets, so it is sensitive to direct gaugino production as well as to tripletons produced in the decays of squarks and gluinos. The analysis cuts have been somewhat optimized for SU2, for which gaugino pair production dominates. Since the dominant source of tripletons in SUSY includes a decay  $\tilde{\chi}_2^0 \rightarrow \tilde{\chi}_1^0 \ell^+ \ell^-$ , at least one OSSF lepton pair is required among the three leptons.

The cuts for this analysis are:

1.  $N_\ell \geq 3$  leptons with  $p_T > 10$  GeV satisfying the usual identification and isolation cuts [1].
2. At least one OSSF dilepton pair with  $M > 20$  GeV to suppress low-mass  $\gamma^*$ ,  $J/\psi$ ,  $\Upsilon$ , and conversion backgrounds.
3. Lepton track isolation:  $p_{T,\text{trk}}^{0.2} < 1$  GeV for muons and  $< 2$  GeV for electrons, where  $p_{T,\text{trk}}^{0.2}$  is the maximum  $p_T$  of any additional track within a cone  $R = 0.2$  around the lepton.

Table 11: Expected event numbers for the 3-leptons +  $E_T^{\text{miss}}$  analysis for  $1 \text{ fb}^{-1}$  for signal and background processes. The  $WW$  and  $Z\gamma$  backgrounds are small and so are not listed.

Process	Cuts 1-2	Cut 3	Cut 4	Cut 5
SU1	42.2	33.0	32.6	24.1
SU2	29.8	24.1	21.1	17.6
SU3	130.1	101.2	98.6	63.9
SU4	968.1	691.5	654.3	544.9
SU8.1	10.2	8.0	8.0	5.3
$WZ$	188.3	166.2	122.5	22.8
$ZZ$	55.9	46.4	10.3	1.6
$Zb$	582.5	221	1.3	0
$t\bar{t}$	283.2	59.9	56.6	47.9

 Table 12: Number of signal ( $S$ ) and background ( $B$ ) events surviving the 3-leptons +  $E_T^{\text{miss}}$  selection and the corresponding values for  $S/\sqrt{B}$  and  $Z_n$ . All numbers are normalized to  $1 \text{ fb}^{-1}$ .

	SU1	SU2	SU3	SU4	SU8
$S$	24.1	17.6	63.9	544.9	5.3
$B$	73.5				
$S/\sqrt{B}$	2.8	2.1	7.5	63.5	0.6
$Z_n$	1.3	1.0	3.5	16.4	0.3

4.  $E_T^{\text{miss}} > 30 \text{ GeV}$ .

5.  $M < M_Z - 10 \text{ GeV}$  for any OSSF dilepton pair.

Cut 3 provides an additional rejection of leptons from  $b$  and  $c$  decays beyond the calorimeter isolation cut, while Cut 4 reduces Standard Model backgrounds containing a  $Z$ .

The significances  $S/\sqrt{B}$  and  $Z_n$  for this second analysis are shown in Table 12, where the  $Z_n$  significance includes the standard 20% background systematic uncertainty. A detailed study of the performance of the lepton isolation cuts is needed to understand the uncertainty on the  $t\bar{t}$  background in particular. Since this analysis does not require jets, one might hope that it would be sensitive to the dominant gaugino pair production for SU2, but only SU4 gives a signal with  $Z_n > 5$  for  $1 \text{ fb}^{-1}$ . For all of the benchmark points studied the 3-leptons + jet analysis is more sensitive than the 3-leptons +  $E_T^{\text{miss}}$  one.

## 6 Tau mode

SUSY models generically violate  $e/\mu/\tau$  universality;  $\tau$  decays can even be dominant, especially for  $\tan\beta \gg 1$ . Hence it is worthwhile to look for signatures involving hadronic  $\tau$  decays even though the fake background from jets is much larger than that for  $e$  or  $\mu$ . Leptonic  $\tau$  decays are indistinguishable from prompt leptons and are already included in the previous analyses.

The cuts used in this analysis are:

1. At least four jets with  $p_T > 50 \text{ GeV}$  and at least one with  $p_T > 100 \text{ GeV}$ .

Table 13: The number of signal ( $S$ ) and background ( $B$ ) events after tau selection and corresponding values of significance, normalised to  $1 \text{ fb}^{-1}$ .

Sample	$S$	$B$	$S/B$	$S/\sqrt{B}$	$Z_n$
SU3	259	51	5.1	36.3	12
SU6	119	51	2.3	16.7	6.8

2.  $E_T^{\text{miss}} > 100 \text{ GeV}$ .
3.  $\Delta\phi(j_i, E_T^{\text{miss}}) > 0.2$  for each of the three leading jets  $j_i, i = 0, 1, 2$ .
4. No isolated leptons using the standard cuts [1].
5. At least one  $\tau$  with  $p_T > 40 \text{ GeV}$  and  $|\eta| < 2.5$  reconstructed by the high  $p_T$   $\tau$  algorithm [17] with a likelihood,  $L > 4$ .
6.  $E_T^{\text{miss}} > 0.2M_{\text{eff}}$ .
7.  $M_T > 100 \text{ GeV}$ , where  $M_T$  is calculated using the visible momentum of the hardest  $\tau$  and  $E_T^{\text{miss}}$ .

Cuts 1, 2, and 6 are standard. Cut 3 requires a large  $\Delta\phi$  between  $E_T^{\text{miss}}$  and the leading jets, thus reducing the background both from mismeasured jets and from  $b$  and  $c$  decays. Cut 4 makes this analysis disjoint from the 1, 2, and 3-lepton analyses described above. There is still overlap with the 0-lepton analysis described in Section 2. Cut 5 defines the  $\tau$  sample; these cuts give an efficiency of  $\sim 50\%$  with a purity of  $\sim 80\%$  for the SU3 sample. Finally, if the  $E_T^{\text{miss}}$  comes from one  $W \rightarrow \tau\nu$  decay, then  $M_T$  used in Cut 7 should satisfy  $M_T < m_W$ . The applied cuts are a superset of the basic cuts for the inclusive 4-jet 0-lepton analysis, which does not employ a  $\tau$  veto and therefore the events selected for this analysis will have an almost complete overlap with the ones selected in the analysis described in the corresponding section. For the same reason, the efficiency of the j70xE70 trigger is expected to be between 97% and  $\sim 100\%$  for all the benchmark points, as was the case for the inclusive multi-jet analysis.

The effect of these cuts is indicated graphically in Figure 8. The requirement of a reconstructed  $\tau$  (Cut 5) eliminates the QCD background. After the  $M_T$  cut the  $S/B$  ratio is high. The resulting signal, background, and significance for points SU3 and SU6 are given in Table 13 assuming the usual 20% systematic uncertainty for the background, which is dominated by  $t\bar{t}$  with some contribution from  $W + \text{jets}$ .

The data-driven uncertainty on  $\tau$  SUSY backgrounds has not yet been studied. Clearly  $\tau$  reconstruction is difficult. However, it should be possible to simulate real  $\tau$  backgrounds by selecting backgrounds with reconstructed  $e$  and  $\mu$  and replacing the leptons with simulated  $\tau$  decays. Fake backgrounds can be similarly determined using reconstructed events combined with the measured jet  $\rightarrow \tau$  fake rate. If the resulting uncertainty on the background is about 20%, as is assumed in Table 13, then both points SU3 and SU6 would be observable in the  $\tau$  mode.

## 7 $b$ -jet mode

SUSY signals are typically rich in  $b$  quarks because the  $\tilde{b}$  and  $\tilde{t}$  tend to be lighter than first- and second-generation squarks and because Higgsino couplings enhance heavy flavour production. In the benchmark points studied the fractions of events containing  $b$  jets range from 14.4% for SU2 to 72.8% for SU4. In QCD events  $b$  quarks typically occur at the percent level. Thus, requiring a  $b$  quark suppresses the QCD background, which may be difficult to control, just as requiring an  $e$  or  $\mu$  does.

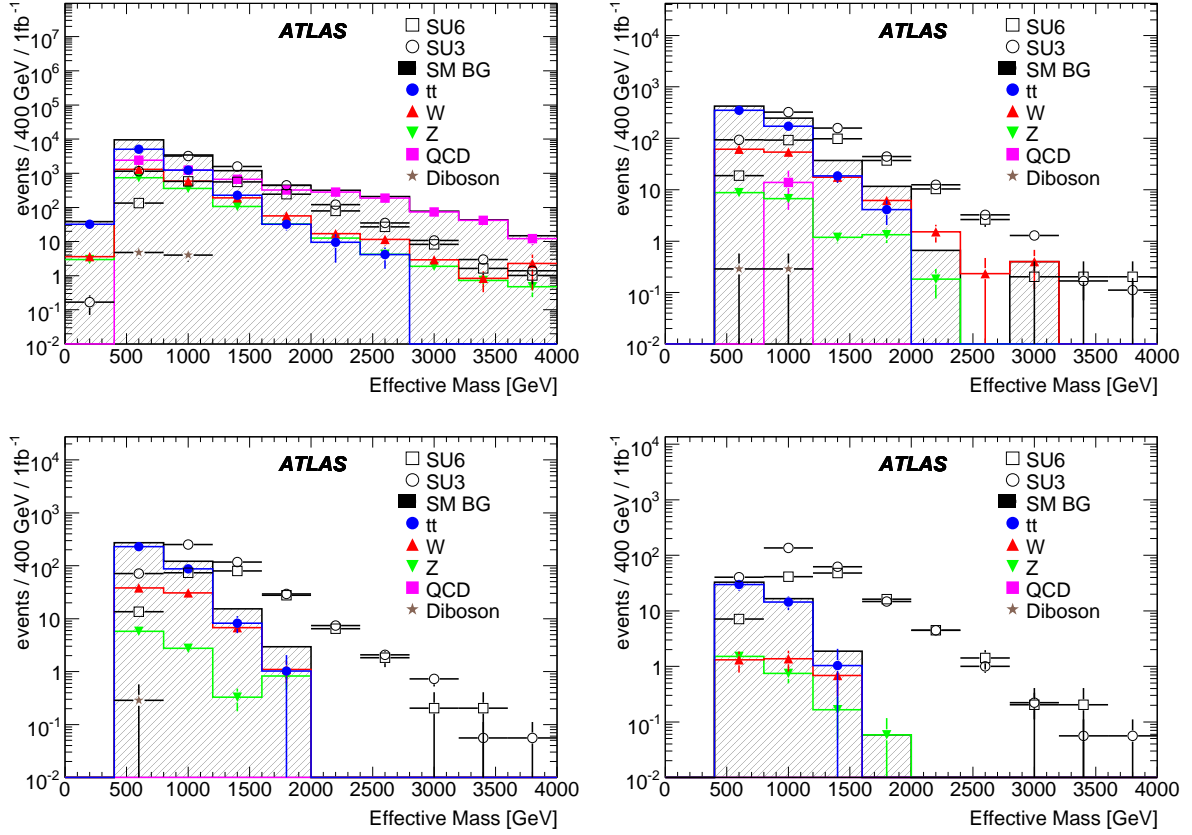

Figure 8: The  $M_{\text{eff}}$  distributions for SUSY signals and Standard Model backgrounds in the  $\tau$  analysis after Cuts 4, 5, 6, and 7.

In this section an analysis of signatures with  $b$  jets is performed for SUSY points SU1, SU3, SU4 and SU6 using full simulation both for the signal and for the Standard Model backgrounds. Isolated leptons may also be present, and all channels with and without leptons are summed. SUSY processes almost always will give  $b\bar{b}$  pairs, and this is taken into account. No equivalent analysis was performed in the Physics TDR.

The cuts used in this analysis are as follows:

1. At least 4 jets in the event with  $p_T > 50$  GeV.
2. Leading jet  $p_T > 100$  GeV.
3. Missing transverse energy,  $E_T^{\text{miss}} > 100$  GeV.
4. Missing transverse energy,  $E_T^{\text{miss}} > 0.2M_{\text{eff}}$ .
5. Transverse sphericity,  $S_T > 0.2$ .
6. At least 2 jets are tagged as  $b$  jets, as described below.
7.  $M_{\text{eff}} > 600, 800, \text{ or } 1000$  GeV.

Note that Cuts 1–3 are also used in Monte Carlo generator filters for some of the background samples. Cut 7 is used to optimize the signal-to-background ratio in the selected events.

Table 14: Number of events surviving selection cuts as defined in the text for the inclusive search with  $b$  jets normalized to  $1\text{fb}^{-1}$  using NLO cross-sections. The results are shown for three different values of the  $M_{\text{eff}}$  cut (Cut 7).

Sample	Cuts 1–3	Cut 4	Cut5	Cut 6	Cut 7		
					600 GeV	800 GeV	1000 GeV
SU1	3469	2806	1994	456	442	375	263
SU2	608	358	299	170	166	141	87
SU3	9357	7279	5474	1158	1086	818	425

Diboson	22	13	8	2	1	0	0
$B_{SM}$	47527	18676	13328	2950	1115	303	69

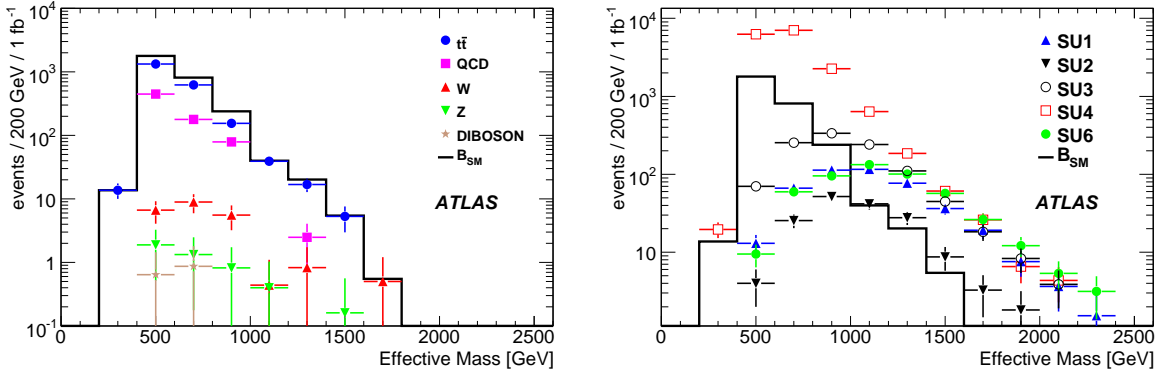

Figure 9:  $M_{\text{eff}}$  distributions for  $b$ -jet analysis. Left: Standard Model backgrounds. Right: SUSY signals with total background.

Jets with  $p_T > 20$  GeV are selected as  $b$  jets using the default tagging algorithm based on the 3-dimensional impact parameter and secondary vertex detection [18] with a cut weight  $> 6.75$ , giving a nominal efficiency of 60%. Above about  $p_T = 100$  GeV both the efficiency and the light-jet rejection decrease as discussed in the introductory SUSY note [1] and references therein. Naively one would expect that the increase of the  $B$  decay length with  $\gamma = E_B/M_B \gg 1$  would offset the  $1/\gamma$  decrease of the angles since the multiple scattering angular errors also decrease similarly. There is also a substantial dependence of  $b$  tagging on the  $\eta$  of the jet. Many of the  $b$  jets in SUSY events have high  $p_T$ : the typical  $p_T$  of the leading jet in SU3 is about 300 GeV, for which the light-jet rejection during  $b$  tagging is  $\mathcal{O}(100)$ .

Events with zero or more leptons and at least two tagged  $b$  jets were combined in a single inclusive analysis. Inevitably this means that there is overlap with the analyses in Sections 2–5. The cut flow is shown in Table 14. After Cut 6 ( $N_b \geq 2$ ) the  $t\bar{t}$  background is dominant, as one might expect, but the

Table 15:  $S/B$  ratio and signal significance  $Z_n$  including systematic effects for the  $b$ -jet analysis with  $0.1\text{ fb}^{-1}$  and  $1\text{ fb}^{-1}$  with  $M_{\text{eff}} > 1000\text{ GeV}$ .

	$S/B$	$Z_n$ for $0.1\text{ fb}^{-1}$	$Z_n$ for $1\text{ fb}^{-1}$
SU1	3.8	6.0	9.3
SU2	1.3	2.3	5.0
SU3	6.2	7.5	13.0
SU4	13.4	12.6	21.7
SU6	4.9	7.1	11.2

QCD background remains substantial. The  $b$ -tagging performance at high  $p_T$  is clearly an important issue for this analysis. As the applied cuts are a superset of the basic cuts for the inclusive 4-jet analyses, the efficiency of the j70xE70 trigger is, as quoted in the corresponding section, between 97% and  $\sim 100\%$  for all the considered benchmark points.

To calculate the significance in this channel an uncertainty of 50% for the QCD background and 20% for the other backgrounds is assumed for  $1\text{ fb}^{-1}$ . The uncertainty on the  $b$ -tagging efficiency of 60% is 5% [2, 18]. This is assumed to be included in the  $t\bar{t}$  uncertainty and is ignored for the other, smaller backgrounds.

The hardest effective mass cut,  $M_{\text{eff}} > 1000\text{ GeV}$ , was found to be the most effective, so only results for it are shown here. The resulting significances,  $Z_n$ , including the above systematic effects, are shown in Table 15, for two luminosities:  $0.1$  and  $1\text{ fb}^{-1}$ , where the same systematic uncertainty is assumed to be the same for both luminosities. All background uncertainties are added linearly. The low-mass point SU4 and perhaps also SU3 could be discovered using this analysis with only  $0.1\text{ fb}^{-1}$  assuming that the background could be understood adequately. All points except SU2 could be discovered with  $1\text{ fb}^{-1}$ , for which the background uncertainties are realistic. This analysis seems to be particularly useful compared to some other analyses for point SU6.

## 8 Scans and optimization

The SUSY points studied so far were chosen to give a variety of signatures, but there is no reason to think that they are representative of what might be found at the LHC. This section uses scans over the parameters of several models for SUSY breaking – all with  $R$  parity conservation – in order to sample a wider range of possibilities. The goal is to develop one or more search strategies covering as wide a subset of the scanned models as possible. Since each scan includes hundreds of points, this section must rely on ATLFAST [19], the fast parameterized simulation of the ATLAS detector.

Data-driven methods [2, 3] will be used to determine the Standard Model backgrounds to the possible SUSY signatures. For  $1\text{ fb}^{-1}$  the estimated errors [2, 3] are typically 50% for QCD jets and 20% for the  $W$ ,  $Z$ , and  $t$  backgrounds. Several approaches were considered to look for an excess above a cut on  $M_{\text{eff}}$  or  $E_{\text{T}}^{\text{miss}}$  after basic jet and lepton selections. The significance is corrected for multiple cuts as described in Section 1.2. Results are shown here only for the  $M_{\text{eff}}$  cut, that yielded best performance. A multivariate optimization using TMVA [20] gave a minor improvement with the available Monte Carlo statistics. This and other cut procedures are still being studied.

The analyses described above in this note have used signal and background cross-sections normalized to next-to-leading-order calculations [1]. This was impractical for scans over many points, each involving many subprocesses. The goal here is not to determine the exact limit or exclusion value but rather to test whether the proposed approaches work for a wide range of models. It was therefore decided to normalize

the signal cross-sections for all scans to the leading-order HERWIG values but to use next-to-leading-order normalizations for the backgrounds. Since next-to-leading-order corrections generally increase cross-sections, the resulting reach estimates are conservative.

## 8.1 SUSY signal samples

It is impossible to scan the 105-dimensional parameter space of the MSSM or even the 19 dimensional subspace with flavour and  $CP$  conservation and degeneracy of the first two generations. Hence a number of SUSY-breaking models with many fewer parameters were used.

Several of these scans (e.g. the first two mSUGRA scans listed below) ignore dark matter and other existing constraints. Of course any true theory must obey such constraints. It is possible, however, to modify the SUSY breaking model to satisfy the constraints while keeping the basic phenomenology unchanged. One such example, the non-universal-Higgs model (NUHM), is discussed below. Since there is no unique model of SUSY-breaking, all these scans should be viewed only as possible patterns of LHC signatures, not as complete theories.

**mSUGRA fixed grid,  $\tan\beta = 10, A_0 = 0, \mu > 0$ :** A  $25 \times 25$  grid was made varying  $m_0$  from 60 GeV to 2940 GeV in 25 steps of 120 GeV, and  $m_{1/2}$  from 30 GeV to 1470 GeV in 25 steps of 60 GeV. SUSY spectra were generated using ISAJET 7.75 [21] with a top quark mass of 175 GeV. Out of the 625 possible points, a spectrum could be successfully generated for 600; the other 25 failed for theoretical reasons. For each good point 20k events were produced using ATLFAST. Constraints other than from direct searches were ignored. While constraints such as the dark-matter relic density constrain specific SUSY-breaking models such as mSUGRA, they are much less restrictive for generic models.

**mSUGRA fixed grid:  $\tan\beta = 50, A_0 = 0, \mu < 0$ :** Large  $\tan\beta$  increases the mixing of  $\tilde{b}_{L,R}$  and  $\tilde{\tau}_{L,R}$ , leading to enhanced  $b$  and  $\tau$  production. A grid of  $25 \times 25$  points was generated with  $m_0$  varied from 200 to 3000 GeV in steps of 200 GeV and with  $m_{1/2}$  varied from 100 to 1500 GeV in steps of 100 GeV. The top mass was fixed at 175 GeV. Constraints other than from direct searches were again ignored.

**mSUGRA random grid with constraints:** In this sample all mSUGRA parameters were varied in two regions<sup>2</sup> previously found [22] to be compatible with dark-matter and other constraints with  $\mu > 0$  and  $m_t = 175$  GeV.

The mSUGRA parameters were chosen randomly (with  $\mu > 0$ ) and their properties calculated using ISAJET 7.75. All selected points satisfy the LEP Higgs mass limit,  $m_h > 114.4$  GeV [23]; the WMAP total dark matter limit,  $\Omega h^2 < 0.14$  [24]; within  $3\sigma$  the branching ratio limits  $B(b \rightarrow s\gamma) = (3.55 \pm 0.26) \times 10^{-4}$  [25] within  $3\sigma$  and  $B(B_s \rightarrow \mu^+\mu^-) < 1.5 \cdot 10^{-7}$  [26]; and with  $\delta a_\mu$  less than the  $3\sigma$  upper limit from the muon anomalous magnetic moment measurement  $a_\mu = (11659208 \pm 6) \times 10^{-10}$  [27].

**GMSB grid:  $M_{\text{mess}} = 500$  TeV,  $N_{\text{mess}} = 5, C_{\text{grav}} = 1$ :** With  $N_{\text{mess}} = 5$  the NLSP is a slepton which decays promptly to leptons or  $\tau$ 's. A fixed grid was made varying  $\Lambda$  was varied from 10 TeV to 80 TeV in steps of 10 TeV and  $\tan\beta$  from 5 to 40 in steps of 5.

**NUHM grid:** The NUHM model is similar to the mSUGRA model but does not assume that the Higgs masses unify with the squark and slepton ones at the GUT scale. This allows more gaugino/Higgsino mixing at the weak scale and so relaxes the mSUGRA dark matter constraints. The scan uses a step size

<sup>2</sup>The parameters are varied within  $\{0 < m_0 < 2 \text{ TeV}, 0.5 < m_{1/2} < 1.3 \text{ TeV}, -0.34 < A_0 < 2.4 \text{ TeV}, 39 < \tan\beta < 55\}$  and  $\{1 < m_0 < 3 \text{ TeV}, m_{1/2} < 0.5 \text{ TeV}, -2.0 < A_0 < 2.0 \text{ TeV}, 20 < \tan\beta < 55\}$

Figure 10: Efficiencies for electrons as a function of  $p_T$  for the SU3 sample (left) and  $\eta$  for the ALPGEN sample  $Z \rightarrow ee$  (right). The solid red line corresponds to the Geant 4 simulation, the solid circles to uncorrected ATLFast, and the open circles to the corrected version of ATLFast used for the reach analyses.

of 100 GeV in both  $m_0$  and  $m_{1/2}$ . For each point the values of  $\mu$  and  $M_A$  at the weak scale are adjusted to give acceptable cold dark matter.

## 8.2 ATLFast corrections

ATLFast is a fast parameterized simulation of the ATLAS detector. The version used here is rather idealized. Corrections to the efficiency for  $e$  reconstruction were applied as a function of  $p_T$  and  $\eta$ . An example of the effect of these corrections is shown in Figure 10. In addition, the ATLFast algorithm finding reconstructed cone jets was missing the split-merge step, so jets matched to the same truth jet were combined. With these corrections the ATLFast and full simulations agree reasonably well. All results shown here use ATLFast with these corrections.

## 8.3 Discovery reach

The reach plots in this subsection are all based on analyses that require a certain number of jets and leptons ( $e$  or  $\mu$ ) and then find an optimal  $M_{\text{eff}}$  cut (in steps of 400 GeV) to maximize the significance  $Z_n$  corrected for multiple cuts of the signal over the Standard Model background, using background errors estimated from studies of data-driven methods [2,3]. Not all modes were studied because of limited time or Monte Carlo statistics.

The analysis most similar to that in the Physics TDR [10], requires four jets with  $p_T > \{100, 50, 50, 50\}$  GeV and  $E_T^{\text{miss}} > \max(100 \text{ GeV}, 0.2M_{\text{eff}})$ . The  $5\sigma$  discovery reach for the analyses requiring zero, one, or two opposite-sign leptons for mSUGRA with  $\tan\beta = 10$  are shown in Figure 11. The plot also shows the trilepton reach with just one jet. The 0-lepton mode has the best estimated reach, close to 1.5 TeV for the smaller of  $m_{\tilde{g}}$  and  $m_{\tilde{q}}$ . The 1-lepton estimated reach is somewhat less, but it is more robust against QCD backgrounds which might result from detector problems. Figure 11 also shows that the reach for  $\tan\beta = 50$  is similar for the zero- and one-lepton channels. Despite the enhanced  $\tau$  decays for  $\tan\beta \gg 1$ , the one- $\tau$  reach is slightly worse than the reach for zero and one leptons. This reflects the lower efficiency and purity for  $\tau$  reconstruction. Compared to  $\tau + 4$  jets, the reach for  $\tau + 3$  jets is slightly better, while  $\tau + 2$  jets is about the same. The curves for the  $\tau + 2$ -jet and the  $\tau + 3$ -jet analyses are not shown.

Requiring four jets is not necessarily the best choice. The  $5\sigma$  reach contours for the 0-lepton plus  $E_T^{\text{miss}}$  and the 1-lepton plus  $E_T^{\text{miss}}$  analyses for various jet multiplicities are shown in Figure 12, again for

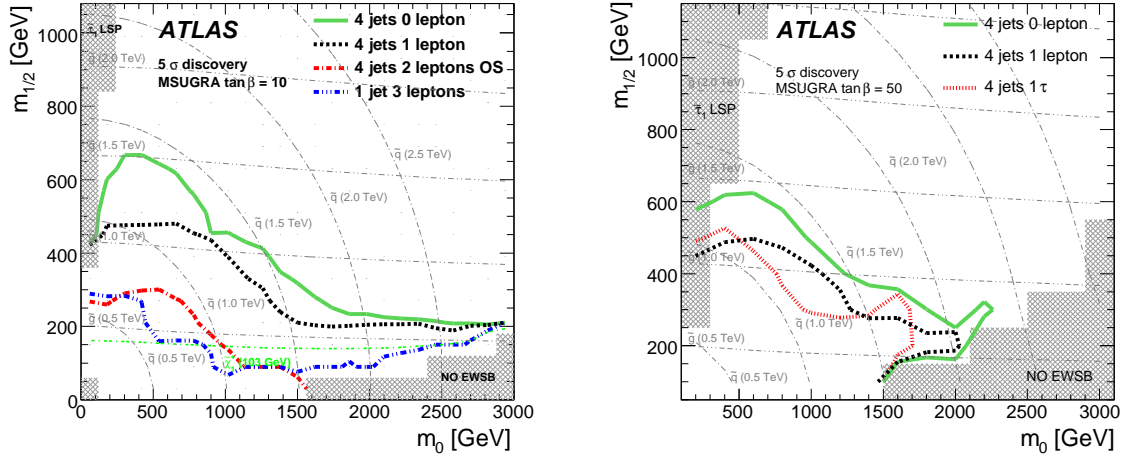

Figure 11: The 1 fb<sup>-1</sup> 5σ reach contours for the 4-jet plus  $E_T^{\text{miss}}$  analyses with various lepton requirements for mSUGRA as a function of  $m_0$  and  $m_{1/2}$ . Left:  $\tan\beta = 10$ . Right:  $\tan\beta = 50$ . The horizontal and curved grey lines indicate gluino and squark mass contours respectively in steps of 500 GeV.

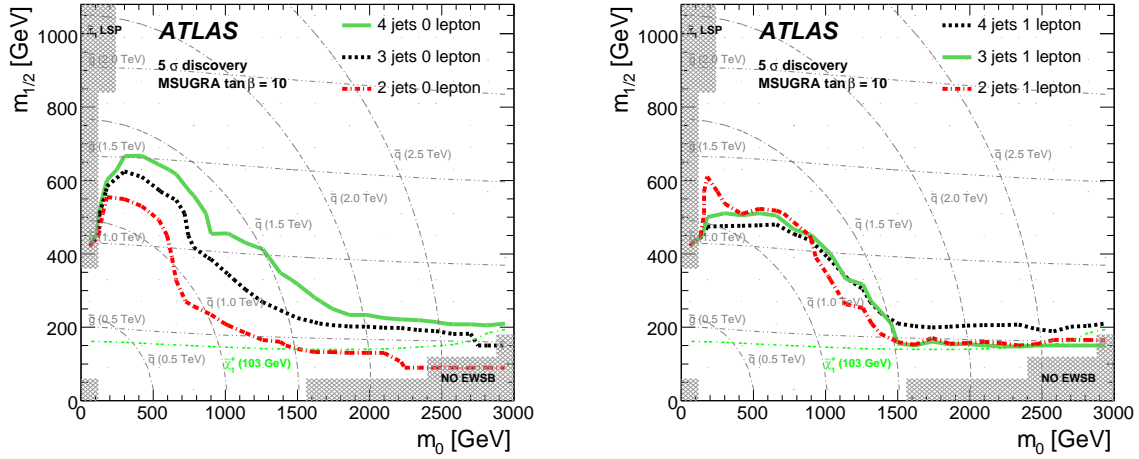

Figure 12: The 1 fb<sup>-1</sup> 5σ reach contours for the 0-lepton and 1-lepton plus  $E_T^{\text{miss}}$  analyses with various jet requirements as a function of  $m_0$  and  $m_{1/2}$  for the  $\tan\beta = 10$  mSUGRA scan. The horizontal and curved grey lines indicate the gluino and squark masses respectively in steps of 500 GeV.

the  $\tan\beta = 10$  mSUGRA scan. For the 0-lepton mode the choice of four jets seems best, while for the 1-lepton mode the 2-jet, 3-jet and 4-jet reaches are all comparable. The reaches (not shown here) for the opposite-sign dilepton plus  $E_T^{\text{miss}}$  signature requiring at least 2, 3, or 4 jets are comparable and in all cases are less than the reaches for the 0-lepton and 1-lepton modes. Observing a signal in multiple channels would provide further confidence that the observed excesses were evidence for new physics.

The mSUGRA “random” scan with low-energy constraints samples only a limited range of parameters and hence of gluino and squark masses. The results of this scan are shown as a scatter plot of points in Figure 13 compared to those for the mSUGRA scans. The reach for those mSUGRA points which are compatible with low-energy constraints is comparable to that for generic points. This is not surprising

Figure 13: Reach for the “random with constraints” mSUGRA scan plotted in the  $m_{\tilde{g}}, m_{\tilde{q}}$  plane. Solid triangles represent points which are observable ( $Z_n > 5$ ) with  $1\text{ fb}^{-1}$ , while open triangles show points which are not.

Figure 14: The  $1\text{ fb}^{-1}$  reach for NUHM models with 4 jets, 0 or 1 leptons, and  $E_T^{\text{miss}}$ . The masses for NUHM are similar to those shown in Figure 11.

given that the SUSY production cross-sections are mainly controlled by the gluino and squark masses, but it adds support to the approach used in this section.

The mSUGRA model is only one possible mechanism for SUSY breaking. The non-universal-Higgs model has qualitatively similar phenomenology but different patterns of masses and decay modes. The reach plots with four jets, zero or one leptons, and  $E_T^{\text{miss}}$  for the NUHM are shown in Figure 14. The reach with zero and one leptons is virtually identical to that for mSUGRA. This is as expected: adding some Higgsino mixing allows  $\tilde{\chi}_1^0$  annihilation but has a minor effect on the other decays.

Another alternative often considered, Anomaly Mediated SUSY Breaking (AMSB), is not examined here. Previous studies [28] have found an overall reach comparable to mSUGRA with similar assump-

Figure 15: The  $1 \text{ fb}^{-1}$   $5\sigma$  reach contours of the 2-lepton and 3-lepton analyses for the GMSB scan. The vertical solid and dashed grey lines indicate the gluino and squark masses respectively in steps of 500 GeV.

tions. The reach in the one-lepton modes is less because the lightest chargino is almost degenerate with the LSP and so does not give visible leptons.

The models considered in the GMSB scan all have at least two leptons or  $\tau$ 's at the Monte Carlo generator level, so the signatures are easier to distinguish from Standard Model backgrounds. The reach plots for this scan are shown in Figure 15. The reach for three leptons is significantly better than for two leptons and extends well beyond 2 TeV for gluinos for large  $\tan\beta$  and is close to 2 TeV for all  $\tan\beta$ . Special signatures that can result from GMSB models are discussed elsewhere in this volume [4].

## 8.4 Summary

The results of the scans presented in this section together with the full simulation analyses presented earlier indicate that ATLAS should discover signals for  $R$ -parity conserving SUSY with gluino and squark masses less than  $\mathcal{O}(1 \text{ TeV})$  after having accumulated and understood an integrated luminosity of about  $1 \text{ fb}^{-1}$ . For favorable models the mass reach could be greater. The luminosity required to discover a given SUSY scenario is greater than that estimated previously [29]. The main differences in this analysis are that the uncertainty in the background (derived from data-driven methods) is taken into account and that the signal and background simulations are more realistic. Given the admittedly qualitative naturalness arguments about SUSY masses, it is plausible that SUSY could be found with  $1 \text{ fb}^{-1}$  if it exists at the TeV scale. Conversely, if SUSY is not found with  $1 \text{ fb}^{-1}$ , it might still eventually be discovered at the LHC, but it will be difficult to study in detail.

# Measurements from Supersymmetric Events

## Abstract

We review the techniques used to reconstruct the decay of supersymmetric particles and measure their properties with ATLAS at the LHC, concentrating on strategies to be applied to a data set of integrated luminosity of  $1 \text{ fb}^{-1}$  that can be expected after the first year of operation of the LHC. These techniques are illustrated using several benchmark points chosen in the mSUGRA parameter space, but they are applicable to a broader range of supersymmetric (and other similar) models. The most appropriate methods will be selected and fine-tuned once (and if) signatures consistent with Supersymmetry are established. Supersymmetric cascade decays typically have large transverse missing energy due to the presence of undetected neutralinos, and have characteristic edges and thresholds in the dilepton, dijet and lepton-jet invariant mass distributions. The reconstruction of such edges is the focus of the first part of the paper. The second part of the paper concentrates on the reconstruction of more specific decay channels, involving light stops, staus and Higgs bosons. The final section indicates how sparticle masses and other supersymmetric parameters could be constrained using such measurements.

## 1 Introduction

Supersymmetry (SUSY) can be discovered by the ATLAS experiment at the LHC during the initial running period if some coloured sparticles have masses of the order hundreds of GeV and hence production cross-sections of the order of a few pb. A strategy to establish SUSY discovery is outlined in another paper in this collection [1], while here we concentrate on parameter measurements that can be performed with the early data. The same particle identification conventions and selection criteria as in [2] are used in this paper.

Once a signature consistent with Supersymmetry has been established, the experimental emphasis will move on to measuring the sparticle mass spectrum and constraining the parameters of the model. In the case of R-parity-conserving models, the decay chain of sparticles cannot be completely reconstructed, as sparticles eventually decay into LSPs that can not be detected. For this reason edge positions, rather than mass peaks, are measured in the invariant mass distribution of sparticle decay products. In R-parity-violating models sparticles can have long lifetimes and can be detected by studying their decay in-flight within the detector. These types of signatures are discussed in [3].

A complete coverage of all allowed SUSY models is impossible, so we limit this study to a subset of the models where SUSY breaking is mediated by gravity (mSUGRA), and to the points in parameter space described in [2], however the measurement techniques and fit methods developed can be adapted for many models. During initial data-taking, the error on such measurements will be limited by statistics, making measurements possible only for models with moderate ( $\lesssim 1 \text{ TeV}$ ) values of the SUSY mass scale where enough events can be isolated. In this paper we study the cases of a total integrated luminosity of  $0.5 \text{ fb}^{-1}$  for the “Low Mass” point (SU4) and of  $1 \text{ fb}^{-1}$  for the “Bulk” point (SU3), with the idea of developing the experimental analyses which might be performed after the first year or so of data taking. Some benchmark points require somewhat larger datasets in order to perform kinematic measurements; as an example we show a measurement of the dilepton mass edges for the “Coannihilation” point (SU1) with a dataset corresponding to  $18 \text{ fb}^{-1}$ .

In sections 3 and 4 we study the decay chain:

$$\tilde{q}_L \rightarrow \tilde{\chi}_2^0 q (\rightarrow \tilde{\ell}^\pm \ell^\mp q) \rightarrow \tilde{\chi}_1^0 \ell^+ \ell^- q \quad (1)$$

in events containing two opposite-sign isolated electrons or muons, hard jets and missing energy. Kinematic endpoints in the invariant mass spectra of lepton pairs and lepton+jet combinations are fitted and used to derive relations between the masses of sparticles. In the case of first- and second-generation squarks, it will often not be possible to experimentally determine squark flavour, so we define  $m_{\tilde{q}_L}$  to be the average of the masses of the  $\tilde{u}_L$  and  $\tilde{d}_L$  squarks, and  $m_{\tilde{q}_R}$ , the average mass of  $\tilde{u}_R$  and  $\tilde{d}_R$ .

Events with tau leptons in the final state are studied in Section 5 and di-tau mass edges in the  $\tilde{\chi}_2^0$  decay chain reconstructed. This signature is particularly important in the co-annihilation region where the decay into tau stau pairs is favoured.

In Section 6 we analyse events with two hard jets and missing energy in order to measure the jet “stransverse mass”. This variable is sensitive to the mass of the right-handed squark in events where a pair of squarks are produced, each decaying as:

$$\tilde{q}_R \rightarrow q\tilde{\chi}_1^0 \quad (2)$$

A kinematical edge depending on the mass of the light stop is reconstructed in Section 7 by exploiting the decay:

$$\tilde{g} \rightarrow \tilde{t}_1 t \rightarrow \tilde{\chi}_1^\pm b t \quad (3)$$

and reconstructing the  $tb$  invariant mass.

The reconstruction of the lightest Higgs bosons, produced by the  $\tilde{\chi}_2^0$  decay followed by the Higgs decay into a pair of  $b$  quarks, is investigated in Section 8. Simulations of the “Higgs” point (SU9) show that if these decays are allowed, then the Standard Model Higgs boson may be initially detected as a SUSY decay product rather than by signatures that involve its production via Standard Model processes.

In Section 9 the parameters measured in sections 3 to 8 are combined to extract information about the SUSY model such as the sparticle mass spectrum and the mSUGRA parameters (under the hypothesis that mSUGRA is realised).

All of these studies use a realistic detector geometry with residual misalignments, and all relevant Standard Model backgrounds are taken into account, as are the trigger efficiencies. The reconstruction of final state objects, the event selection criteria, the strategy used to simulate both signal and background events, and the methods for estimating systematic uncertainties are common across all SUSY analyses and are discussed in the introduction to this chapter [2].

## 2 Measurement of endpoints

The decay chain in Eq. (1) is particularly suited to measure the mass of SUSY particles, as the presence in the final state of charged leptons, missing energy from the escaping neutralino and hadronic jets ensures a large signal to background ratio. Thus, fit results are not very dependent on the precise measurement of the Standard Model background. Although we discuss the reconstruction of edges and thresholds within the mSUGRA framework, the same methodology can be applied to the large variety of SUSY models where the  $\tilde{q}_L$  decay channel in Eq. (1) is open. In the following we indicate with  $\ell$  only electrons and muons (with  $\tilde{\ell}$  being their superpartners) while  $\tau$  leptons are indicated explicitly.

The endpoint in the di-lepton invariant mass distribution is a function of the masses of the particles involved in the decay. If the sleptons are heavier than the  $\tilde{\chi}_2^0$  then the decay proceeds through the three body channel  $\tilde{\chi}_2^0 \rightarrow \tilde{\chi}_1^0 \ell^+ \ell^-$  as in the SU4 model. In this case, the distribution of the invariant mass of the two leptons has a non-triangular shape described in [4, 5] with an endpoint equal to the difference of the mass of the two neutralinos:

$$m_{\ell\ell}^{\text{edge}} = m_{\tilde{\chi}_2^0} - m_{\tilde{\chi}_1^0} \quad (4)$$

If at least one of the sleptons is lighter than the  $\tilde{\chi}_2^0$  then the two-body decay channel  $\tilde{\chi}_2^0 \rightarrow \tilde{\ell}^\pm \ell^\mp \rightarrow \tilde{\chi}_1^0 \ell^+ \ell^-$  dominates. The distribution of the invariant mass of the two leptons is triangular with an endpoint at:

$$m_{\ell\ell}^{\text{edge}} = m_{\tilde{\chi}_2^0} \sqrt{1 - \left(\frac{m_{\tilde{\ell}}}{m_{\tilde{\chi}_2^0}}\right)^2} \sqrt{1 - \left(\frac{m_{\tilde{\chi}_1^0}}{m_{\tilde{\ell}}}\right)^2}. \quad (5)$$

For the SU3 point, where the  $\tilde{\ell}_R$  and the  $\tilde{\tau}_1$  are lighter than the  $\tilde{\chi}_2^0$ , such an endpoint is expected in the  $\ell^+ \ell^-$  ( $\tau^+ \tau^-$ ) distribution for  $m_{\ell\ell}^{\text{edge}} = 100.2$  GeV ( $m_{\tau\tau}^{\text{edge}} = 98.3$  GeV). For the SU1 point both  $\tilde{\ell}_R$  and  $\tilde{\ell}_L$  as well as  $\tilde{\tau}_1$  and  $\tilde{\tau}_2$  are lighter than  $\tilde{\chi}_2^0$ , resulting in a double triangular distribution for the dilepton invariant mass with two edges.

Measuring the dilepton endpoint allows us to establish a relationship between the masses of the two lightest neutralinos and any sleptons that are lighter than the  $\tilde{\chi}_2^0$ . For a determination of the masses of all the particles involved in the decay chain Eq. (1), further mass distributions involving a jet are used:  $m_{\ell\ell q}$ ,  $m_{\ell\ell q}^{\text{thr}}$ ,  $m_{\ell q(\text{low})}$  and  $m_{\ell q(\text{high})}$ . Since it is not possible to identify the quark from the  $\tilde{q}_L$  decay, we make the assumption that it generates one of the two highest  $p_T$  jets in the event, as is normally the case if the  $\tilde{q}_L$  is much heavier than the  $\tilde{\chi}_2^0$ . Hence only the two leading jets are considered. For the  $m_{\ell\ell q}$  distribution a maximum value of the distribution is expected so the jet giving the lowest  $m_{\ell\ell q}$  value is used. The  $m_{\ell\ell q}^{\text{thr}}$  distribution is defined by the additional constraint  $m_{\ell\ell} > m_{\ell\ell}^{\text{edge}}/\sqrt{2}$ , giving a non-zero threshold value [6, 7]. Since a minimum is sought, the jet giving the highest  $m_{\ell\ell q}$  value is used in this distribution. The distributions  $m_{\ell q(\text{low})}$  and  $m_{\ell q(\text{high})}$  are formed from the lower and higher  $m_{\ell q}$  value of each event using the same jet as for  $m_{\ell\ell q}$ . Both distributions have well-defined endpoints.

The theoretical values of the kinematic threshold and endpoints listed above can be calculated using the analytical expressions given in [6, 7]. The theoretical positions of the end points for the SU1, SU3 and SU4 models are summarised in Table 1.

Table 1: Value of the end points of the invariant mass distributions for the three benchmark points considered in this section. For SU1 the two endpoints correspond to the two available decay chains of the  $\tilde{\chi}_2^0$  involving a right or left slepton.

Mass Distribution	SU1 end point (GeV)	SU3 end point (GeV)	SU4 end point (GeV)
$m_{\ell\ell}^{\text{edge}}$	56.1, 97.9	100.2	53.6
$m_{\tau\tau}^{\text{edge}}$	77.7, 49.8	98.3	53.6
$m_{\ell\ell q}^{\text{edge}}$	611, 611	501	340
$m_{\ell\ell q}^{\text{thr}}$	133, 235	249	168
$m_{\ell q(\text{low})}^{\text{max}}$	180, 298	325	240
$m_{\ell q(\text{high})}^{\text{max}}$	604, 581	418	340

Another advantage of the decay chain in 1 is the possibility of estimating both the SUSY combinatorial background and the Standard Model background from the data with high accuracy. The technique, known as *flavour subtraction*, is based on the fact that the signal contains two opposite-sign same-flavour (OSSF) leptons, while the background leptons come from different decay chains, which can be of the same flavour or of different flavour with the same probability. The background thus cancels in the subtraction:

$$N(e^+ e^-)/\beta + \beta N(\mu^+ \mu^-) - N(e^\pm \mu^\mp) \quad (6)$$

where  $\beta = 0.86$  is an efficiency correction factor equal to the ratio of the electron and muon reconstruction efficiencies. The value of  $\beta$  is taken from [8, 9], and is assumed in the following to be known with an uncertainty of 10%.

### 3 Dilepton edges

#### 3.1 Event Selection

Events with two or three isolated leptons (electrons or muons) with  $p_T > 10$  GeV and  $|\eta| < 2.5$  are selected. If two leptons are selected, they are required to have opposite signs. If three leptons are present, the two opposite-sign combinations are considered and treated independently in the rest of the analysis.

In order to select SUSY events and reject the Standard Model background it is necessary to require the presence of energetic jets and missing energy. The variables used to discriminate SUSY from the SM background are the transverse missing energy, the transverse momenta of the four leading jets, the ratio between the transverse missing energy and the effective mass, and the transverse sphericity ( $S_T$ ). In order to optimise the cuts on these variables, the value of:

$$S \equiv (N_{\text{OSSF}} - N_{\text{OSDF}}) / \sqrt{N_{\text{OSSF}} + N_{\text{OSDF}}} \quad (7)$$

is maximized for each SUSY point, where  $N_{\text{OSSF}}$  and  $N_{\text{OSDF}}$  are the number of same-flavour and different-flavour lepton pairs respectively.

The  $S$  variable can be computed from collider data, since no Monte Carlo information is used. By maximizing the value of  $S$  we are maximizing the selection efficiency for signal events while suppressing the Standard Model and the SUSY combinatorial backgrounds.

In order to improve the sensitivity to the signal, only lepton pairs with an invariant mass  $m_{\ell\ell} < m_{\ell\ell}^{\text{edge}} + 10$  GeV are considered. Since the true value of the endpoint is *a priori* unknown, this choice implies that the edge has already been observed, and that afterwards the selection cuts are optimised as described here in order to improve the separation between signal and background and the measurement of the endpoint. We are thus focusing here on determining selection cuts that would allow a precise measurement of the endpoint with moderate statistics, rather than on finding the first evidence for an excess of different-flavour lepton pairs or the first evidence for the presence of the edge.

In Table 2 the optimal selection resulting from the scan is shown. For all three points a 2-jet selection is preferred, leaving out cuts on the third and fourth jets, on  $S_T$  and on the ratio  $E_T^{\text{miss}}/M_{\text{eff}}$ . For the “Coannihilation” point (SU1) and the “Bulk” point (SU3) the  $S$ -value is found to be stable in an interval around the maximum value. For the “Low Mass” point (SU4) the best  $S$ -value is found for the loosest cut allowed by the available Monte Carlo samples. Hence even looser cuts may be preferred as far as the value of  $S$  is concerned. The cuts on  $E_T^{\text{miss}}$  and the  $p_T$  of leading jet are however required in order to have a high trigger efficiency<sup>1</sup>.

The number of signal and background lepton pairs passing the selection cuts is shown in Table 3. All numbers are for  $1 \text{ fb}^{-1}$ . The main Standard Model background is always  $t\bar{t}$  accounting for about 95% of the total background. The remaining background events are from W, Z and WW, WZ, ZZ production. The background due to QCD jets is negligible. The fraction of SUSY events in the selected sample with OSSF leptons is 59% for SU1, 77% for SU3, and 80% for SU4.

Table 2: Results of the event-selection optimisation for the S-variable Eq. (7) for signal ( $s$ ) and Standard Model background ( $b$ ) with range limit  $m_{\ell\ell} < m_{\ell\ell}^{\text{edge}} + 10$  GeV, for SU1, SU3 and SU4 for  $1 \text{ fb}^{-1}$ . The best selection is shown.

	$p_T^{j1}$	$p_T^{j2}$	$p_T^{j3}$	$p_T^{j4}$	$E_T^{\text{miss}}$	$E_T^{\text{miss}}/M_{\text{eff}}$	$S_T$	$s_{\text{OSSF}}$	$s_{\text{OSDF}}$	$b_{\text{OSSF}}$	$b_{\text{OSDF}}$	$S$
<b>SU1</b>	200	150	-	-	120	-	-	120	64	69	53	5.1
<b>SU3</b>	180	100	-	-	120	-	-	615	149	93	92	15.1
<b>SU4</b>	100	50	-	-	100	-	-	3048	1574	411	419	19.9

Table 3: Number of lepton pairs passing the selection cuts optimized for the SUSY sample SU1 (above), SU3 (middle) and SU4 (below), for  $1 \text{ fb}^{-1}$  of integrated luminosity. The contribution from  $t\bar{t}$  production is indicated separately as it constitutes most of the Standard Model background. The remaining background events are from W, Z and WW, WZ, ZZ production. The background due to QCD jets is negligible.

Sample	$e^+e^-$	$\mu^+\mu^-$	OSSF	OSDF
SUSY SU1	56	88	144	84
Standard Model ( $t\bar{t}$ )	35 (35)	65 (63)	101 (99)	72 (68)
SUSY SU3	274	371	645	178
Standard Model ( $t\bar{t}$ )	76 (75)	120 (115)	196 (190)	172 (165)

Standard Model ( $t\bar{t}$ )	392 (377)	688 (657)	1081 (1035)	1104 (1063)

### 3.2 Reconstruction of the dilepton edge

The distribution of the invariant mass of same-flavour and different-flavour lepton pairs is shown in Fig. 1 for the SUSY benchmark points and backgrounds, after the selection cuts optimized for SU3 (left plot) and SU4 (right plot), and for an integrated luminosity of  $1 \text{ fb}^{-1}$  and  $0.5 \text{ fb}^{-1}$  respectively. It can be seen from regions where the signal does not contribute (i.e. for the Standard Model backgrounds and for  $m_{\ell\ell} > m_{\ell\ell}^{\text{edge}}$  for SUSY) that the different-flavour distributions are similar to the same-flavour backgrounds.

The invariant mass distribution after flavour subtraction is shown in the left plot of Fig. 2 in the presence of the SU3 signal and for an integrated luminosity of  $1 \text{ fb}^{-1}$ . The distribution has been fitted with a triangle smeared with a Gaussian. The value obtained for the endpoint is  $(99.7 \pm 1.4 \pm 0.3) \text{ GeV}$  where the first error is due to statistics and the second is the systematic error on the lepton energy scale and on the  $\beta$  parameter [2]. This result is consistent with the true value of 100.2 GeV calculated from Eq. (5).

The right plot of Fig. 2 shows the flavour-subtracted distribution in the presence of the SU4 signal for an integrated luminosity of  $0.5 \text{ fb}^{-1}$ . The fit was performed using the function from [5] which describes the theoretical distribution for the 3-body decay in the limit of large slepton masses, smeared for the experimental resolution. This function vanishes near the endpoint and is a better description of the true distribution for SU4 than the triangle with a sharp edge. The endpoint from the fit is  $(52.7 \pm 2.4 \pm$

<sup>1</sup>For this channel, both the lepton triggers and the trigger based on  $E_T^{\text{miss}}$  may be relied upon. The latter are however less efficient, and they would imply different  $p_T$  thresholds for electrons and muons.

Figure 1: Left: distribution of the invariant mass of same-flavour and different-flavour lepton pairs for the SUSY benchmark points and backgrounds after the cuts optimized from data in presence of the SU3 signal (left), and the SU4 signal (right). The integrated luminosities are  $1 \text{ fb}^{-1}$  and  $0.5 \text{ fb}^{-1}$  respectively.

Figure 2: Left: Distribution of invariant mass after flavour subtraction for the SU3 benchmark point with an integrated luminosity of  $1 \text{ fb}^{-1}$ . Right: the same distribution is shown for the SU4 benchmark point and an integrated luminosity of  $0.5 \text{ fb}^{-1}$ . The line histogram is the Standard Model contribution, while the points are the sum of Standard Model and SUSY contributions. The fitting function is superimposed and the expected position of the endpoint is indicated by a dashed line.

0.2) GeV, consistent with the theoretical endpoint of 53.6 GeV.

Since the true distribution will not be known for data, the distribution was also fitted with the smeared triangle expected for the 2-body decay chain. This also gives a good  $\chi^2$  with an endpoint of  $(49.1 \pm 1.5 \pm 0.2) \text{ GeV}$ . A larger integrated luminosity will be required to use the shape of the distribution to discriminate between the two-body and the three-body decays.

In Fig. 3 the flavour-subtracted distribution of the dilepton mass is shown for the SU1 point at an integrated luminosity of  $1 \text{ fb}^{-1}$  (left) and  $18 \text{ fb}^{-1}$  (right)<sup>2</sup>. While there is already a clear excess of SF-OF entries at  $1 \text{ fb}^{-1}$ , a very convincing edge structure cannot be located. At  $18 \text{ fb}^{-1}$  the two edges are visible. A fit function consisting of a double triangle convoluted with a Gaussian, the latter

<sup>2</sup>Only  $1 \text{ fb}^{-1}$  of simulated Standard Model background was available. To scale the Standard Model contribution to higher luminosities a probability density function for the  $m(l)$  distribution was constructed by fitting a Landau function to the  $1 \text{ fb}^{-1}$  distribution, assuming statistically identical shapes for  $e^+e^-$ ,  $\mu^+\mu^-$  and  $e^\pm\mu^\mp$  and normalisation according to a  $\beta$  of 0.86. The systematic uncertainty on the endpoint determination from this procedure was estimated to be a small fraction of the statistical uncertainty.

Figure 3: Distribution of invariant mass after flavour subtraction for the SU1 point and for an integrated luminosity of  $1 \text{ fb}^{-1}$  (left) and  $18 \text{ fb}^{-1}$  (right). The points with error bars show SUSY plus Standard Model, the solid histogram shows the Standard Model contribution alone. The fitted function is superimposed (right), the vertical lines indicate the theoretical endpoint values.

having a fixed width of 2 GeV, returns endpoint values of  $55.8 \pm 1.2 \pm 0.2 \text{ GeV}$  for the lower edge and  $99.3 \pm 1.3 \pm 0.3 \text{ GeV}$  for the upper edge, consistent with the true values of 56.1 and 97.9 GeV. As can be seen from Fig. 3 (right) the  $m_{\ell\ell}$  distribution also contains a noticeable contribution from the leptonic decay of Z bosons present in SUSY events. Even though the upper edge is located close to the Z mass, adding a Z peak of fixed mass and width to the fit function only affects the endpoints at the 0.2-0.3 GeV level. However the Z peak changes the normalisation of the upper triangle so for considerations of couplings and branching ratios it should be included.

## 4 Leptons+Jets edges

In events selected for the dilepton analysis in the previous section, jets are added to construct further distributions as described in Sect. 2. Additional selection cuts are applied to refine the distributions:

$$m_{\ell\ell} < m_{\ell\ell}^{\text{edge}} + \Delta_1 \quad (\text{all distributions}) \quad (8)$$

$$m_{\ell\ell q} < m_{\ell\ell q}^{\text{edge}} + \Delta_2 \quad (m_{\ell q} \text{ distributions}) \quad (9)$$

Here  $m_{\ell\ell}^{\text{edge}}$  and  $m_{\ell\ell q}^{\text{edge}}$  refer to experimental values found in this and the previous section. The value  $\Delta_1$  is a small number, 10 (3.3) GeV for SU3 (SU4), to account for the fact that the edge stretches slightly beyond the fitted endpoint. One can see from Fig. 1 that this cut should be very effective for SU4, but much less so for SU3. The value  $\Delta_2$  serves a similar purpose, but since the determination of  $m_{\ell\ell q}^{\text{edge}}$  is less reliable, a looser cut is used, 155 (37) GeV for SU3 (SU4).

The invariant mass distributions  $m_{\ell\ell q}$  and  $m_{\ell q}$  are shown in Figures 4 and 5 for both the “Bulk” point (SU3) and the “Low Mass” point (SU4) after efficiency-corrected flavour subtraction.

While the Standard Model background causes considerable bin-by-bin fluctuations for integrated luminosities  $\lesssim 1 \text{ fb}^{-1}$ , the net contribution of entries beyond the endpoints is mainly due to combinatorics from choosing the wrong jet in a true SUSY event. For the distributions where a clear tail is visible, a straight line is assumed for the background, otherwise it is set to zero. (The statistics box of the plots indicates which background hypothesis is used.) Since the tail is due to SUSY events, it will not be known beforehand and a data-driven approach (not described here) would be required.

The lepton+jet distributions have shapes which depend on the sparticle masses [10]. Depending on the sparticle spectrum, the edge region may contain non-trivial features such as experimentally unde-

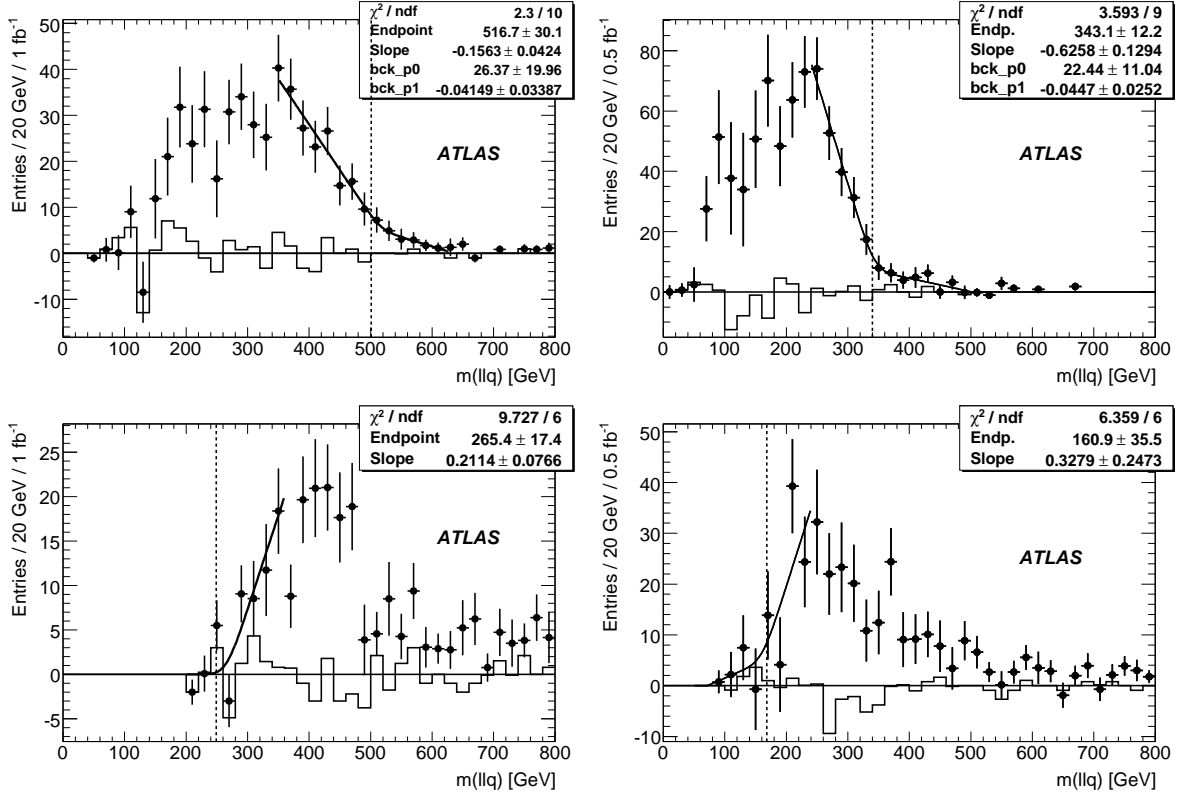

Figure 4: Efficiency-corrected flavour-subtracted distributions of  $m_{\ell\ell q}$  (top) and  $m_{\ell\ell q}^{\text{thr}}$  (bottom) for SU3 (left) for 1 fb<sup>-1</sup> and SU4 (right) with 0.5 fb<sup>-1</sup> of integrated luminosity. The points with error bars show SUSY plus Standard Model, the solid histogram shows the Standard Model contribution alone. The fitted function is superimposed, the vertical line indicates the theoretical endpoint value.

tectable ‘feet’ containing very few events or vertical drops. For all the relevant distributions of two-body scenarios, analytic formulas describing the shape in terms of the sparticle masses are known [11, 12]. With low statistics a straight-line fit is likely to give a sufficiently good description in many cases. All the edges and thresholds were fitted with the following formula,

$$f(m) = \frac{1}{\sqrt{2\pi}\sigma} \int \exp\left(-\frac{(m-m')^2}{2\sigma^2}\right) \max\{A(m' - m^{\text{EP}}), 0\} dm' + \max\{a + bm, 0\}, \quad (10)$$

where  $m^{\text{EP}}$  represents the endpoint (or threshold),  $A$  is the slope of the signal distribution, while  $a$  and  $b$  are the background parameters. The Gaussian smearing gives a smooth transition between the two straight lines and mimics in a simple way the smearing of an edge due to mismeasurement of jet momenta. The smearing parameter  $\sigma$  was fixed to 15 GeV. The fitted endpoint values were found not to be very sensitive to the choice of  $\sigma$  in the range 0–20 GeV. For  $m_{\ell\ell q}$  and the  $m_{\ell q}$  distributions the integration range is  $(0, m^{\text{EP}})$ . For the  $m_{\ell\ell q}^{\text{thr}}$  distribution the lower integration limit is  $m^{\text{EP}}$  while some 100–200 GeV above the upper fit range is a safe upper integration limit. The endpoints resulting from the fits to the distributions in Figures 4 and 5 are summarised in Table 4.

For the ‘Bulk’ point (SU3) the edges are found to be sufficiently well described by a straight line in Eq. (10) for the signal region, however describing the background region by a straight line results in large systematic uncertainties in the endpoint fit. In particular, the  $m_{\ell\ell q}$  distribution does not have a clear edge. Even though the  $m_{\ell\ell q}$  cut in Eq. (9) removes a considerable amount of background for the  $m_{\ell q(\text{low})}$

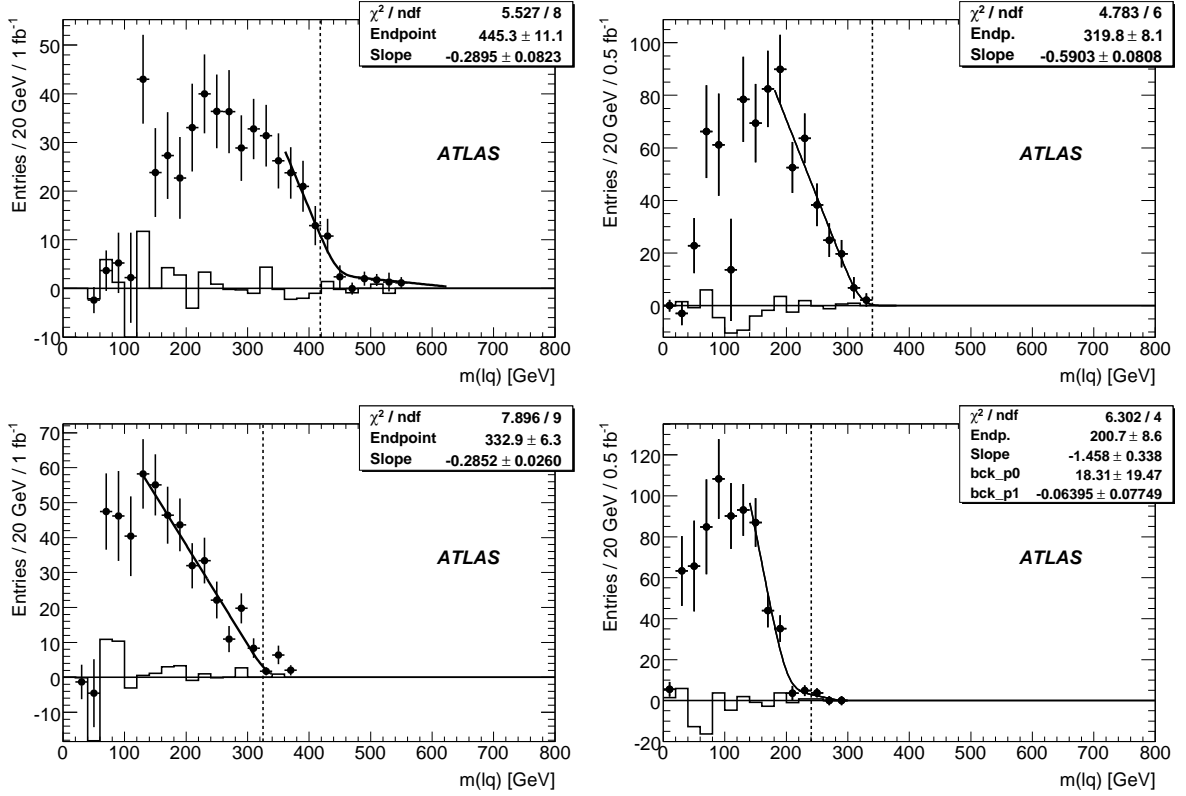

Figure 5: Efficiency-corrected flavour-subtracted distributions of  $m_{lq}^{(high)}$  (top) and  $m_{lq}^{(low)}$  (bottom) for SU3 (left) with 1 fb<sup>-1</sup> and SU4 (right) with 0.5 fb<sup>-1</sup> of integrated luminosity. The points with error bars show SUSY plus Standard Model, the solid histogram shows the Standard Model contribution alone. The fitted function is superimposed, the vertical line indicates the theoretical endpoint value.

distribution there is still some background left for the  $m_{lq}^{(high)}$  distribution. A systematic uncertainty is assigned to account for the background estimation for both fits. In case of  $m_{lq}^{(low)}$  a background-free fit can be made resulting in a few GeV uncertainty. The  $m_{\ell\ell q}^{\text{thr}}$  distribution is expected to be concave, so a systematic uncertainty is added in the estimation when fitting the threshold by a straight line fit.

For SU4, the  $m_{\ell\ell q}$  and both of the  $m_{lq}$  distributions have edges which are well described by the fit function Eq. (10). This is confirmed by the dominance of the statistical errors over the systematics ones. The  $m_{\ell\ell q}^{\text{thr}}$  fit is more problematic resulting in somewhat larger errors. This could be expected since the contributions from different-family and non-signal same-family peaks in this mass region, whereas they are close to vanishing in the edge regions of the other distributions. Another reason (although probably of less importance at 0.5 fb<sup>-1</sup>) is that the threshold edge is concave and only moderately well described by a straight line.

While the fit values of  $m_{\ell\ell q}^{\text{edge}}$  and  $m_{\ell\ell q}^{\text{thr}}$  are compatible with the theoretical values, the fitted  $m_{lq}^{\text{max}^{(high)}}$  and  $m_{lq}^{\text{max}^{(low)}}$  are off by 2 $\sigma$  and 4 $\sigma$ , respectively. This comes from the fact that in SU4 the decay of  $\tilde{\chi}_2^0$  is a three-body decay. In such scenarios the  $m_{lq}$  distributions, and in particular  $m_{lq}^{(low)}$  are often so sparsely populated towards the high mass values that the endpoints are not experimentally deducible from the edges. Note, however, that there is no hint from the  $\chi^2$  of the  $m_{lq}^{(low)}$  fit that we are in such a situation. This topic is discussed further in Sect. 9.1 where endpoint relations are inverted to give sparticle masses.

Table 4: Endpoint positions for SU3 and SU4, in GeV. The first error is statistical, the second and third are the systematic and the jet energy scale uncertainty, respectively. The theoretical values are also given for ease of comparison to the left of the fitted values. The integrated luminosity assumed is  $1 \text{ fb}^{-1}$  for SU3 and  $0.5 \text{ fb}^{-1}$  for SU4.

Endpoint	SU3 truth	SU3 measured	SU4 truth	SU4 measured
$m_{\ell\ell q}^{\text{edge}}$	501	$517 \pm 30 \pm 10 \pm 13$	340	$343 \pm 12 \pm 3 \pm 9$
$m_{\ell\ell q}^{\text{thr}}$	249	$265 \pm 17 \pm 15 \pm 7$	168	$161 \pm 36 \pm 20 \pm 4$
$m_{lq(\text{low})}^{\text{max}}$	325	$333 \pm 6 \pm 6 \pm 8$	240	$201 \pm 9 \pm 3 \pm 5$
$m_{lq(\text{high})}^{\text{max}}$	418	$445 \pm 11 \pm 11 \pm 11$	340	$320 \pm 8 \pm 3 \pm 8$

## 5 Tau signatures

### 5.1 Determination of the di-tau endpoint position

The endpoint of the invariant mass distribution from two taus emerging from a  $\tilde{\chi}_2^0$  decay,

$$\tilde{\chi}_2^0 \rightarrow \tilde{\tau}_1 \tau \rightarrow \tilde{\chi}_1^0 \tau^\pm \tau^\mp, \quad (11)$$

depends on the masses of the  $\tilde{\chi}_2^0$ , the  $\tilde{\chi}_1^0$  and the  $\tilde{\tau}_1$ , and therefore can contribute to the determination of SUSY parameters.

Taus play an important role in scenarios like mSUGRA where  $\tilde{\chi}_2^0$  is mostly wino, and therefore preferentially couples to  $L$ -type sfermions. The large  $L$ - $R$  mixing in the stau sector significantly enhances the branching ratio for the decay  $\tilde{\chi}_2^0 \rightarrow \tilde{\tau}_1^\pm \tau^\mp$  with respect to other leptons. In the scenarios SU1 and SU3 studied here, for example, the branching ratio for the decays into taus is a factor of 10 larger than for decays into electrons or muons. Since in many models (including mSUGRA) the  $\tilde{\tau}_1$  is the lightest slepton, for certain values of the SUSY parameters the only allowed two body decay is  $\tilde{\chi}_2^0 \rightarrow \tilde{\tau} \tau$  as  $\tilde{\chi}_2^0 \rightarrow \tilde{\chi}_1^0 h$ ,  $\tilde{\chi}_2^0 \rightarrow \tilde{\chi}_1^0 Z$ , and  $\tilde{\chi}_2^0 \rightarrow \tilde{e} e$  or  $\tilde{\mu} \mu$  are kinematically forbidden.

Finally, whereas mass information about  $\tilde{\chi}_1^0$  and  $\tilde{\chi}_2^0$  can often be obtained more precisely from  $\tilde{\chi}_2^0$  decays into electrons and muons (if these decays are open), decays into taus are needed to probe the  $\tilde{\tau}$  mass parameters.

In contrast to  $\tilde{\chi}_2^0$  decays into electrons or muons, the di-tau invariant mass spectrum does not have a sharp endpoint at the maximum kinematic value. Due to the presence of neutrinos from the tau decays, the  $m_{\tau\tau}$  distribution (where  $m_{\tau\tau}$  indicates the invariant mass of the visible decay products of the tau pair) falls off smoothly below the maximum value given by either Eq. (4) or Eq. (5). Only hadronic tau decays are considered for tau identification: the tracking-seeded reconstruction algorithm [13] is used to reconstruct taus in the ‘‘Coannihilation’’ point (SU1), while the calorimeter-seeded algorithm [13] is used for the ‘‘Bulk’’ point model (SU3). This choice is motivated by the higher efficiency of the former in reconstructing the low  $p_T$  taus that are present in the SU1 model.

The SU1 point also has a considerably lower cross-section than the SU3 point, so different selection procedures are used to maximize the signal significance. For the SU3 point events are selected with two taus,  $E_T^{\text{miss}} > 230 \text{ GeV}$ , and at least four jets with  $p_T$  greater than 220, 50, 50, 30 GeV respectively. For the SU1 point the cut on  $E_T^{\text{miss}}$  is relaxed to 100 GeV and at least two jets with  $p_T$  greater than 100 and 50 GeV respectively. In addition, an elliptical cut in the space of  $E_T^{\text{miss}}$  and the sum  $p_T(1) + p_T(2)$  of the two highest  $p_T$  jets is applied to SU1. The semi-axes of the ellipse are 450 GeV for  $E_T^{\text{miss}}$  and 500 GeV for the sum of jet  $p_T$ . This cut exploits the anticorrelation between  $E_T^{\text{miss}}$  and  $(p_T(1) + p_T(2))$  which is different for the signal and the Standard Model background.

Figure 6: Invariant mass distribution of opposite-sign tau pairs with same-sign tau distribution subtracted, for the SU1 (18 fb<sup>-1</sup>, left) and SU3 scenarios (1 fb<sup>-1</sup>, right). The dashed histogram in the left plot shows the distribution at the generator level, while points show the reconstruction-level distribution.

The invariant mass distribution emerging after the above cuts are applied is shown in Figure 6 for the SU1 and SU3 scenarios, where the corresponding distribution of two taus with the same sign of electric charge is subtracted from tau pairs with opposite sign in order to reduce combinatorial background. This is possible because uncorrelated and fake taus should arise about as often with the same charge as with opposite charges. To decrease the SUSY background further, the two taus arising from the same decay chain are required to have a maximum separation  $\Delta R < 2$  in the  $\eta$ - $\phi$ -plane.

The following log normal function with three parameters, inspired by [14], is used to fit the  $m_{\tau\tau}$  distribution:

$$f(x) = \frac{p_0}{x} \cdot \exp\left(-\frac{1}{2p_2^2}(\ln(x) - p_1)^2\right) \quad (12)$$

This function does not contain the endpoint position explicitly, but approaches the x-axis asymptotically. The endpoint is then derived from the inflection point  $m_{IP}$  of the fit function:

$$m_{IP} = \exp\left(-\frac{1}{2}p_2^2\left(3 - \sqrt{1 + \frac{4}{p_2^2}}\right) + p_1\right) \quad (13)$$

using a Monte Carlo-based calibration procedure.

The inflection point obtained for 14 SU3-like models is plotted against the theoretical endpoint value for each of these models. The SU3-like points are generated using the ATLAS fast simulation program [15] and varying the masses of the  $\tilde{\chi}_2^0$ , the  $\tilde{\tau}_1$  and the  $\tilde{\chi}_1^0$  separately, while keeping the other two masses fixed. In Figure 7 the inflection point is plotted as a function of the endpoint  $m_{EP}$  and fitted with a straight line, yielding the following calibration function:

$$m_{IP} = (0.47 \pm 0.02)m_{EP} + (15 \pm 2) \text{ GeV} \quad (14)$$

The covariance between the slope and the axis intercept is  $-0.034$  GeV.

The fit using function Eq. (12) for the SU1 and SU3 models is shown in Fig. 6 giving an inflection point at  $m_{IP} = 48 \pm 3$  GeV and  $m_{IP} = 62 \pm 8$  GeV respectively, which translates into endpoints at  $m_{EP} = (70 \pm 6.5^{\text{stat}} \pm 5^{\text{syst}})$  GeV (SU1) and  $(102 \pm 17^{\text{stat}} \pm 5.5^{\text{syst}})$  GeV (SU3) using the calibration relation in Eq. (14). The systematic uncertainty is dominated by the fitting procedure and is evaluated by changing the binning and fit ranges. The effects of 1% and 5% jet energy scale uncertainties have been tested and found to introduce an additional systematic uncertainty on the endpoint measurement well below 3%, so

Figure 7: Calibration curve showing the relation between the position of the inflection point (measured and fitted with function Eq. (12) after ATLAS based detector simulation) and the endpoint (calculated with equation Eq. (5)) of the di-tau mass distribution. The SU3 point is not included.

they are negligible compared to the systematic error introduced by the fitting procedure. The theoretical expectation for the SU1 (SU3) endpoint is 78 GeV (98 GeV). The difference between the theoretical and the extracted endpoint comes from the fitting and fit-calibration procedure rather than from detector effects. As Fig. 6 (left) shows, the generator-level distribution of the visible products is close to the reconstruction-level distribution and after fitting gives an endpoint value of 70 GeV for the SU1 scenario which is the same as for the reconstructed distribution.

## 5.2 Impact of the tau polarization on the di-tau mass spectrum

The method discussed in the previous section assumes a fixed polarization of the two taus from the  $\tilde{\chi}_2^0$  and therefore neglects the effect of the polarization on the invariant mass spectra. However, the polarization of the taus from the decay cascade can vary significantly between different SUSY models. Polarization effects on the di-tau mass distribution are studied by simulating samples of events where the polarization of the two taus from the decay Eq. (11) is allowed to vary. The ATLAS fast simulation program [15] is used to simulate a data sample equivalent to  $51 \text{ fb}^{-1}$  of data.

Parity violation in weak interactions in conjunction with momentum and angular momentum conservation leads to a correlation between the visible tau energy and the polarization of the tau. In case of the decay  $\tau^- \rightarrow \nu_\tau \pi^-$ , since the pion is a scalar particle the neutrino spin is forced to be parallel to that of the tau and therefore the fixed neutrino helicity determines the neutrino momentum direction. Thus, to conserve momentum, the direction of the pion momentum is forced to be parallel or antiparallel to that of the tau depending on the tau polarization. This leads to the pion getting a boost parallel or antiparallel to the tau momentum resulting in harder and softer pions. This affects the di-tau mass spectrum, as shown in Fig. 8. The curves in the plot are theoretical predictions from [16]. The invariant masses of taus with left chirality (LL) are on average smaller than for right (RR) taus.

For decays via the vector mesons  $\rho$  and  $a_1$ , the momentum of the vector meson has the same (opposite) direction as in the case of pions for longitudinal (transverse) polarization of the vector meson.

Adding all hadronic tau decay modes finally yields the invariant mass distributions shown in Figure 8 for the chirality options LL, RR and LR/RL. The position of the trailing edge is clearly shifted for different polarizations whereas the shape difference calculated in [16] is barely visible after detector

simulation.

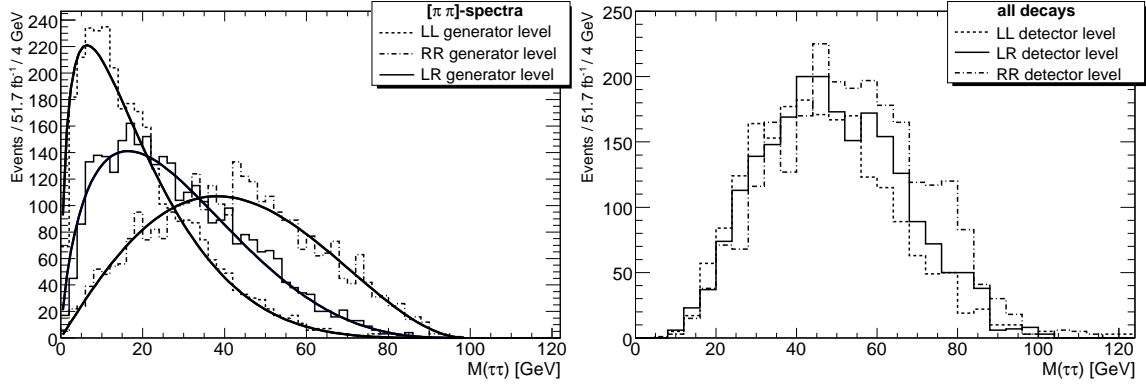

Figure 8: Left: Di-tau invariant mass spectrum for  $\tau \rightarrow \pi \nu_\tau$  decays as obtained from Monte Carlo truth information together with the expectation from theory. Right: Di-tau invariant mass spectrum for all hadronic decays after an ATLFast based detector simulation. Both plots show the mass distributions for the chirality states  $LL$ ,  $RR$  and  $LR/RL$ .

As a consequence, the inflection point of the distribution is shifted due to polarization effects. The maximum difference in the inflection point measurement  $\Delta m_{IPA}(RR - LL)$  has been found to be 7 GeV which is comparable to the statistical error on the position of the inflection point presented in the previous section. Without additional information on the tau polarization we might quickly reach a point where it is not possible to improve the di-tau endpoint measurement. In this case the achievable precision for an integrated luminosity of  $1 \text{ fb}^{-1}$  for the SU3 model is:

$$m_{\tau\tau}^{\max} = 102 \pm 17^{\text{stat}} \pm 5.5^{\text{syst}} \pm 7^{\text{pol}}$$

The uncertainty due to the polarization effects dominates over the other systematic uncertainties and therefore needs special attention. A study of the different polarization dependencies of the decay kinematics for different decay modes of the tau might be helpful. As the emission direction of vector mesons is opposite for longitudinal and transversal states the net effect is determined by the branching ratio into the two states. It turns out that for the  $a_1$  there are as many longitudinal as transverse polarized whereas for the  $\rho$  there are more longitudinal vector mesons, leading to different polarization dependencies.

## 6 $\tilde{q}_R$ pair reconstruction

Events where a pair of  $\tilde{q}_R$  particles is produced, and where each decays through the process

$$\tilde{q}_R \rightarrow \tilde{\chi}_1^0 q \quad (15)$$

lead to a characteristic signature with two high- $p_T$  jets and large  $E_T^{\text{miss}}$  from the escaping neutralinos.  $\tilde{q}_R$  pair production represents about 10% (5%) of the total SUSY production cross-section for the “Bulk” point SU3 (“Low Mass” SU4). For both points (and more generally in most of mSUGRA parameter space) the  $\tilde{q}_R$  decays almost entirely through the process in Eq. (15).

Events with large  $E_T^{\text{miss}}$  and a pair of high- $p_T$  jets are selected by requiring:

- $E_T^{\text{miss}} > \max(200 \text{ GeV}, 0.25M_{\text{eff}})$  and  $M_{\text{eff}} > 500 \text{ GeV}$
- Two jets with  $p_T > \max(200 \text{ GeV}, 0.25M_{\text{eff}})$ ,  $|\eta| < 1$  and  $\Delta R > 1$

Table 5: The total event yield and the number of Standard Model background events satisfying selection criteria for  $m_{T2}$  reconstruction, signal-to-background ratio and signal statistical significance. Only errors from the detector systematic uncertainties are quoted.

	Integrated luminosity ( $\text{fb}^{-1}$ )	Event yield	Standard Model	$S/B_{SM}$	$S/\sqrt{B_{SM}}$
SU3	1.0	$282 \pm 20$	18	$14.7 \pm 1.1$	$62.2 \pm 4.7$
SU4	0.5	$258 \pm 65$	9	$27.7 \pm 7.2$	$83.0 \pm 21.7$

- No additional jet with  $p_T > \min(200 \text{ GeV}, 0.15M_{\text{eff}})$
- No isolated leptons and no jets tagged as  $b$  jets
- Transverse sphericity  $S_T > 0.2$

These selection cuts are tuned using the information from the event generation to select  $\tilde{q}_R$  pair production.

The systematic uncertainty originating from the jet and  $E_T^{\text{miss}}$  energy scale and resolution [2] change the event yield by 7% for the case of SU3 and by 25% for the case of SU4. The systematic effect on the energy scale and resolution of leptons is negligible.

The total event yield and the number of Standard Model background events satisfying the selection criteria for  $1 \text{ fb}^{-1}$  for SU3 and  $0.50 \text{ fb}^{-1}$  for SU4 are given in Table 5 together with the signal-to-background ratio and the signal statistical significance.

To reconstruct the  $\tilde{q}_R$  mass we use the  $m_{T2}$  variable [2, 17, 18], sometimes referred to as “stranverse” mass. This variable uses the kinematic features of the  $\tilde{q}_R$  decays to reconstruct  $m_{\tilde{q}_R}$ <sup>3</sup> making the assumption that  $m_{\tilde{\chi}_1^0}$  is known from the measurements in Section 4. The  $m_{T2}$  distributions for the SU3 and SU4 points are shown in Figure 9. As is common for SUSY measurements, the distribution is expected to have an edge at  $m_{\tilde{q}_R}$  rather than a peak. A linear fit is applied to the right part of the distribution to determine the edge position at  $590 \pm 9(\text{stat})_{-6}^{+13}(\text{sys}) \text{ GeV}$  for SU3 and  $421 \pm 17(\text{stat})_{-3}^{+10}(\text{sys}) \text{ GeV}$  for SU4. This can be compared to the expected positions of  $m_{\tilde{q}_R} = 611 \text{ GeV}$  for SU3 and  $m_{\tilde{q}_R} = 406 \text{ GeV}$  for SU4. The systematic error accounts for the choice of the fit limits as well as the jet energy scale systematic.

## 7 Light stop signature

In the “Low Mass” benchmark point (SU4), the SUSY masses are all in the range  $m_{\tilde{\chi}_1^0} = 60 \text{ GeV} < m < m_{\tilde{t}_2} = 445 \text{ GeV}$ . The stop  $\tilde{t}_1$  is light ( $m_{\tilde{t}_1} = 206 \text{ GeV}$ ) and always decays by  $\tilde{t}_1 \rightarrow \tilde{\chi}_1^\pm b$ . A detailed analysis of the phenomenology of this point can be found in [19].

At this SU4 benchmark point the light stop is produced in the gluino decay Eq. (3) which has a branching ratio of 42%. Associated gluino production with a  $\tilde{q}_L$  or  $\tilde{q}_R$  followed by the decay in Eq. (3) occurs in  $\sim 18\%$  of all SU4 events. In the decay Eq. (3) the final state  $t\bar{b}$  invariant mass distribution has

<sup>3</sup>For the benchmark point considered here, the effect of the SUSY background (i.e. events other than the  $\tilde{q}_R$  pair production which pass the event selection) on the position of the edge is small. This has also been shown to be true for other benchmark points [10]. However, the identification of the edge as a measurement of the  $\tilde{q}_R$  mass may not hold for all the SUSY parameter space.

Figure 9: Fit of the sum of the reconstructed  $m_{T2}$  distributions in the selected SUSY and the remaining Standard Model background events with  $1 \text{ fb}^{-1}$  for SU3 and  $0.5 \text{ fb}^{-1}$  for SU4.

the upper kinematic endpoint:

$$M^{\text{max}}(tb) = \left[ m_t^2 + \frac{m_{\tilde{t}_1}^2 - m_{\tilde{\chi}_1^\pm}^2}{2m_{\tilde{t}_1}^2} \left( (m_{\tilde{g}}^2 - m_{\tilde{t}_1}^2 - m_t^2) + \sqrt{(m_{\tilde{g}}^2 - (m_{\tilde{t}_1} - m_t)^2)(m_{\tilde{g}}^2 - (m_{\tilde{t}_1} + m_t)^2)} \right) \right]^{1/2}. \quad (16)$$

With  $m_{\tilde{g}} = 413 \text{ GeV}$ ,  $m_{\tilde{\chi}_1^\pm} = 113 \text{ GeV}$  and a top mass of  $175 \text{ GeV}$ , Eq. (16) gives

$$M^{\text{max}}(tb) \sim 300 \text{ GeV}. \quad (17)$$

The other significant decays at this benchmark point which lead to the same final state are:

$$\tilde{g} \rightarrow \tilde{b}_1 b \rightarrow \tilde{\chi}_1^\pm tb, \quad (18)$$

$$\tilde{g} \rightarrow \tilde{b}_1 b \rightarrow \tilde{t}_1 W b \rightarrow \tilde{\chi}_1^\pm bbW, \quad (19)$$

$$\tilde{g} \rightarrow \tilde{b}_2 b \rightarrow \tilde{\chi}_1^\pm tb, \quad (20)$$

$$\tilde{g} \rightarrow \tilde{b}_2 b \rightarrow \tilde{t}_1 W b \rightarrow \tilde{\chi}_1^\pm bbW. \quad (21)$$

The final states from the decays Eq. (19) and Eq. (21) are equivalent to the final state from the decay Eq. (3) if the  $bW$  invariant mass is close to the top mass. Associated gluino production with left or right squark followed by these decays occurs in 4% (Eq. (18)), 9% (Eq. (19)), 0.1% (Eq. (20)) and 0.9% (Eq. (21)) of all SU4 events. Due to the small mass difference between  $\tilde{g}$  and the  $\tilde{b}_1$  or  $\tilde{b}_2$ , the final states Eq. (18) and Eq. (19) can be suppressed by imposing a minimum cut on the  $p_T$  of the  $b$  jet, while the final states Eq. (20) and Eq. (21) are suppressed because  $b$  jets originating from the gluino decay  $\tilde{g} \rightarrow \tilde{b}_2 b$  are on the average below the detection threshold.

In order to extract light stop signal from the  $\tilde{g}\tilde{q}$  events where gluino decays to stop and top, the final state  $tb$  invariant mass distribution in Eq. (3) is reconstructed for top quark decays into hadronic final states only:

$$t \rightarrow Wb \rightarrow qqb \quad (22)$$

making no assumptions about the  $\tilde{\chi}_1^\pm$  decay modes which dominantly produce two additional light-quark jets. The hardest jet in the event is assumed to be the light-quark jet originating from the decay of the left or right squark produced in association with the gluino.

We select jets with  $p_T > 20 \text{ GeV}$  and  $|\eta| < 2.5$ . In this range the  $b$ -tagging efficiency is about 60% [1]. The event selection requires the following:

- At least 5 jets in the event with  $p_T > 30$  GeV, where
  - The hardest jet is a light-quark jet with  $p_T > 100$  GeV,
  - 2 and only 2 jets are tagged as  $b$  jets and they have  $p_T > 50$  GeV and
  - At least 2 of the light-quark jets have  $p_T > 30$  GeV
- $E_T^{\text{miss}} > 150$  GeV,  $M_{\text{eff}} > 400$  GeV,  $E_T^{\text{miss}}/M_{\text{eff}} > 0.2$
- $S_T > 0.1$ .

Of the Standard Model backgrounds simulated, only events from our  $t\bar{t}$  and QCD samples satisfy these selection criteria. No  $W$  + jets or  $Z$  + jets events pass the cuts.

The dominant detector-performance systematic uncertainties come from the jet and  $E_T^{\text{miss}}$  energy scale and resolution. Assuming that the uncertainties for  $200 \text{ pb}^{-1}$  are the same as for  $100 \text{ pb}^{-1}$ , i.e. 10% uncertainties on the jet and  $E_T^{\text{miss}}$  energy scale and resolution [20], and including 5% uncertainty on the  $b$ -tagging efficiency, the resulting systematic uncertainty in the number of selected events would be  $\sim 40\%$  for SU4 and  $\sim 50\%$  for  $t\bar{t}$ .

The top-bottom invariant mass is reconstructed for events satisfying the selection criteria for the light stop search:

- Excluding the hardest jet, all light-quark jets with  $p_T^{\text{jet}} > 30$  GeV are combined into dijet pairs.
- All such pairs with invariant mass within the window  $|m_{jj} - m_W| < 15$  GeV are combined with each of the two  $b$  jets and the  $bjj$  combination with invariant mass closest to the top mass is selected.
- The four-vectors of this dijet pair are rescaled such that  $m_{jj} = m_W$  and  $m_{bjj}$  is recalculated and accepted as top candidate if  $|m_{bjj} - m_{top}| < 30$  GeV.
- The same  $bjj$  combination is combined with the other  $b$  jet and  $m_{tb}$  calculated, with the requirement that the angle between top and bottom be  $\Delta R(t, b) < 2$ .

The  $W$  sideband method [21–23] is used to estimate SUSY combinatorial background originating from supersymmetric processes in which jet pairs accidentally have an invariant mass within our  $W$ -mass window, and so fake  $W$  bosons. The sidebands used are the regions of dijet invariant mass 30 GeV below and 30 GeV above our  $W$ -mass window. The fake  $W$  boson contribution to the  $m_{tb}$  distribution is evaluated as the average contribution of the jet pairs from the  $W$  sidebands after they have been scaled linearly to the  $W$  mass zone and the procedure of  $m_{tb}$  reconstruction has been repeated.

The numbers of signal and the remaining Standard Model background events, together with the total event yield at  $200 \text{ pb}^{-1}$ , are listed in Table 6. The  $m_{tb}$  distribution reconstructed in signal events without the subtraction of the SUSY combinatorial background and the SUSY combinatorial background itself are plotted in Figure 10. The contribution of fake  $W$  bosons in SU4 is higher than the number of events remaining after subtraction.

The  $m_{tb}$  distributions before and after the subtraction of the SUSY combinatorial background are shown in Figure 10. The background-subtracted distribution is fitted in order to extract the endpoint. The resulting  $m_{tb}$  distribution is fitted with a triangular function smeared with a Gaussian:

$$f(M) = A \int_{-1}^1 e^{-\frac{(M-M^{\text{max}}\sqrt{\frac{1+x}{2}})^2}{2\sigma^2}} dx + (a + bM),$$

where the kinematic endpoint,  $M^{\text{max}}$ , and the smearing,  $\sigma$ , are two of the five fit parameters. The smearing,  $\sigma$ , models the experimental resolution of the reconstructed  $m_{tb}$ . The position of the upper kinematic

Table 6: The number of signal and remaining Standard Model background events and the total event yield at  $200 \text{ pb}^{-1}$ . The last row gives the signal-to-background ratio. The errors quoted are from detector sources of systematic uncertainty.

$L = 200 \text{ pb}^{-1}$	Initial selection	$ m_{bjj} - m_t  < 30 \text{ GeV}$		$\Delta R(t, b) < 2$	
		without $W$ sub.	with $W$ sub.	without $W$ sub.	with $W$ sub.
SU4	963	537	224	267	120

## 8 Higgs signatures in SUSY events

In the context of supersymmetric models, Higgs bosons at the LHC can be produced in proton collisions either through direct interaction of Standard Model particles, such as gluon-gluon fusion, or through the decay of a supersymmetric particle produced in the initial interaction.

We will consider the possibility of observing the lightest CP-even  $h$  boson via the second mechanism. In this case, a missing transverse energy signature, typical of R-parity conserving SUSY scenarios, can be reconstructed in association with the Higgs boson and exploited to reduce the background, making it possible to study the dominant decay channel  $h \rightarrow b\bar{b}$ , which is otherwise hidden by the enormous QCD continuum.

Within mSUGRA the most promising source of Higgs production is the decay of a second-lightest neutralino. Indeed,  $\tilde{\chi}_2^0 \rightarrow \tilde{\chi}_1^0 h$ , if open, dominates the  $\tilde{\chi}_2^0 \rightarrow \tilde{\chi}_1^0 Z$  mode, because the two lightest neutralinos are basically gauginos, so that the higgsino-gaugino-Higgs vertex is enhanced with respect to the higgsino-higgsino-gauge one. However, if the sleptons are lighter than the  $\tilde{\chi}_2^0$ , the decay channels  $\tilde{\ell}^\pm \ell^\mp$  and  $\tilde{\nu}_\ell \bar{\nu}_\ell$  open up, dominating the  $\tilde{\chi}_2^0$  width. As a consequence, we expect that mSUGRA points interesting for Higgs searches will not show a clear di-lepton signature. The benchmark point chosen for this analysis is SU9, at which  $BR(\tilde{\chi}_2^0 \rightarrow \tilde{\chi}_1^0 h) \sim 87\%$ .

Exploiting the capabilities of the ATLAS detector in missing transverse energy measurement and  $b$  tagging, the passage of weakly interacting particles may be revealed and a  $b\bar{b}$  pair with invariant mass peaking around the Higgs mass can be reconstructed.

Standard Model events with similar signatures which are backgrounds for this analysis, include events with neutrino production causing a genuine  $E_T^{\text{miss}}$  signal and QCD events with fake  $E_T^{\text{miss}}$  generated by instrumental effects. SUSY events can themselves constitute a background, as they contain many  $b$ -jet candidates, both true and mistagged. These can be divided into two categories: SUSY cascades without and with production of a Higgs decaying to  $b\bar{b}$ . In the latter case potential signal events may be incorrectly reconstructed as the selected  $b\bar{b}$  pair is not the one coming from the Higgs decay. We will refer to the former type simply as ‘‘SUSY background’’ and to the latter as ‘‘combinatorial background’’.

The following selection cuts are applied:

1.  $E_T^{\text{miss}} > 300$  GeV;
2. two light-flavoured jets with  $p_T > 100$  GeV;
3. two  $b$  jets with  $p_T > 50$  GeV;
4. no leptons with  $p_T > 10$  GeV.

The first two cuts are typical of SUSY analyses, while the purpose of the last cut is to suppress backgrounds from  $t\bar{t}$  and  $W$  production.

When three or more  $b$  jets with transverse momentum greater than 50 GeV are found in a single event, the second and third leading- $p_T$   $b$ -jets are chosen as the candidate Higgs decay pair. This is because an important source of  $b$  jets is the decay of a bottom squark to  $\tilde{\chi}_2^0$  and  $b$  and since  $m_{\tilde{b}} - m_{\tilde{\chi}_2^0} \sim 500$  GeV  $> m_h$  the sbottom daughters get more allowed phase space than the Higgs daughters and thus, in general, higher  $p_T$ .

In Figure 11 (left) the invariant mass of the selected  $b$  jet pairs is shown assuming  $10 \text{ fb}^{-1}$  of collected luminosity. The shaded histogram corresponds to the sum of the Standard Model backgrounds, the dashed and dotted lines are the SUSY and combinatorial backgrounds respectively. These last two, together with the  $t\bar{t}$  production, are the most important backgrounds. The black curve is the result of a least squares fit to a Gaussian function, representing the Higgs resonance, superimposed on a second degree polynomial background. The estimated number of signal and background events is obtained by counting the  $b$  pairs with invariant mass inside a  $\pm 25$  GeV range around the fitted peak centre. The signal significance, computed in the Gaussian approximation as the number of signal events over the square root of the background, is about 14.

Table 7 summarises the expected event rates after the application of the selection cuts and after the additional mass window request.

SUSY mass spectrum information is reconstructed in the SU9 model by studying the decay:

$$\tilde{q}_L \rightarrow \tilde{\chi}_2^0 q \rightarrow \tilde{\chi}_1^0 h q. \quad (23)$$

Figure 11: Invariant mass of the selected  $b$ -jet pairs (left) and invariant mass of the system consisting of the Higgs plus the jet minimising  $m_{hq}$  (right) for  $10 \text{ fb}^{-1}$  of integrated luminosity.

Table 7: Summary of the number of expected SUSY and Standard Model events after the application of the different selection cuts, for  $10 \text{ fb}^{-1}$  of integrated luminosity.

<b>SU9</b>	Signal	Comb BG	Susy BG
No cuts		11050	21950
Cut 1, 2, 3	356	946	908
Cut 4	230	449	433
$\pm 25 \text{ GeV}$ mass window	179	76	76

<b>Standard Model</b>	$t\bar{t}$	$Z$	$W$	$b\bar{b}$
Cut 1, 2, 3	133	12	22	43
Cut 4	53	8	10	21
$\pm 25 \text{ GeV}$ mass window	11	2	4	4

As a consequence of two-body kinematics, the invariant mass of the Higgs-quark system shows both a minimum and a maximum value, related to different combinations of the masses of the SUSY particles involved.

The events passing the previous selection cuts, including the mass window cut, are also required to have at least one  $b$  jet with  $p_T > 100 \text{ GeV}$ . Furthermore, a veto is imposed on additional  $b$ -tagged jets with  $p_T > 50 \text{ GeV}$ . This will result in fewer signal events, but also in a reduced background contamination yielding a clear distribution shape, albeit with lower signal significance. As in Section 4 the quark from the  $\tilde{q}_L$  is expected to produce one of the two highest- $p_T$  jets and the two distributions  $m_{hq}^{\min}$  and  $m_{hq}^{\max}$  are reconstructed using the jet that maximises and minimises the  $m_{hq}$  value, respectively. Since the background events will tend to concentrate toward low mass values, the  $m_{hq}^{\min}$  (Figure 11, right) is used to determine the mass upper limit  $m_{hq,\text{edge}}$ . The  $m_{hq,\text{threshold}}$  value can be determined from the  $m_{hq}^{\min}$  distribution.

The mass edge value is obtained by fitting a triangular shape convolved with a Gaussian:

$$m_{hq,\text{edge}} = 695 \pm 15 \text{ (stat)} \pm 3 \text{ (syst)} \pm 35 \text{ (JES)},$$

to be compared to the true value of  $732 \text{ GeV}$ . The statistical uncertainty is the error on the fitted parameter,

while the systematic comes from the parameter dependence on the fitting boundaries. An additional 5% systematic error is expected from the jet energy scale (JES) uncertainty.

The mass threshold evaluation is more challenging, since background events tend to populate the low mass region. For an integrated luminosity of  $10 \text{ fb}^{-1}$ , it was not possible to fit to the mass distribution. However, high-statistics studies performed with a fast simulation of the ATLAS detector show that a mass threshold value could be extracted from  $300 \text{ fb}^{-1}$  of collected data, expected after 3 years of LHC running at design luminosity.

## 9 Mass and parameters measurement

This section is devoted to the extraction of SUSY mass spectra and parameters from the measurements described in the previous sections of this note. As an example, the mSUGRA benchmark points SU3 (with a luminosity of  $1 \text{ fb}^{-1}$ ) and SU4 (with  $0.5 \text{ fb}^{-1}$ ) are chosen to give a flavour of what might be expected in the initial phase of the experiment in case of a rather optimistic SUSY scenario. The small luminosity at this stage results in a limited number of available measurements and rather large uncertainties. In such a situation only models with few parameters can be fitted. In Section 9.1 the masses of the decay chain Eq. (1) are derived from the measurement of the kinematic endpoints described in Section 3 and 4. In Sections 9.2 to 9.4 the parameters of the mSUGRA model are derived instead.

### 9.1 Measurement of masses from SUSY decays

We use the information from the experimentally measured endpoints to extract the masses of the SUSY particles. As described earlier in this paper, in many cases analytic expressions have been deduced for the endpoints expressed in terms of the masses. Examples are shown in Eq. (4) and Eq. (5). If sufficient endpoints are known, then the masses can be deduced. Here we use a numerical  $\chi^2$  minimization based on the MINUIT package to extract the SUSY particle masses from a combination of endpoints. We define the  $\chi^2$  as

$$\chi^2 = \sum_{k=1}^n \frac{(m_k^{\max} - t_k^{\max}(m_{\tilde{\chi}_1^0}, m_{\tilde{\chi}_2^0}, m_{\tilde{\ell}_R}, m_{\tilde{q}_L}))^2}{\sigma_k^2}. \quad (24)$$

For each of the  $n$  endpoint measurements,  $k$ , the quantities  $m_k^{\max}$  and  $\sigma_k$  denote the fit value and its uncertainty respectively. The  $t_k^{\max}$  are the theoretical endpoint expressions [6, 10], which contain as parameters the masses of the two lightest neutralinos, the scalar quark  $\tilde{q}_L$ , and (for the two-body decay chain only) the scalar lepton  $\tilde{\ell}_R$ . As a starting point for the fit the generated masses are used. The masses are constrained to be positive in the fit and the mass hierarchies from the model input are enforced.

With the statistics expected for an integrated luminosity of  $1 \text{ fb}^{-1}$  ( $0.5 \text{ fb}^{-1}$ ) for SU3 (SU4) we observe instabilities in the fit. Depending on the fluctuation and precision of the endpoint measurements the fit does not converge. Some of the measured endpoints have shown possible deviations from the generated values of up to several standard deviations. Systematic effects to explain such discrepancies are identified in earlier sections of this article. Significant deviations distort the results and also negatively affect the fit convergence, especially in the presence of degenerate kinematic endpoint equations. We also note large correlations (typically larger than 95%) among the fitted parameters. This is expected, since the endpoints are most sensitive to mass differences. The correlations can also lead to difficulties with convergence and result in larger uncertainties for the fitted masses.

To show a potential result with early data, we quote here the results from converging fits for both the SU3 and SU4 points. We use the endpoints from the lepton+jets edges summarized in Table 4 and the dilepton edge fit from Section 3 ( $99.7 \pm 1.4 \pm 0.3 \text{ GeV}$  for SU3 and  $52.7 \pm 2.4 \pm 0.3 \text{ GeV}$  for SU4). For the SU3 fit, all dilepton+jets edges are used. In the SU4-fit, we discard the  $m_{\ell q(\text{low})}$  measurement as it has been shown not to be very reliable and does not provide additional constraints in three-body

Table 8: Resulting SUSY particle masses and mass differences within SU3 and SU4 from the  $\chi^2$  minimization fit using the dilepton and lepton+jets edges. Shown are the measured masses  $m_{\text{meas}}$  and mass differences  $\Delta m_{\text{meas}}$  followed first by the parabolic errors as returned by MIGRAD and then by the jet energy scale errors. When the measured parameter is anticorrelated with the jet energy scale variation, this is indicated by a  $\mp$  sign. The input Monte Carlo masses  $m_{\text{MC}}$  and mass differences  $\Delta m_{\text{MC}}$  are also shown. The integrated luminosity assumed is  $1 \text{ fb}^{-1}$  for SU3 and  $0.5 \text{ fb}^{-1}$  for SU4.

Observable	SU3 $m_{\text{meas}}$ [GeV]	SU3 $m_{\text{MC}}$ [GeV]	SU4 $m_{\text{meas}}$ [GeV]	SU4 $m_{\text{MC}}$ [GeV]
$m_{\tilde{\chi}_1^0}$	$88 \pm 60 \mp 2$	118	$62 \pm 126 \mp 0.4$	60
$m_{\tilde{\chi}_2^0}$	$189 \pm 60 \mp 2$	219	$115 \pm 126 \mp 0.4$	114
$m_{\tilde{q}}$	$614 \pm 91 \pm 11$	634	$406 \pm 180 \pm 9$	416
$m_{\tilde{\ell}}$	$122 \pm 61 \mp 2$	155		
Observable	SU3 $\Delta m_{\text{meas}}$ [GeV]	SU3 $\Delta m_{\text{MC}}$ [GeV]	SU4 $\Delta m_{\text{meas}}$ [GeV]	SU4 $\Delta m_{\text{MC}}$ [GeV]
$m_{\tilde{\chi}_2^0} - m_{\tilde{\chi}_1^0}$	$100.6 \pm 1.9 \mp 0.0$	100.7	$52.7 \pm 2.4 \mp 0.0$	53.6
$m_{\tilde{q}} - m_{\tilde{\chi}_1^0}$	$526 \pm 34 \pm 13$	516.0	$344 \pm 53 \pm 9$	356
$m_{\tilde{\ell}} - m_{\tilde{\chi}_1^0}$	$34.2 \pm 3.8 \mp 0.1$	37.6		

decay scenarios such as SU4. The  $m_{\ell q(\text{high})}$  endpoint can be measured more reliably and its kinematic expression only differs from the one of  $m_{\ell q(\text{low})}$  by a constant factor. The di-tau edges are not used here.

The masses resulting from the  $\chi^2$  fit are shown in Table 8 (upper part). The parabolic errors are the first errors shown in the table and the jet energy scale errors are the second. Asymmetric errors show a large uncertainty on the positive side. The jet energy scale errors are determined by varying all the endpoints along with their fully correlated jet energy scale uncertainties and refitting the masses. The difference in the central values of the fit is taken as the jet energy scale uncertainty for Table 8. One can see that the jet energy scale errors are small compared to the error on the masses, but might be relevant to the mass difference measurements.

We note that a fit with SU3 kinematic assumptions applied to the SU4 endpoints also returns consistent masses. The decision about the mass hierarchy would thus have to be based on additional information from collider data. A possible source is the shape of the dilepton edge as discussed in Section 3.

Besides the masses we can also extract differences of SUSY particle masses. These are more directly related to the endpoints and we expect to be able to determine them more reliably than the masses of individual sparticles. For mass differences, a  $\chi^2$  similar to Eq. (24) is used, where the parameters are written in terms of mass differences to the neutralino  $\tilde{\chi}_1^0$ . We obtain the results shown in Table 8 (bottom part).

We conclude that a first look at sparticle masses is possible with early data, although with large uncertainties. Appropriate model assumptions and additional information will probably have to be used to constrain the fits.

## 9.2 Observables and fit assumptions

To demonstrate the feasibility of parameter determination with initial data, we show the constraints one would obtain for our benchmark points if one assumed an mSUGRA framework.

The SUSY parameter-fitting package Fittino version 1.4.1 [24] is used, interfaced to a beta version of SPheno3 [25] to perform the theoretical calculations for a given set of parameters.

Figure 12: Two-dimensional Markov chain likelihood maps for mSUGRA parameters  $M_0$  and  $M_{1/2}$  (left) as well as  $\tan\beta$  and  $A_0$  (right) for sign  $\mu = +1$ , for benchmark point SU3, with integrated luminosity of  $1 \text{ fb}^{-1}$ . The crosses indicate the actual values of the parameters for that benchmark point.

The fit is given the measurements presented in sections 3, 4 and 6. The lepton and the jet energy scale uncertainties are each considered to be 100% correlated between measurements. Uncertainties on the theoretical predictions are not taken into account. For illustration purposes an additional parameter determination is performed where – following a prescription used in [26] – 1% (0.5%) uncertainty on the theoretical calculation of the pole masses of coloured (un-coloured) sparticles is assumed. No correlations between the theoretical uncertainties on the pole masses are considered.

### 9.3 Markov chain analysis

To obtain a first glimpse of the possible parameter space a Markov chain analysis is performed. With this technique it is possible to efficiently sample from a large-dimensional parameter spaces. This allows us to check whether there are several topologically disconnected parameter regions which are favoured by the given measurements.

Figure 12 shows two-dimensional likelihood maps for  $M_0$  and  $M_{1/2}$  (left) as well as  $\tan\beta$  and  $A_0$  (right) for sign  $\mu = +1$  obtained for the given set of measurements. The plots demonstrate that for a given sign  $\mu$  preferred parameters are found around the true parameter points independent of the starting point. No further preferred regions occur. For  $M_0$  and  $M_{1/2}$  a clearly preferred region is found around the SU3 values of 100 GeV and 300 GeV, respectively. As expected, given the measurements used, the determination of  $\tan\beta$  and  $A_0$  is more difficult. Nevertheless, here too the region around the nominal SU3 values is the preferred one.

### 9.4 Parameter determination

In order to determine the derived central values of the parameters and their uncertainties, for each assumption of the sign of  $\mu$  a set of 500 toy fits are performed. For each fit the observables are smeared using the full correlation matrix. Simulated annealing followed by a Minuit fit started with the best parameter estimates from simulated annealing is subsequently run using the smeared observables. The four-dimensional distribution of parameters obtained from the toy fits is used to derive the parameter uncertainties and their correlations. Figure 13 shows the one-dimensional projections of parameter distributions for  $M_0$ ,  $M_{1/2}$ ,  $\tan\beta$  and  $A_0$ . The mean and RMS values of the results of the fit are reported in Table 9. As already indicated by the Markov chain analysis  $M_0$  and  $M_{1/2}$  can be derived reliably with

uncertainties  $\pm 9.3$  GeV and  $\pm 6.9$  GeV (RMS of the toy fit results), respectively whereas for  $\tan\beta$  and  $A_0$  only the order of magnitude can be derived from these measurements. The  $\chi^2$  distribution of the toy

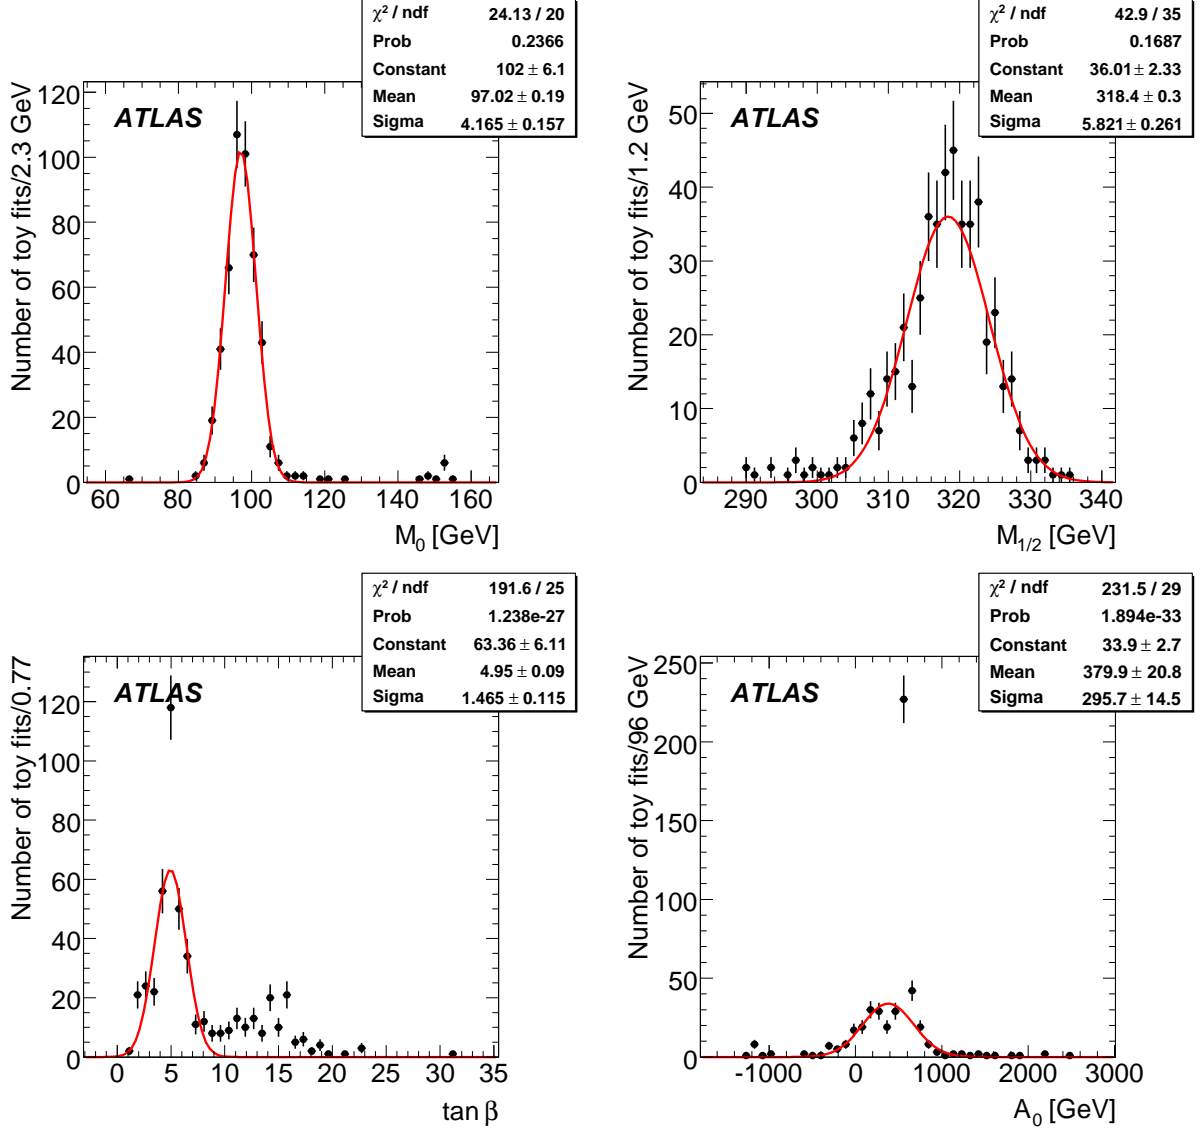

Figure 13: Distributions of the mSUGRA parameters obtained with the fits to pseudo-experiment results.

fits can be used to evaluate the toy fit performance. The observed mean  $\chi^2 = 12.6 \pm 0.2$  for sign  $\mu = +1$  is compatible with the expected value of  $N_{\text{dof}} = 11$ . The solutions for the wrong assumption sign  $\mu = -1$ , also reported in Table 9, cannot however be ruled out as the observed mean  $\chi^2 = 15.4 \pm 0.3$  is also acceptable.

## 10 Conclusions

If the supersymmetric partners of quarks and gluons exist at a moderate mass scale ( $\lesssim 1$  TeV) they will be abundantly produced in  $pp$  collisions at the LHC centre-of-mass energy of 14 TeV. In this scenario, a few  $\text{fb}^{-1}$  of ATLAS data will allow the discovery of the new particles [1], once the commissioning of

Table 9: Results of a fit of the mSUGRA parameters to the observables listed in Sections 3, 4 and 6 for the SU3 point. The mean and RMS of the distribution of the results from the toy fits is reported. The two possible assumptions for the digital parameter  $\text{sign}(\mu) = +1$   $\text{sign}(\mu) = \pm 1$  have been used, resulting in different preferred regions for the other parameters. The effect of different assumptions on theoretical uncertainties is also shown.

Parameter	SU3 value	fitted value	exp. unc.
$\text{sign}(\mu) = +1$			
$\tan\beta$	6	7.4	4.6
$M_0$	100 GeV	98.5 GeV	$\pm 9.3$ GeV
$M_{1/2}$	300 GeV	317.7 GeV	$\pm 6.9$ GeV
$A_0$	-300 GeV	445 GeV	$\pm 408$ GeV
$\text{sign}(\mu) = -1$			
$\tan\beta$		13.9	$\pm 2.8$
$M_0$		104 GeV	$\pm 18$ GeV
$M_{1/2}$		309.6 GeV	$\pm 5.9$ GeV
$A_0$		489 GeV	$\pm 189$ GeV

the detector has been completed and the Standard Model backgrounds have been well understood.

The next step after discovery will be to select specific supersymmetric decay chains to measure the properties of the new particles. Here we have focused on those measurements that will be possible using  $1 \text{ fb}^{-1}$  of integrated luminosity. Specific benchmarks in parameter space have been used to demonstrate the precision that can be expected from these measurements, but the same (or similar) techniques can be applied to much of the SUSY parameter space accessible with early LHC data.

For the benchmark points considered, the most promising decay chain involves the leptonic decay of the next-to-lightest neutralino ( $\tilde{\chi}_2^0 \rightarrow \tilde{\chi}_1^0 \ell^+ \ell^-$ ). The invariant mass of the two leptons shows a clear kinematic maximum (Section 3) which could already be measured with a precision of a few per cent with the limited data set considered. The combination of one or both leptons with the hardest jets in the event would allow observation of several other kinematic minima and maxima (Section 4).

For high values of  $\tan\beta$  the decays into taus will be far more abundant than those involving electrons or muons; the excellent performance expected for the identification and measurement of hadronic  $\tau$  decays in ATLAS will also allow observation of the dilepton edge in the  $\tau^+ \tau^-$  invariant mass distribution (Section 5).

The leptonic decays will not be the only channel for early measurements with supersymmetric decays. The  $\tilde{q}_R \rightarrow q \tilde{\chi}_1^0$  decay can be used to determine the  $\tilde{q}_R$  mass (Section 6). The combination of hadronically decaying top quarks and  $b$ -jets in supersymmetric events is also a promising possibility for low-scale Supersymmetry with decay chains involving scalar top and bottom quarks, as shown by the reconstruction of the edge of the  $t\bar{b}$  invariant mass discussed in Section 7.

If the  $\tilde{\chi}_2^0 \rightarrow \tilde{\chi}_1^0 h$  decay is open, it will provide a substantial source of Higgs bosons. Since the Standard Model backgrounds can be suppressed by the usual SUSY cuts, it will then become possible to observe the  $h \rightarrow b\bar{b}$  decay with moderate ( $5 \text{ fb}^{-1}$ ) integrated luminosity (Section 8).

The different channels will provide complementary information about the SUSY mass phenomenology. The various measurements will have to be combined to reconstruct the SUSY mass spectrum and attempt to understand the SUSY-breaking mechanism. In Section 9 it is discussed how a selected set

of early studies can be combined to obtain the first measurements of supersymmetric masses and of the parameters of the mSUGRA model. With  $1\text{ fb}^{-1}$  the reconstruction of part of the supersymmetric mass spectrum will only be possible for favourable SUSY scenarios and with some assumptions about the decay chains involved. Larger integrated luminosity will help to overcome these limitations, as more measurements become possible and the precision of each increases.

# Multi-Lepton Supersymmetry Searches

## Abstract

We investigate the potential of the ATLAS detector to discover new physics events containing three leptons and missing transverse momentum. Such final states are predicted in a variety of extensions to the Standard Model. In the context of supersymmetric models, they could result from direct production of gaugino pairs. Using Monte Carlo simulations we present the discovery potential for several benchmark Supersymmetry points. We pay particular attention to the case where all strongly interacting sparticles are heavy. We investigate trigger and reconstruction efficiencies and discuss methods for measuring various systematic uncertainties. A solid discovery is expected with an integrated luminosity of the order of several inverse fb. If coloured particles are heavy direct production of gauginos dominates. In such scenarios, discovery would require about an order of magnitude larger luminosity.

## 1 Introduction

If supersymmetric (or other partner) particle production at the LHC is dominated by particles without colour charge, then one of the most promising discovery channels is in multi-lepton + missing transverse momentum ( $E_T^{\text{miss}}$ ) final states with little hadronic activity. In this section we investigate the ability of the ATLAS experiment to discover new physics in events containing three (or more) leptons – either electrons or muons – of which two must have opposite signs but the same flavour (OSSF). We determine the sensitivity which would be obtained for discovery of five benchmark points with an integrated luminosity of  $10 \text{ fb}^{-1}$ .

While an analysis of this channel is clearly sensitive to other models, in this section we use Supersymmetry as our example signature, we assume R-parity conservation, and that the lightest SUSY particle (LSP) is the weakly interacting  $\tilde{\chi}_1^0$ , which provides the missing transverse energy signal.

In the supersymmetric case, the final states of interest could come from leptonic decay of pairs of heavy gauginos (such as  $\tilde{\chi}_2^0$  and  $\tilde{\chi}_1^+$ ) through real or virtual  $W^\pm$ ,  $Z^0$  or sleptons to leptons and a pair of LSPs. The heavy gauginos may be produced directly, or in the decay of heavier partner particles.

The primary aim is to make the most realistic determination which is possible at this time of the discovery potential in this channel. We also wish to identify the most important Standard Model backgrounds, so that analyses can be prepared to measure them in control regions with the ATLAS data.

Throughout this study we use the inclusive Supersymmetry production Monte Carlo samples described in [1]. The points lie in various regions of mSUGRA parameter space in which the LSP relic density is broadly consistent with the observed cold dark matter density.

The Standard Model backgrounds simulated are listed in Table 1. The most important backgrounds are found to be  $t\bar{t}$ ,  $Zb$  and  $ZW$ . Fully leptonic  $ZW$  events represent one significant source of events containing three leptons and missing energy. Their contribution can be reduced by rejecting OSSF lepton pairs with invariant masses consistent with the  $Z$  mass. Leptonic decays of  $t\bar{t}$ , and  $Zb$  are expected to produce two leptons but can generate a third from leptonic  $b$  quark decay. These backgrounds have large cross-sections, but can be reduced by the introduction of stringent cuts on the isolation of the lepton tracks – as we will discuss in Section 3.

A particularly important benchmark point for the trilepton analysis is the point SU2 [1]. This point lies within the ‘focus point’ region of mSUGRA parameter space which is characterised by very large masses for squarks and sleptons and relatively light gauginos. The heavy squarks and sleptons (see Figure 1 and Table 2 for the SUSY mass hierarchy at SU2), will have very small production cross-sections

Table 1: List of the background samples used, with Monte Carlo generator cross-sections ( $\sigma$ ), next-to-leading-order to leading-order  $k$  factors (where known for leading-order generators), average weights ( $\langle w \rangle$ ) and corresponding integrated luminosities. The cross-sections for  $WW$ ,  $WZ$ ,  $ZZ$ ,  $Z\gamma$  and  $Zb$  are quoted after a filter is applied on the generator output requiring at least one lepton with pseudorapidity,  $|\eta| < 2.8$  and transverse momentum,  $p_T > 10$  GeV. The diboson ( $WW$ ,  $WZ$ ,  $ZZ$ ) samples have a different cross-section than the diboson MC@NLO samples (found elsewhere in this volume) because they also include contributions from (and interference with) the photon pole.

Process	$\sigma$ [pb]	$k$ factor	$\langle w \rangle$	$\int dt \mathcal{L}$ [fb $^{-1}$ ]
$WW$	24.5	1.67	1	1.22
$WZ$	7.8	2.05	1	2.98
$ZZ$	2.1	1.88	1	12.7
$Z\gamma$	2.6	1.30	1	2.98
$Zb$	154	1	0.66	0.75
$t\bar{t}$	450	-	0.73	0.92

at the LHC and make it a difficult region in which to discover SUSY using the analyses described in [2] based on the selection of hadronic jets and missing transverse momentum [3]. However, gaugino and gluino production will still be abundant, so we expect good discovery potential in multi-lepton events. The branching ratios of gauginos for SU2 can be found in Table 3<sup>1</sup>.

Figure 1: SU2 sparticle mass spectrum.

Table 2: Particle masses for SU2.

Sparticle	Mass [GeV]	Sparticle	Mass [GeV]
$\tilde{\chi}_1^0$	103	$\tilde{g}$	857
$\tilde{\chi}_2^0$	160	$\tilde{u}_L$	3563
$\tilde{\chi}_3^0$	180	$\tilde{u}_R$	3574
$\tilde{\chi}_4^0$	295	$\tilde{d}_L$	3564
$\tilde{\chi}_1^\pm$	149	$\tilde{d}_R$	3576
$\tilde{\chi}_2^\pm$	287	$\tilde{b}_1$	2925
$\tilde{\ell}_L$	3548	$\tilde{b}_2$	3501
$\tilde{\ell}_R$	3547	$\tilde{t}_1$	2131
$\tilde{\nu}_L$	3546	$\tilde{t}_2$	2935

The total cross-section times branching ratio for chargino-neutralino direct pair production and decay to a tripleton final state is 32.6 fb. Table 4 shows the contribution from each  $\tilde{\chi}^\pm \tilde{\chi}^0$  pair production to a tripleton final state. The contribution from  $\tilde{\chi}^\pm \tilde{\chi}^\mp$  and  $\tilde{\chi}^0 \tilde{\chi}^0$  pair production to a tripleton final state is not tabulated, but also adds a small contribution to the signal. Exclusive tripleton signal for SU2 is dominated by the pair production  $\tilde{\chi}_1^\pm \tilde{\chi}_2^0$  followed by  $\tilde{\chi}_1^\pm \rightarrow \tilde{\chi}_1^0 \ell \nu$  and  $\tilde{\chi}_2^0 \rightarrow \tilde{\chi}_1^0 \ell^+ \ell^-$  decays.

The tripleton signal may include contributions both from direct gaugino pair events and from other SUSY events. The latter can lead to tripleton final states when cascades initiated by heavier sparticles decay via gauginos or sleptons. In a search it is not necessary to distinguish between the various contributions to new physics and so both classes of event form part of the signal. However in this study we are particularly interested in the scenario in which all strongly interacting particles are heavy, since in those cases other analyses (requiring jets) will have more difficulty making a discovery. Since we want to be sensitive to SUSY even in this harder case, we define the signal in two different ways:

<sup>1</sup>The masses and branching ratios were calculated using Isajet v7.71 [4] using a top mass of 175 GeV.

Table 3: Some important branching ratios for the benchmark point SU2.

Sparticle	Decay Mode	B.R.
$\tilde{\chi}_2^0$	$\tilde{\chi}_1^0 \ell^+ \ell^-$	7%
$\tilde{\chi}_3^0$	$\tilde{\chi}_1^0 \ell^+ \ell^-$	7%
$\tilde{\chi}_4^0$	$\tilde{\chi}_1^\pm W^\mp$	81%
	$\tilde{\chi}_3^0 Z$	12%
$\tilde{\chi}_1^\pm$	$\tilde{\chi}_1^0 \ell \nu$	22%
$\tilde{\chi}_2^\pm$	$\tilde{\chi}_2^0 W^\pm$	38%
	$\tilde{\chi}_3^0 W^\pm$	18%
	$\tilde{\chi}_1^\pm Z$	30%

 Table 4: Leading-order cross-sections and number of trilepton events for integrated luminosity of  $10 \text{ fb}^{-1}$  for SU2.

Production	$\sigma$ [fb]	Trilepton events / $10 \text{ fb}^{-1}$
$\tilde{\chi}_1^\pm \tilde{\chi}_2^0$	1138.0	175
$\tilde{\chi}_1^\pm \tilde{\chi}_3^0$	679.3	105
$\tilde{\chi}_1^\pm \tilde{\chi}_4^0$	51.4	6
$\tilde{\chi}_2^\pm \tilde{\chi}_2^0$	58.5	7
$\tilde{\chi}_2^\pm \tilde{\chi}_3^0$	61.6	7
$\tilde{\chi}_2^\pm \tilde{\chi}_4^0$	310.3	26
TOTAL		326

- “Inclusive SUSY” : Inclusive supersymmetric particle pair production (any sparticles)
- “Direct gaugino” : Direct production of charginos and neutralinos only

Inclusive SUSY represents the signal we would obtain at the benchmark points. Direct gaugino represents a more pessimistic scenario, where coloured sparticles are heavy so have no significant LHC cross-section.

## 2 Lepton selection

The final selection will require three leptons – electrons or muons – which must consist of an OSSF pair and a further third lepton. The initial lepton selection requirements are based on the ATLAS standard criteria. The main definitions are summarised in Table 5, and are briefly discussed below. The relatively low  $p_T$  threshold for electrons and muons of 10 GeV in these analyses is an attempt to increase the number of trilepton events, despite lower lepton reconstruction efficiencies at low  $p_T$ .

- **Muons** must satisfy  $p_T > 10 \text{ GeV}$  and  $|\eta| < 2.5$ , and tracks found in the muon spectrometer must match inner detector tracks. For each muon spectrometer track only the best matching track in the inner detector is taken. It is required that the  $\chi^2$  for the match of the muon track to the points on the track [5] is less than 100. A primary isolation criterion requires less than 10 GeV of transverse energy<sup>2</sup> in the calorimeter in a cone of radius  $\Delta R = 0.2$  around the muon<sup>3</sup>.
- **Electrons** must satisfy  $p_T > 10 \text{ GeV}$  and  $|\eta| < 2.5$ . They must satisfy shower shape and isolation requirements as described in [6]. The entire event is rejected if any electron candidate is found in the barrel-endcap transition region ( $1.37 < |\eta| < 1.52$ ) due to the lower electron identification performance in this region. A primary isolation criterion is that electrons must have less than 10 GeV of transverse energy in an annulus of radius  $\Delta R=0.2$  surrounding the electron.

Electrons and muons are then subject to further vetoes as follows: electrons and muons within  $\Delta R < 0.4$  of a jet are removed from the event, along with OSSF pairs with invariant mass  $M_{\text{OSSF}} < 20 \text{ GeV}$ , which are likely to have been produced from photon conversions or hadronic decays.

<sup>2</sup>Transverse energy,  $E_T = E \sin \theta$ , where  $E$  is the energy and  $\theta$  is the polar angle relative to the beam direction.

<sup>3</sup> $\Delta R \equiv \sqrt{\Delta \eta^2 + \Delta \phi^2}$  where  $\Delta \eta$  is the pseudorapidity difference, with  $\eta \equiv -\log \tan(\theta/2)$ , and  $\Delta \phi$  is the difference in azimuthal angle.

Table 5: Selection criteria for muons, electrons and jets.

	Muon	Electron	Jet
$p_T$ cut	$> 10$ GeV	$> 10$ GeV	$> 10$ GeV
$\eta$ cut	$ \eta  < 2.5$	$ \eta  < 1.37$ or $1.52 <  \eta  < 2.5$	$ \eta  < 2.5$
Calorimeter Isolation	$ E  < 10$ GeV in $\Delta R = 0.2$	$ E  < 10$ GeV in $\Delta R = 0.2$	- -

## 2.1 Single lepton selection efficiencies

Searches for SUSY final states with three leptons require both a high lepton reconstruction efficiency and low fake rates. There are few Standard Model processes with similar signatures, but the high cross section backgrounds  $t\bar{t}$  and  $Zb$  can pass the trilepton requirement as there are both primary leptons in the event and a number of jets, in particular  $b$  jets which can introduce secondary leptons. Good isolation criteria are therefore important in order to reduce the fake rate and thus the background. This section presents a study of the lepton efficiency, fake rate and purity for the common object definition which includes a calorimeter based isolation criterion as well as the performance of a track-based alternative.

When collision data are available, the best determination of these quantities will be made from the ATLAS data using the methods described in [7]. Since most of our events of interest will have a similar environment – isolated leptons and little jet activity – we may expect that the values found in those studies should closely match the corresponding quantities in our search. However since those measurements require collision data, in this section we present the efficiencies, fake rates and purities as determined from Monte Carlo information only.

The following isolation criteria have been studied:

- **No isolation cut** - showed as a reference;
- **Calorimeter-based isolation**  $E_{\text{cal}}^{\Delta R=0.2} < 10$  GeV.  $E_{\text{cal}}^{\Delta R=0.2}$  is the energy deposited in a cone with  $\Delta R = 0.2$  around the lepton candidate;
- **Maximum- $p_T$  track-based isolation**  $p_{T\text{track,max}}^{\Delta R=0.2}(\ell) < 2/1$  GeV for  $e/\mu$ , where  $p_{T\text{track,max}}^{\Delta R=0.2}(\ell)$  is the maximum  $p_T$  of any track in a  $\Delta R = 0.2$  cone around the lepton;
- **Sum- $p_T$  track-based isolation**  $p_{T\text{track},\Sigma}^{\Delta R=0.3}(\ell) < 4$  GeV, where  $p_{T\text{track},\Sigma}^{\Delta R=0.3}$  is the sum of the  $p_T$  of all tracks above 1 GeV in a  $\Delta R = 0.3$  cone around the lepton.

The lepton reconstruction efficiency is defined to be

$$\mathcal{E}_\ell \equiv \frac{n_\ell^{\text{match}}}{n_\ell^{\text{MC}}} , \quad (1)$$

where  $n_\ell^{\text{match}}$  is the number of *generator-level* leptons matched to a reconstructed candidate and  $n_\ell^{\text{MC}}$  is the total number of generator-level leptons.

In this study generator-level leptons are defined to be charged leptons ( $\ell \in \{e, \mu\}$ ) which have come from decays of SUSY particles (sleptons and gauginos), Standard Model gauge bosons and tau leptons, but do *not* include leptons from other sources (such as hadronic decays, bremsstrahlung, or photon conversions). No isolation cut has been applied on these generator-level leptons. Generator-level particles are matched to reconstructed candidates which have passed kinematics cuts and object selection according to the definition in Section 2. A match is required to be found within  $\Delta R = 0.02$ . Figure 2 shows

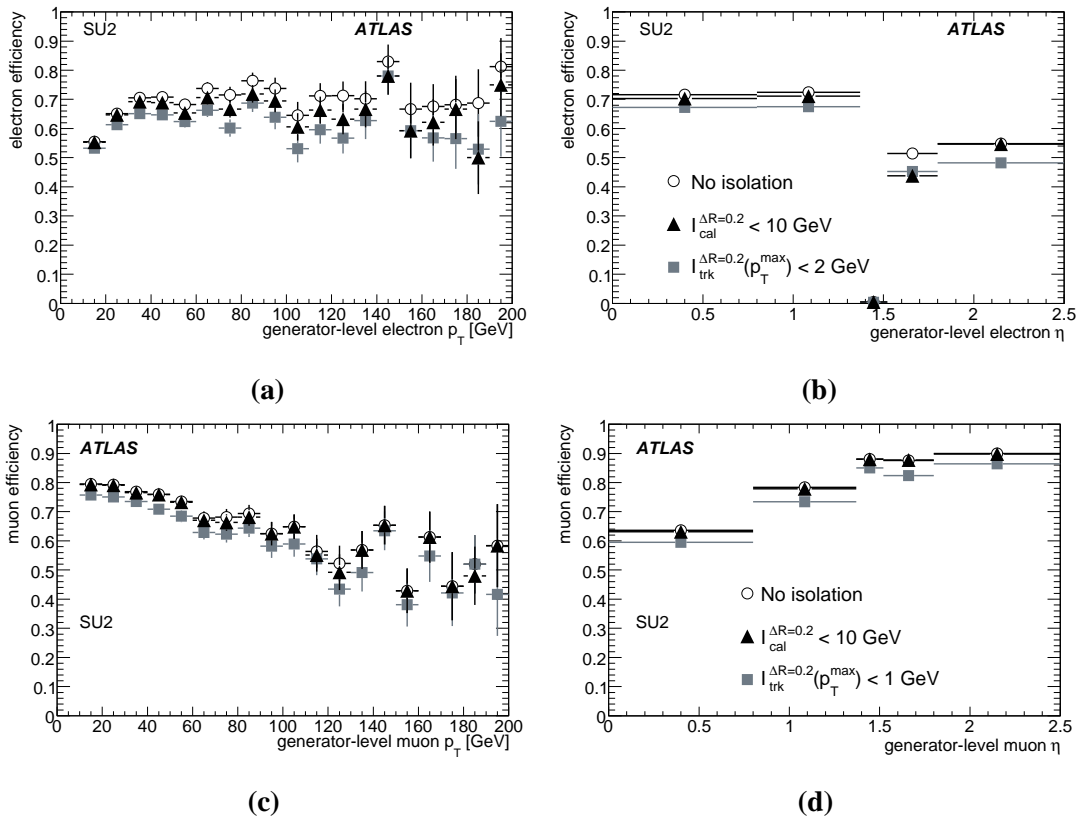

Figure 2: The efficiency for electrons (a,b) and muons (c,d) to be reconstructed and to pass various isolation criteria, for the SU2 sample. The plots are shown as a function of the  $p_T$  (a,c) and  $\eta$  (b,d) of the matched Monte Carlo lepton.

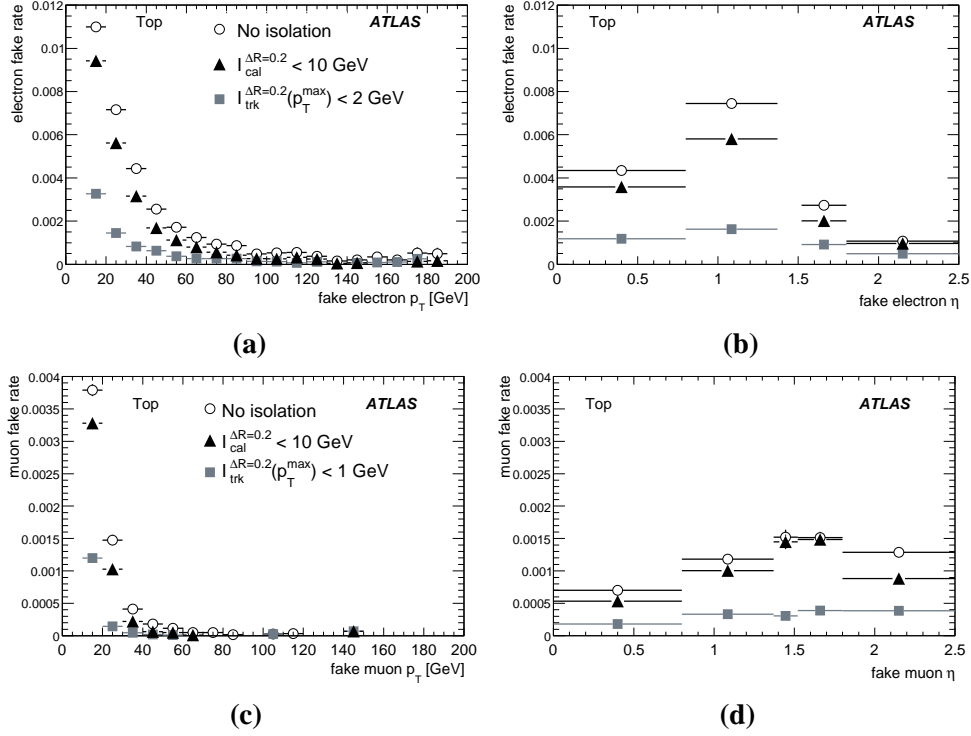

Figure 3: The fake rate for electrons (a,b) and muons (c,d) in the  $t\bar{t}$  sample as function of the  $p_T$  (a,c) and  $\eta$  (b,d) of the fake lepton.

the reconstruction efficiency for electrons and muons from the SU2 sample using different isolation requirements as function of the  $p_T$  and  $\eta$  of the matched Monte Carlo lepton.

The requirement that leptons should be separated from selected jets by  $\Delta R > 0.4$  (referred to as the  $\Delta R(\ell, \text{jet}) > 0.4$  cut) is already a strong isolation requirement which reduces the efficiency by  $\sim 5\%$  for electrons and  $\sim 15\%$  for muons. For the case of  $t\bar{t}$  events (not shown in the figures) the effect is even larger as there are more jets in the events.

For the muons, one can see that after introducing the  $\Delta R(\ell, \text{jet}) > 0.4$  cut, the efficiency decreases with increasing  $p_T$ , while the  $|\eta|$  distribution decreases in the central region  $|\eta| \lesssim 1.4$ . A clear drop in electron efficiency can be found near  $|\eta| \approx 1.4$  which is the barrel-endcap transition region.

After applying only the  $\Delta R(\ell, \text{jet}) > 0.4$  cut (referred to as “no isolation” in the plots), the total efficiency is  $(65.5 \pm 0.5)\%$  and  $(75.2 \pm 0.5)\%$  for electrons and muons respectively. The calorimeter-based isolation  $E_{\text{cal}}^{\Delta R=0.2} < 10 \text{ GeV}$  reduces the electron efficiency by  $\approx 3\%$  to  $(63.6 \pm 0.5)\%$  while leaving the muon efficiency almost unchanged. The track-based alternative has similar effect on both lepton flavours causing a loss of about 7 to 8% with respect to the “no isolation” performance.

The fake rate is defined as

$$\mathcal{F}_\ell \equiv \frac{n_{\ell}^{\text{MC,match}}}{n_{\text{jet}}^{\text{MC}}}, \quad (2)$$

where  $n_{\ell}^{\text{MC,match}}$  is the number of reconstructed leptons which are *not* matched to a generator-level lepton and  $n_{\text{jet}}^{\text{MC}}$  is the number of jets at the generator level<sup>4</sup>.

Only generator-level jets with  $|\eta| < 2.5$  are considered. They are rejected if there is an overlap with an electrons within  $\Delta R < 0.2$ , but in general include photons, hadronic tau jets and  $b$  jets. The generator

<sup>4</sup>i.e. jets found by running a jet algorithm over the Monte Carlo generator final state, before detector simulation.

jet must have energy,  $E > 7$  GeV. Asymmetric  $p_T$  cuts are applied to the reconstructed objects compared to their Monte Carlo equivalents. For the efficiency calculation  $p_{T\ell}^{\text{MC}} > 10$  compared to  $p_{T\ell} > 5$  GeV, while for the fake rate calculation  $p_T^{\text{MC}} > 5$  and  $p_{T\ell} > 10$  GeV. This reduces the number of mismatches which would be found near the edge of the fiducial region from small mismeasurements of  $p_T$ .

Figure 3 shows the fake rate as function of the  $p_T$  and  $\eta$  of the fake lepton for the  $t\bar{t}$  sample (one of the major backgrounds). The  $p_T$  distribution is clearly peaked at low values typical for leptons from  $b$ -jet decays. The  $\eta$  distribution follows the detector layout with higher fake rate in the transition region between the barrel and end caps.

The  $\Delta R(\ell, \text{jet}) > 0.4$  requirement provides a reduction in the fake rate of about  $\approx 80\%$  for muons and  $\approx 5\%$  for electrons (as compared to leptons passing the standard selection with  $E_{\text{cal}}^{\Delta R=0.2} < 10$ ). With no isolation other than the  $\Delta R(\mu, \text{jet}) > 0.4$  requirement one obtains a fake rate of  $(4.1 \pm 0.1) \times 10^{-3}$  and  $(1.1 \pm 0.1) \times 10^{-3}$  for electrons and muons respectively. The isolation criteria provide a similar relative suppression of the electron and muon fake:  $\approx 20\%$  for  $I_{\text{cal}}^{\Delta R=0.2} < 10$  and  $\approx 74\%$  for  $p_{T\text{track,max}}^{\Delta R=0.2}(\ell) < 2/1$  GeV for  $e/\mu$ . The effect of the isolation cuts is very similar in the case of the SU2 sample, but the fake rates are almost an order of magnitude lower than in  $t\bar{t}$  events.

We define purity by:

$$\mathcal{P}_\ell = \frac{n_\ell^{\text{match}}}{n_\ell}, \quad (3)$$

where  $n_\ell$  is the number of reconstructed leptons, and the matching criteria are as described above. The lepton selection described in Section 2 provide samples with a purity of 92% (e) and 97% ( $\mu$ ) with very similar results for both the SU2 and  $t\bar{t}$  samples. However after requiring at least 3 leptons in the event there is a clear difference between the two. The purity is almost unchanged for SU2, while, in  $t\bar{t}$  trilepton events the purity drops to  $\sim 50\%$  for electrons and  $\sim 70\%$  for muons.

### 3 Event selection

Events are required to pass either of the two single-lepton triggers, labelled L2\_22i and L2\_mu20, which are well-suited for the tri-lepton analysis at  $\mathcal{L} = 10^{31-32} \text{ cm}^{-2}\text{s}^{-1}$ . A more detailed discussion of the motivation for using these triggers can be found in Section 5.

Distributions of some important event variables for Standard Model backgrounds and for the benchmark point SU2 (both for inclusive SUSY and direct gaugino) can be found in Figure 4. We show the  $p_T$  distributions of reconstructed leptons (electron or muon) and jets. Requiring at least three leptons in the event results in mainly  $t\bar{t}$  and  $Zb$  Standard Model backgrounds, with larger contributions from dibosons in four lepton events. It can be seen in Figures 4a and 4b that  $p_T$  distributions of the two hardest leptons in three lepton events are similar in SU2 and  $t\bar{t}$ , with  $Zb$  adding a significant contribution in the low  $p_T$  region. The  $p_T$  distributions for the third-hardest leptons are plotted in Figure 4c where it can be seen that whilst  $t\bar{t}$  and  $Zb$  are the major backgrounds in the low  $p_T$  region, there is a large contribution from the dibosons across the entire  $p_T$  range. This is because the third leptons from  $t\bar{t}$  and  $Zb$  are soft leptons from leptonic  $b$ -quark decay, whereas all the leptons from dibosons are from  $Z/W^\pm$  boson decays. The  $p_T$  distributions of the reconstructed jets are plotted in Figure 4d for events with three or more leptons.

Since an OSSF lepton pair is expected from the  $\tilde{\chi}_2^0$  decay, a selection requiring two OSSF leptons is applied (i.e. we require  $e^+e^- + \ell$  or  $\mu^+\mu^- + \ell$ , where  $\ell \in e, \mu$ )<sup>5</sup>. A further cut requires three or more leptons in the event.

A stringent cut on the isolation of the tracks of the leptons is made next, using the  $p_{T\text{track,max}}^{\Delta R=0.2}$  variable described in Section 2.1. The purpose is to reduce backgrounds from bremsstrahlung, hadron decays and

<sup>5</sup>Trilepton events where all three leptons have the Same Sign, (SS,  $\ell^\pm \ell^\pm \ell^\pm$ , where  $\ell \in e, \mu$ ) have also been investigated, however due to the very low statistics associated with the channel in the signal samples investigated, it is not considered further here.

Figure 4: Transverse momentum of the leading three leptons (a-c) and leading-jet  $p_T$  (d) after an initial three-lepton requirement has made.

 Figure 5:  $p_{T,track,max}^{\Delta R=0.2}$  for (a) electrons and (b) muons.

 Figure 6: (a) OSSF dilepton invariant mass distribution. (b)  $E_T^{\text{miss}}$  distribution after the  $Z$  mass window cut. (c) The  $p_T$  distribution of the leading jet after the  $E_T^{\text{miss}}$  cut is applied.

photon conversions. The relevant distributions for electrons and muons are plotted in Figure 5a and 5b. The plots contain negative entries when no track is found within  $\Delta R$ . We require  $p_{T,track,max}^{\Delta R=0.2} < 1$  GeV for muons and  $< 2$  GeV for electrons. This reduces the number of background events to 23% ( $t\bar{t}$ ) and 37% ( $Zb$ ) of their previous levels, whilst keeping 82% (inclusive SUSY), 86% (direct gaugino) of the signal for our SU2 benchmark point.

The diboson and  $Zb$  backgrounds will produce the two OSSF leptons mainly from  $Z$  decays, which will not be the case for three-body decays of neutralinos. The dilepton invariant mass distribution is shown in Figure 6a, (after applying the cuts already described) and shows the expected peak at the  $Z$  mass. A simple way to reduce these backgrounds is to discard events which have any OSSF dilepton pair with invariant mass in the mass window  $81.2 \text{ GeV} < M_{OSSF} < 101.2 \text{ GeV}$ . Note that this exclusion window also offers an excellent control region in which to measure the size of these backgrounds from the data. It is however somewhat model-dependent. Some points in SUSY parameter space preferentially decay through *real*  $Z$  bosons, rather than through three-body decays. At those points the OSSF dilepton mass distribution would also be strongly peaked at the  $Z$  mass.

A large missing-transverse-momentum cut is used in most SUSY analyses, but in this analysis a smaller cut at 30 GeV is applied since in direct gaugino production the two invisible  $\tilde{\chi}_1^0$ s are often almost back-to-back in the transverse plane, resulting in a lower overall  $E_T^{\text{miss}}$  (Figure 6b). Missing transverse momentum is calculated as described in [8].

Finally there is the possibility of adding a cut that can be made on the hadronic activity in the event. This

could be useful in the case where direct gaugino production dominates, since it can be expected to reduce the  $t\bar{t}$  background to a greater extent than the signal. Whether this cut is appropriate will depend on the SUSY scenario presented by nature, so analyses both with and without this cut will be necessary.

Selected jets must satisfy  $p_T > 10$  GeV and  $|\eta| < 2.5$ , and are reconstructed based on calorimeter tower signals [9] using a seeded cone algorithm with radius  $\Delta R = 0.4$ . Jets are initially selected with  $p_T > 10$  GeV and  $|\eta| < 2.5$ . Jets are not considered if they overlap with a reconstructed electron within  $\Delta R < 0.2$ .

The  $p_T$  distribution of the leading jet in the event is plotted in Figure 6c, where it is seen that the direct gaugino production has jets with lower  $p_T$  than the Standard Model backgrounds. The level of this cut is chosen at  $p_T > 20$  GeV.

The complete event selection is then:

1. At least one pair of OSSF leptons ( $e^+e^-$  or  $\mu^+\mu^-$ )
2.  $N_\ell \geq 3$  ( $\ell \in \{e, \mu\}$ ), and where all  $\ell_i$  satisfy the requirements in Section 2
3.  $p_{T\text{track,max}}^{\Delta R=0.2} < 2$  GeV for electrons,  $p_{T\text{track,max}}^{\Delta R=0.2} < 1$  GeV for muons
4. No OSSF dilepton pair has invariant mass in the range  $81.2 \text{ GeV} < M_{\text{OSSF}} < 102.2 \text{ GeV}$
5.  $E_T^{\text{miss}} > 30 \text{ GeV}$
6. Optional – no jet with  $p_T > 20 \text{ GeV}$

In Figure 7 we show distributions of the invariant mass of the dilepton pair after all cuts. The distributions have been flavour subtracted; the quantity plotted is

$$n^{\text{OSSF}} - n^{\overline{\text{OSSF}}}, \quad (4)$$

where  $n^{\text{OSSF}}$  is the number of events in the signal selection (containing OSSF dilepton pairs) as described earlier in this section, and  $n^{\overline{\text{OSSF}}}$  is the number of events in which there are three leptons, but no OSSF pair. The non-OSSF events give an indication of the expected background size since many background sources do not necessarily produce OSSF pairs.

## 4 Discovery potential

The numbers of events and the resulting significance at each stage of the analysis are listed in Table 6 for the benchmark point SU2. We use the following definition of signal significance,

$$\mathcal{S} = \frac{S}{\sqrt{S+B}} \quad (5)$$

where  $S$  is the number of signal events and  $B$  is the number of background events. After applying the event selection above (including the jet veto), 29 events remain for SU2 inclusive SUSY all of which are direct gaugino, with an expected background of 210 events (mainly  $ZW$  production). This corresponds to  $\mathcal{S}$  of 1.87 for  $10 \text{ fb}^{-1}$ . This yields a  $5\sigma$  discovery signal after  $\sim 80 \text{ fb}^{-1}$  of integrated luminosity. With the jet veto selection,  $ZW$  is the dominant remaining Standard Model background. Without the jet veto, 177 signal events (95 of them direct gaugino) remain. Statistical significances of 5.94 and 3.34 are found for the inclusive SUSY and direct gaugino signals respectively.

The expected statistical significances for various mSUGRA benchmark points are summarised in Table 7 excluding the jet veto unless indicated otherwise by “SUx+JV”.

Figure 7: Distributions of the OSSF dilepton invariant mass after all selections have been applied (a) without the jet veto and (b) including a jet veto.

Table 6: Numbers of events and statistical significance as selection is applied for the benchmark point SU2, for integrated luminosity of  $10 \text{ fb}^{-1}$ .

Kinematic Cut	No Cuts	$N_L \geq 2$	OSSF	$N_L \geq 3$	TrackIsol	$m_{\ell\ell}$	$E_T^{\text{miss}}$	JetVeto
SU2 gauginos	64.0k	1647	1108	178	153	120	95	29
SU2 other	7081	776	353	127	95	85	82	0
$t\bar{t}$	4.41M	234k	104k	2812	634	507	476	42
ZZ	38.2k	10.4k	9984	580	476	57	13	6
ZW	156k	17.2k	14.5k	1910	1682	322	218	154
WW	400k	22.7k	10.7k	25	8	8	8	8
$Z\gamma$	32.8k	7184	6970	91	27	7	3	0
$Zb$	1.59M	57.4k	559k	6523	2409	386	0	0
inclusive SUSY $\mathcal{S}$		2.60	1.74	2.76	3.36	5.31	<b>5.94</b>	<b>1.87</b>
direct gaugino $\mathcal{S}$		1.77	1.32	1.61	2.09	3.20	<b>3.34</b>	<b>1.87</b>

The discovery prospects for inclusive SUSY, reflected in columns titled “SUx”, are rather encouraging: a  $5\sigma$  discovery can be expected with several  $\text{fb}^{-1}$  of integrated luminosity<sup>6</sup>. The direct gaugino pair production is highlighted in columns marked as SU2 $\chi$  and SU3 $\chi$ . Both for SU2 and SU3 we see a drop in significance which roughly corresponds to the fraction of the direct gaugino production compared to the total SUSY cross-section. In fact, the drop is somewhat higher, since the  $p_T$  spectrum tends to be softer for direct gaugino pair production compared to strong SUSY production with its characteristic decay chains. Here, a discovery can be expected with several tens of  $\text{fb}^{-1}$ .

## 5 Lepton trigger study

Unlike most SUSY searches, in this channel we cannot rely on jet or  $E_T^{\text{miss}}$  triggers. We have studied a variety of triggers at the second level<sup>7</sup>, after the first level trigger has been applied. Other studies [10, 11]

<sup>6</sup>Taking into account statistical errors only. Systematic uncertainties are discussed in Section 6.5.

<sup>7</sup>ATLAS has three trigger levels: a first level (L1) hardware trigger, a software-based second level trigger (L2) that examines regions of interest within the detector, and finally a software-based event filter (EF). More details about the electromagnetic [10] and muon [11] triggers may be found elsewhere in this volume.

Table 7: Discovery potential, and integrated luminosity required for  $5\sigma$  discovery. The jet veto is only applied in columns headed ‘+JV’. For a fuller description of the notation, see the text.

	SU1	SU2	SU3	SU4	SU8	SU2 $\chi$	SU3 $\chi$	SU2+JV	SU3+JV
$\mathcal{S}, 10 \text{ fb}^{-1}$	7.7	5.9	17.2	69.3	1.9	3.3	1.6	1.9	1.4
$\int dt \mathcal{L} \text{ for } 5\sigma$	4.2	7.1	0.8	0.1	70.5	22.4	92.9	66.9	119.3

Table 8: Fraction of events triggered at L2 at three selection stages of the selection for the heavy coloured sparton scenario in SU2 (first block), the direct gaugino production in SU3 (second block), and the inclusive SU3 signal (third block). “ $\cup$ ” stands for the OR-combination of L2\_e22i and L2\_mu20.

Selection Stage	SU2 $\chi$			SU3 $\chi$			SU3 incl.		
	L2_e22i	L2_mu20	$\cup$	L2_e22i	L2_mu20	$\cup$	L2_e22i	L2_mu20	$\cup$
OSSF pair	41%	54%	89%	42%	54%	92%	51%	51%	94%
OSSF+3 <sup>rd</sup> $\ell$	58%	67%	93%	59%	63%	95%	66%	68%	98%
after all cuts	57%	66%	92%	58%	57%	94%	66%	64%	97%

demonstrate that objects passing L2 have a high efficiency for passing EF.

As a figure of merit, the fractions of triggered events

- after selecting for an OSSF pair;
- after requiring a further third lepton;
- after all cuts, including the jet veto;

are studied.

We have identified two single-lepton triggers, labelled L2\_e22i and L2\_mu20, that are well-suited for the tri-lepton analysis at  $\mathcal{L} = 10^{31-32} \text{ cm}^{-2}\text{s}^{-1}$ . At high luminosity it is planned to have corresponding triggers with additional isolation criteria (e22i\_tight and mu20i) which will remain unscaled. The resulting event-triggering efficiencies are listed in Table 8. OR-combined, they have  $\approx 92\%$  probability for direct gaugino production for the benchmark point SU2. They have sufficiently high  $p_T$  thresholds to be easily studied with leptonic  $Z$  decays.

The same trigger set was studied for the direct gaugino and inclusive SUSY for another benchmark point, SU3, that has lighter squarks than SU2. Again the OR-combination of L2\_e22i and L2\_mu20 shows a good performance of  $\sim 92, 95, 94\%$ . Their individual L2 event efficiencies are summarised in the middle block of Table 8.

In addition we have studied the performance of the L2\_e22i and L2\_mu20 triggers for the tri-lepton analysis, outside of the heavy coloured sparton scenario, for inclusive SU3 production. Again in this case we find L2 event efficiencies of around  $\sim 94, 98, 97\%$ .

The efficiency is relatively high for lepton triggers even though the trigger thresholds are fairly high compared to the offline cuts on lepton transverse momenta. The reason for that is simple combinatorics: since the 3 leptons are ordered by their transverse momenta, it is likely that the leading lepton has a high  $p_T$  if the third one passes the offline threshold. On the other hand, cases where *all* the three leptons are below 20 – 30 GeV but above 10 GeV are unlikely.

We have investigated how the leptonic trigger efficiencies for the inclusive SUSY and direct gaugino for the benchmark point SU2 change as a function of the progressive event selection stages described in Section 3. In both cases, the trigger efficiencies reach their approximate maxima after the three-lepton selection stage. Beyond this cut stage, the efficiency values plateau, indicating that our event

selection requirements should not bias signal trigger efficiencies. It can be concluded that the L2\_e22i and L2\_mu20 single lepton triggers provide a good performance for the tri-lepton analysis in the early days of ATLAS running at  $\mathcal{L} = 10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ . Di-leptonic triggers with lower thresholds like 2e12i, 2mu10, and e15i\_mu10 can be used to recover events where all three leptons have low transverse momenta around 20 GeV.

## 6 Systematic uncertainties

The dominant sources of systematic uncertainty for this search are different to other SUSY search channels that focus on final states containing jets. For our multi-lepton search the main sources of uncertainty in the backgrounds are described below.

### 6.1 Background rates

The production rates for the majority of background processes such as diboson production and  $t\bar{t}$  are known at the parton level at better than next-to-leading order. However, it is generally better to determine the rate of these backgrounds from the ATLAS data themselves, reducing any uncertainty from luminosity, PDFs and other systematics (e.g. from acceptances, efficiencies etc). The background rate measurements should be made in “control regions” in which they dominate. For the  $WZ$  background a sensible control region is the region of phase space where the OSSF lepton pair has an invariant mass near the  $m_Z$  [12]. For the  $t\bar{t}$  background, one would examine single lepton and OSSF dilepton channels [13]. Any statistical uncertainty in the background measurements forms a systematic uncertainty in our analysis. The expected integrated luminosities for cleanly measuring each background and the resulting statistical uncertainties can be found in Table 9.

Any further systematic uncertainties in the background rates are not considered here so as not to double-counting their effects<sup>8</sup>. One must be careful that the extrapolation from the ‘control’ to the ‘measurement’ region of parameter space is well understood. The extrapolation for the backgrounds involving the  $Z$  peak relies on the  $Z$  line-shape, which is theoretically well-known. The extrapolation from dilepton to trilepton final states for  $t\bar{t}$  relies on a good knowledge of the rate at which  $b$  quarks (from top decays) produce isolated leptons. A method of determining this rate from the ATLAS data is presented in Section 6.3.

Table 9: Expected rates to cleanly select background samples in control regions, and the corresponding statistical uncertainties.

Background	Statistical uncertainty after $10 \text{ fb}^{-1}$ [%]	Reference
$WW$	1.3	[12]
$WZ$	2.6	[12]
$ZZ$	6.6	[12]
$t\bar{t}$	$\ll 1$	[13]

One can see from Table 6 that, after event selection and jet veto, the  $WZ$  and  $t\bar{t}$  backgrounds are most significant in the signal region. The systematic uncertainty in measuring the rate of the backgrounds in

<sup>8</sup>In fact, uncertainties on background rates that positively correlate between the selection region and the control region will actually tend to cancel.

the control regions is expected to be of the order of a few percent maximum for the  $WZ$  and even smaller for the  $t\bar{t}$  (Table 9). Our estimate for the total systematic uncertainty due to statistical fluctuations in the background control sample is therefore dominated by the  $WZ$  background. When multiplied by the fraction of the final background that comes from  $WZ$ , this generates 1.9% (0.8%) uncertainty in the background rate for the analysis with (without) the jet veto.

## 6.2 Trigger and reconstruction efficiencies

Lepton trigger and reconstruction efficiencies can be determined using the “tag-and-probe” method for electrons and muons coming from  $Z \rightarrow \ell\ell$  [7].

Table 10: Expected systematic uncertainties on background rates from other ATLAS measurements using the tag-and-probe method, and resultant estimated uncertainties for this analysis. The label ‘reco’ refers to combined reconstruction and selection efficiencies.

Source	Tag-and-probe [7] ( $1\ell^\pm, 1\text{fb}^{-1}$ )	This analysis ( $10\text{fb}^{-1}$ )	
		$1\ell^\pm$	$3\ell^\pm$
$e$ (trigger)	$\ll 1\%$	} 0.5 %	} 2.3%
$\mu$ (trigger)	0.4 %		
$e$ (reco)	0.5 %	1 %	
$\mu$ (reco)	$\ll 1\%$	$\ll 1\%$	

The precision with which lepton trigger and reconstruction efficiency can be determined has been studied in [7] for an integrated luminosity scaled to  $1\text{fb}^{-1}$ . The statistical uncertainty on the trigger efficiency for  $1\text{fb}^{-1}$  is very small ( $\ll 1\%$ ) and is negligible for  $10\text{fb}^{-1}$ . The systematic uncertainties in determining the trigger efficiencies are shown in Table 10. The trigger efficiency uncertainty for our analysis, for which the highest- $p_T$  lepton has similar kinematics to the sample used in [7], is therefore estimated to be  $\lesssim 0.5\%$  for  $\int dt \mathcal{L} = 10\text{fb}^{-1}$ .

Reconstruction and selection efficiencies have also been studied using a similar method [7]. The estimates of the uncertainties in the efficiencies are also contained in Table 10. We have increased the expected uncertainty in the electron reconstruction efficiency from the “tag-and-probe” value of 0.5% to our own estimate of 1% to reflect a somewhat larger uncertainty for our lower  $p_T$  electrons.

In the final column of Table 10 we estimate the resulting systematic uncertainty for the trilepton selection efficiency of this analysis. Since we propose using single lepton triggers (Section 5), only the highest  $p_T$  lepton contributes, and our event trigger uncertainties are the same as the single-lepton trigger ones. All three leptons are assumed to contribute to reconstruction and selection uncertainties, with equal contributions from electrons and muons. Our resulting uncertainty from combined trigger, reconstruction and selection efficiencies is 2.3%.

For this study we assume that similar uncertainties will apply with and without the jet veto, but we note that there may be larger systematic uncertainties in lepton efficiencies if jets are permitted in the final state.

## 6.3 Lepton fake rates

The  $t\bar{t}$  and  $Z + b$  backgrounds contribute to the trilepton final state when (along with a lepton pair from dileptonic  $t\bar{t}$  decay or  $Z$  decay) a  $B$  hadron decays leptonically, producing a third isolated lepton. The third lepton requirement reduces each of these backgrounds by a large factor – about two orders of magnitude in each case. About one order of magnitude of reduction can be accounted for by the

branching ratio of  $B$  hadrons to leptons, while the other factor of about ten arises from our rejection of non-isolated leptons. We are therefore sensitive to the rate at which leptons from  $b$  decays pass the isolation criteria, which we denote  $R_{b \rightarrow \ell}$  (it should be understood to include leptons both from direct  $b \rightarrow \ell$  and also from  $b \rightarrow c \rightarrow \ell$ ).

We hereby propose a method by which  $R_{b \rightarrow \ell}$  could be measured in the ATLAS data, and estimate the remaining systematic uncertainty after that measurement. The control sample we suggest is semi-leptonic  $t\bar{t}$  decays in which a lepton from one (probe)  $b$  decay generates a same-sign dilepton pair. To cleanly select the control sample we would require events with  $t\bar{t}$  kinematics (*e.g.* consistent invariant masses for  $t$  and  $W$ ) and one clean vertex tag from the other (probe)  $b$  jet. This sample has the further advantage that the  $b$  quarks have the correct kinematical distributions for the background of interest (dileptonic  $t\bar{t}$ ). The same-sign dilepton requirement removes contamination from normal dileptonic  $t\bar{t}$  decays since the latter will produce opposite-sign lepton pairs.

Dedicated studies [13] suggest that we can expect to cleanly select about  $n_{t\bar{t} \rightarrow \ell\ell} = 5 \times 10^4$  semi-leptonic  $t\bar{t}$  events ( $e$  and  $\mu$  combined) for  $\int dt \mathcal{L} = 10 \text{ fb}^{-1}$ . The fractional statistical uncertainty,  $\delta$ , that we could expect from the proposed measurement of  $R_{b \rightarrow \ell}$  is then,

$$\delta(R_{b \rightarrow \ell}) = \frac{1}{\sqrt{R_{b \rightarrow \ell} \times n_{t\bar{t} \rightarrow \ell\ell}}} . \quad (6)$$

From examination of the event record in our Monte Carlo samples, we found  $R_{b \rightarrow \ell}$  to be approximately  $5 \times 10^{-3}$ . If a similar rate were to be found from measurements of the semi-leptonic  $t\bar{t}$  events, then the corresponding value for  $\delta(R_{b \rightarrow \ell})$  would be 6%.

With a jet veto,  $t\bar{t}$  forms about 20% of the background after full selection (and  $Z + b$  a very small contribution), and there is a resulting  $\approx 1.2\%$  uncertainty in the total background. Without the jet veto, the  $t\bar{t}$  contribution is much larger (about 66%) and a 4% systematic uncertainty results.

## 6.4 Jet and missing energy scales

The global uncertainty on the jet energy scale is currently conservatively expected to be about 5%, but the true value is difficult to determine without collision data. In events in which the missing transverse momentum is dominated by hadronic activity, the fractional uncertainty in  $E_T^{\text{miss}}$  will be of a similar size, since the two measurements will be highly correlated. We therefore determined the effect of a 5% systematic uncertainty in the missing energy when no jet veto is used.

For the analysis which includes a jet veto, we expect missing energy scale uncertainty to be rather smaller than 5%, since the majority of the missing energy will recoil against the (well-measured) leptons. We also assume that in this case the systematic uncertainties in the jet energy scale and the missing energy should also be largely uncorrelated (for the same reason). Measurements of recoil of jets against  $Z$  bosons and photons allow the missing energy resolution to be well-determined as a function of jet energy [8]. Any residual uncertainty in the missing energy scale is estimated by us to be about 2% at low hadronic energies (based on systematic differences between methods in [8]).

For the jet-veto analysis, we determined the effects of a 5% variation in the hadronic energy scale and (an independent) 2% variation in the missing energy scale. The results are shown along with the systematic uncertainties from other sources in Table 11.

As well as the uncertainty from the energy scales, there can be some contribution to the uncertainty in the number of events failing the jet veto from our lack of knowledge of initial-state radiation (ISR) in electro-weak processes (such as  $WZ$  production). However the ISR spectrum can be readily determined from other electroweak production control regions (as described in [14] for single electroweak gauge boson production). The resulting statistical uncertainties in those control measurements will be small, and the systematic effects tend to cancel with those described in this section, so no additional systematic uncertainty is added here.

## 6.5 Summary of systematic uncertainties

Table 11: Estimates of the dominant uncertainties in the background determination for  $\int dt \mathcal{L} = 10 \text{ fb}^{-1}$ .

Source	Uncertainty	
	No jet veto	With jet veto
Background production rates	0.8%	1.9%
Lepton Efficiency	2.3%	2.3%
Fakes ( $R_{b \rightarrow \ell}$ )	4.0%	1.2%
Hadronic energy scale	–	1.8%
Missing energy scale	1.5%	1.0%
<i>Total systematic</i>	4.9%	3.8%
<i>Statistical</i>	3.7%	6.9%
<i>Statistical + Systematic</i>	6.2%	7.9%

Our best current estimates of the various sources of uncertainty are summarised in Table 11. One can see that with the full selection, including the jet veto, and if the supporting measurements can be made with the precision expected, then the SUSY-search analysis will be limited by statistical fluctuations in the background samples (about 6.9%) rather than by systematic sources of uncertainty (about 3.8%).

Without the jet veto, the statistical uncertainty is smaller, however the systematic contribution to the total uncertainty increases to 4.9%, largely because we have an increased sensitivity to  $R_{b \rightarrow \ell}$  since the top background is much larger if no jet veto is applied.

## 7 Conclusions

The ATLAS experiment will have sensitivity to new physics, including supersymmetry, in events with three leptons in association with missing transverse momentum. For most of the SUSY benchmark points studied, a discovery of new physics could be made in this channel with integrated luminosity of several  $\text{fb}^{-1}$ . Models in which all strongly interacting partner particles are heavy would have smaller cross-sections, but could also be discovered with integrated luminosity of the order of several tens of  $\text{fb}^{-1}$ .

The major sources of systematic uncertainty were indicated and methods for determining these from data discussed. While the actual sizes of these uncertainties can only be estimated reliably with collision data, estimates based on existing information were presented. In particular, knowledge of the rate at which  $b$  jets lead to seemingly-isolated leptons was found to be an important element in understanding Standard Model backgrounds. A method of measuring this rate from the data using  $t\bar{t}$  events was proposed.

# Supersymmetry Signatures with High- $p_T$ Photons or Long-Lived Heavy Particles

## Abstract

In certain Supersymmetry breaking scenarios, characteristic signatures can be expected which would not necessarily be found in generic SUSY searches for events containing high  $p_T$  multi-jets and large missing transverse energy. This paper describes the expected response of the ATLAS detector to four signatures: high- $p_T$  photons which may or may not appear to point back to the primary collision vertex and long-lived charged sleptons and  $R$  hadrons. Such processes often have the advantage of small Standard Model backgrounds and their observation could provide unique constraints on the different SUSY breaking scenarios. Using these signatures discovery potentials are estimated for either Gauge-Mediated Supersymmetry Breaking or Split-Supersymmetry scenarios. Using Monte Carlo samples of SUSY and background processes corresponding to integrated luminosity of about  $1 \text{ fb}^{-1}$  we study all aspects of the analysis, including the expected trigger response and offline data reconstruction.

## 1 Introduction

Supersymmetry (SUSY) is one of the most widely investigated theories of physics beyond the Standard Model [1–4]. Searches for signatures of new physics processes predicted within SUSY models are thus central to the physics program of the ATLAS experiment [5], which will be sensitive to the production of SUSY particles with masses up to several TeV [6]. To facilitate the exploitation of early LHC data, a number of preparatory studies have been undertaken by the ATLAS SUSY group to estimate the response of the ATLAS detector to a variety of physics processes and to optimise and test the software which is necessary for the analysis of collider data. As a part of this exercise, the ATLAS SUSY group has performed a number of studies. Techniques to estimate Standard Model backgrounds have been developed [7, 8] and calculations have been made of the discovery potential for generic inclusive SUSY signatures [9], based largely on the minimal SUGRA model [10–14] for which the principal observables are high- $p_T$  jets and missing transverse energy. However, there exist a number of SUSY scenarios which predict specific final state topologies which may not be observed by generic searches, such as prompt photons and long-lived stable massive particles. In this work, the response of the ATLAS detector to such signatures is studied and, where appropriate, calculations are made of discovery potentials for early LHC running for which an integrated luminosity of around  $1 \text{ fb}^{-1}$  is assumed. Although the work is performed within the framework of SUSY searches, the techniques which have been developed are more generally applicable to searches for new phenomena.

The theoretical models used in this work are based on the minimal Gauge Mediated Supersymmetry Breaking (GMSB) model [6, 15–21], the Split-SUSY model [22–25] and the gravitino LSP model [26]. A description of the models is given in Section 2.1 while specific choices of parameters are found in the sections devoted to each of the studied signatures. Four signatures are investigated and are described below.

**Two high- $p_T$  photons +  $E_T^{\text{miss}}$**  : In a GMSB scenario in which the next lightest supersymmetric particle (NLSP) is the  $\tilde{\chi}_1^0$ , two high- $p_T$  photons are expected in each signal event each arising from the decay of a  $\tilde{\chi}_1^0$  to a  $\tilde{G}$  and photon. Such events with two isolated high- $p_T$  photons plus large  $E_T^{\text{miss}}$  have small Standard Model backgrounds and a high mass discovery reach is expected even in the early LHC

running. In the high mass regime, however, the production cross-section for SUSY events and the signal is of the same order as the instrumental background which includes misidentified photons arising from electrons or jets, and the irreducible background of radiation from leptons. Earlier experiments have exclusions limits of 93 GeV in  $\tilde{\chi}_1^0$  mass and 167 GeV in  $\tilde{\chi}_1^\pm$  mass [27].

**Non-pointing photons:** In certain GMSB scenarios, the  $\tilde{\chi}_1^0$  could be relatively long-lived. When the decay length is comparable to the size of ATLAS inner-detector, high- $p_T$  photons could enter the electromagnetic calorimeter surface at large incident angles with respect to a pointing direction to the beam interaction point. An estimation of how the photon reconstruction and identification efficiency is degraded for such non-pointing photons is essential in any measurement of the  $\tilde{\chi}_1^0$  lifetime, which is directly connected to the SUSY breaking scale. Current lower limits on the mass and lifetime are 101 GeV and 5 ns, respectively [28].

**Stable sleptons:** Stable<sup>1</sup> heavy charged sleptons appear in certain regions of parameter space in GMSB scenarios. This signature consists of a penetrating charged track. Since interactions with detectors are ionizations only, the observed tracks will look more like muons, except for their higher energy deposition and longer time of flight than muons. The ATLAS muon system provides a time of flight measurement with an excellent time resolution ( $\sigma_{tof} \approx 0.7\text{ns}$ ) [29], which allows for a precise particle mass measurements for slow particles. Owing to the very high LHC bunch crossing rate, the development of an appropriate triggering scheme is critical to the ensuring the detection of such particles. Previous experiments have provided a lower limit of around 105 GeV in slepton mass [30].

**Stable  $R$  hadrons:** Stable massive supersymmetric hadrons ( $R$  hadrons) are predicted in Split-SUSY models or in the gravitino LSP scenario of SUGRA models [26]. The signature of  $R$  hadrons is similar to that of stable sleptons although multiple nuclear interactions before reaching the muon system lead to characteristic event topologies, such as the appearance of high- $p_T$  tracks in the muon system with no matching track in the inner-detector, or the electric charge flipping between the inner-detector and the muon system. Lower mass limits of around 200 GeV have already been established by other experiments [31].

This paper is organized as follows. Section 2 provides an overview of the different models and a description of the Monte Carlo datasets which were used in this work. Sections 3-6 describe the studies of signatures described above. Finally, a conclusion is given in Section 7.

## 2 Overview of the SUSY models and Monte Carlo datasets

The signal Monte Carlo data samples used in this paper are based on the specific supersymmetry breaking scenarios. These models are described in Section 2.1. Some technical details and parameter values used in individual datasets are summarized in Section 2.2. Common background samples are used which are described in the introduction to this chapter [32]. In some cases, fast simulation (ATLFAST-I [33]) samples are also used when estimating the background contributions.

### 2.1 SUSY scenarios considered in this paper

- **GMSB (Gauge-Mediated Supersymmetry Breaking) scenarios:** in GMSB, SUSY breaking which takes place in hidden sector is transmitted to visible MSSM fields through a messenger sector whose mass scale is much below the Planck scale ( $M_m \ll M_P$ ) via the ordinary Standard Model gauge interactions. The gravitino is very light (in general  $\ll 1$  GeV) and is always the LSP. In the minimal model of GMSB, all Supersymmetry breaking interactions are determined by a few

---

<sup>1</sup>The term stable is used throughout this chapter to refer to particles which, although they may possess finite lifetimes, do not decay during their traversal of the ATLAS detector.

parameters. The phenomenologies studied in this paper are based on this minimal model. Discussions of the non-minimal GMSB models are found elsewhere [34, 35].

The squarks, the sleptons, and the gauginos obtain their masses radiatively from the gauge interactions with the massive messengers; their masses therefore depend on the number of messenger generations,  $N_5$  (the index 5 comes from the fact that the messenger fields form complete  $SU(5)$  representations).

The gaugino masses scale like  $N_5$  while the scalar masses scale like  $\sqrt{N_5}$ . Hence for  $N_5 = 1$ , the NLSP is the lightest neutralino ( $\tilde{\chi}_1^0$ ) which decays into photon and a gravitino ( $\tilde{G}$ ). For  $N_5 \geq 2$ , the NLSP is a charged stau ( $\tilde{\tau}_1$ ). When  $\tan\beta$  is not too large, the mass splitting between the  $\tilde{\tau}_1$  and the right-handed selectrons, smuons ( $\tilde{e}_R, \tilde{\mu}_R$ ) is small, rendering them co-NLSP's which decay into leptons and gravitinos. In contrast, in the large  $\tan\beta$  region, the stau is the sole NLSP.

The effective SUSY breaking order parameter  $F_S$ , felt by the messengers, may not coincide with the intrinsic underlying SUSY breaking order parameter  $F$ , which determines the coupling strength. When  $F_S$  is smaller, the NLSP decay length becomes longer. The dimensionless factor  $C_G = F/F_S (\geq 1)$  is introduced to control the NLSP decay length with all the other parameters fixed. The decay length is proportional to the square of the control parameter, i.e. scales as  $C_G^2$ .

The effective visible sector SUSY breaking parameter,  $\Lambda (= F_S/M_m)$  sets the overall mass scale for all the MSSM superpartners, which scales linearly with  $\Lambda$ . On the other hand, these masses only depend logarithmically on the messenger scale  $M_m$ . The MSSM masses are therefore predominantly determined by the scale  $\Lambda$ .

- Split-SUSY scenario: Stable exotic hadrons feature in a number of SUSY scenarios. Split-SUSY is one such model. Within this approach the hierarchy problem and the fine tuning of the Higgs mass is accepted, or assumed to be set by another, as yet unknown, mechanism. Phenomenologically, within Split-SUSY scenarios the gauginos and higgsinos have light masses of order the weak scale, which are protected by the chiral symmetry while the scalars have a mass scale  $m_s$  which can be near the GUT scale. Since gluino decays proceed via internal squark lines, gluinos can be meta-stable. A meta-stable gluino will form a bound state, a so-called  $R_{\tilde{g}}$ -hadron.
- A gravitino LSP and a stop NLSP scenario: in addition to stable gluinos, meta-stable stops are also features of some SUSY models. Here, the stops are usually the NLSP and decay to a gravitino LSP with gravitational strength interactions. The generic possible candidate for NLSP is the lightest stop  $\tilde{t}_1$ , which, like the gluino case in split SUSY scenario, would form stable bound states, denoted  $R_{\tilde{t}}$ .

## 2.2 Parameter values used in this work

The basic feature of the samples used in this paper are similar to those introduced in [32]. However, our studies also investigate sparticles which decay with a measurable decay length, and new techniques have been introduced to allow these to be simulated. As in Ref. [32], ISAJET7.74 [36] was used to generate the sparticle mass spectrum in the context of minimal GMSB scenarios. The leading order (LO) and the next-to-leading order (NLO) cross-sections were assessed independently using PROSPINO2.0 [37–39]. The mass spectrum tables from ISAJET were used by HERWIG/JIMMY [40, 41] to generate the sparticle cascade decays, parton showers, hadronisations, and underlying events. The HERWIG option *plcut* (lifetime threshold above which the Herwig does not decay the particles) was set to  $3.3 \times 10^{-11}$  s, hence sparticles with finite decay length are not decayed at event generator level<sup>2</sup>. In the detector

---

<sup>2</sup>the value is set in order not to decay  $K^0$  and  $\Lambda$  at event generator level, but at detector simulation level.

Table 1: Summary of the neutralino NLSP samples. Dataset GMSB1 is a prompt photon decay sample, while dataset GMSB2 and GMSB3 are the non-pointing photon samples.  $N_5 = 1, \tan \beta = 5, \text{sgn}(\mu) = +$  are used at each point.

name	NLO (LO) $\sigma$ [pb]	$\Lambda$ [TeV]	$M_m$ [TeV]	$C_G$	$c\tau$ [mm]	$M_{\tilde{\chi}_1^0}$ [GeV]
GMSB1	7.8 (5.1)	90	500	1.0	1.1	118.8
GMSB2	7.8 (5.1)	90	500	30.0	$9.5 \cdot 10^2$	118.8
GMSB3	7.8 (5.1)	90	500	55.0	$3.2 \cdot 10^3$	118.8

Table 2: Summary of the slepton NLSP sample.  $N_5 = 3, \tan \beta = 5, \text{sgn}(\mu) = +$ , and no decay of slepton is assumed.

name	NLO (LO) $\sigma$ [pb]	$\Lambda$ [TeV]	$M_m$ [TeV]	$M_{\tilde{\tau}_1}$ [GeV]
GMSB5	21.0 (15.5)	30	250	102.3

Table 3:  $R$ -hadron samples. Dataset R-Hadron1 – R-Hadron6 are the  $R_{\tilde{g}}$  samples, while dataset R-Hadron7 – R-Hadron9 are the  $R_{\tilde{t}}$  samples.

name	NLO (LO) cross-section [pb]	sparticle	Mass [GeV]
R-Hadron1	567 (335)	$\tilde{g}$	300
R-Hadron2	12.2 (6.9)	$\tilde{g}$	600
R-Hadron3	0.43 (0.23)	$\tilde{g}$	1000
R-Hadron4	0.063 (0.033)	$\tilde{g}$	1300
R-Hadron5	0.011 (0.006)	$\tilde{g}$	1600
R-Hadron6	0.0014 (0.00075)	$\tilde{g}$	2000
R-Hadron7	11.4 (7.8)	$\tilde{t}$	300
R-Hadron8	0.27 (0.18)	$\tilde{t}$	600
R-Hadron9	0.010 (0.0064)	$\tilde{t}$	900

simulation phase, the  $\tilde{\chi}_1^0$  decaying into  $\tilde{G}$  and  $\gamma$ , decay length was passed to the ATLAS interface to GEANT4 and the sleptons ( $\tilde{\tau}_1, \tilde{e}_R$  and  $\tilde{\mu}_R$ ), interaction with detector materials, i.e. ionization loss was implemented.

In  $R$ -hadrons scenarios, the masses of the stable sparticles ( $M_{\tilde{g}}, M_{\tilde{t}}$ ) fully determine the phenomenology and other supersymmetric parameters (other sparticle masses) do not enter into any calculation. The generated samples are therefore highly model independent, and the only parameter that varies is the mass of the stable sparticle.

Tables 1-2 summarize the properties of the Monte Carlo signal samples used in this note. Tables 1 and 2 describe the GMSB samples with a neutralino or slepton NLSP, respectively, while Table 3 summarizes the  $R$ -hadron samples.

### 3 Discovery potential of GMSB SUSY with photon signatures

In GMSB models with  $N_5 = 1$  and low  $\tan \beta$  the lightest neutralino  $\tilde{\chi}_1^0$  is the NLSP and decays to a gravitino  $\tilde{G}$  and, in scenarios where the neutralino is mainly a photino, to a photon. Therefore the standard SUSY decay cascade of squarks and gluinos is extended by the decay  $\tilde{\chi}_1^0 \rightarrow \gamma \tilde{G}$ , as shown in Figure 1. Depending on the branching ratios of the squarks and gluinos decaying to various types of SUSY particles, this decay chain may also contain multiple jets. Events with two high energy photons are expected in  $pp$  collisions, if the NLSP lifetime is not too long ( $C_{\text{grav}} \sim 1$ ). These photons originate close to the

Figure 1: Typical SUSY decay chain for a neutralino NLSP decaying to a photon and a gravitino.

primary interaction vertex (“prompt photons”). The corresponding event signatures and the discovery potential for these models are discussed in this section. The case of large  $C_{\text{grav}}$  and therefore long lived neutralinos, resulting in non-pointing photons, is discussed in Section 3.3. For detailed reconstruction and trigger studies we consider the GMSB1 model point as a typical example (see Table 1). For this point the branching ratio of the decay of the lightest neutralino to a photon and a gravitino is  $\sim 97\%$ , and the total SUSY production cross-section is  $\sim 7.8\text{pb}$ .

In the following we discuss the optimisation of the signal selection, including the trigger selection, the expected background from Standard Model processes and a detailed study of the discovery potential with early data. Since for the latter a fast simulation approach is used, a comparison of fast and full simulation results is also presented.

### 3.1 GMSB1 full simulation studies

#### 3.1.1 Signal trigger strategy

The signal events studied here possess the standard SUSY event properties at the LHC: large  $E_T^{\text{miss}}$  and multiple jets with high  $p_T$ . These can be used for triggering the events. In addition, the feature of two high energy photons gives an additional way to trigger on these events independently of  $E_T^{\text{miss}}$  and jet triggers. In the following we consider two different trigger menus:

- The first menu is the ATLAS initial menu foreseen for data-taking at a luminosity of  $10^{31}\text{cm}^{-2}\text{s}^{-1}$  [42]. This menu includes various combinations of jet (J) and  $E_T^{\text{miss}}$  triggers (XE) and photon triggers (EM) as shown in Table 4. No prescale values are foreseen for these triggers, whereas the selection of the EM100 trigger is based entirely on the Level-1 (L1) trigger, with no selections envisaged at the Level-2 (L2) trigger or in the event filter. In the following, the trigger efficiency is defined as the ratio of the number of events without any preselection passing a trigger item divided

 Figure 2: The g55 event filter trigger efficiency (see text) for the GMSB1 sample as a function of the reconstructed  $p_T$  of the leading photon.

by the total number of events. The total efficiencies for the L1 trigger for the various triggers of this initial menu are summarised in Table 4. It can be seen, that in addition to the standard SUSY triggers based on jets and  $E_T^{\text{miss}}$ , the photon triggers have very high efficiencies for selecting GMSB1 events and can be used for initial running.

- The second menu investigated here is the standard ATLAS trigger menu foreseen for the stable running at a luminosity of  $\mathcal{L} = 10^{33} \text{ cm}^{-2} \text{ s}^{-1}$ . In this menu all three trigger levels are used in the selection. The triggers investigated are combinations of jet (j),  $E_T^{\text{miss}}$  (xE) and photon (g) signatures, see Table 5. Again, no prescale values are foreseen for these items. The trigger efficiencies for the signal at L1, L2 and event filter are summarised in Table 5, where the L2 and event filter efficiencies also contain the efficiencies of the previous levels. It can be seen that for both of the planned running phases the photon triggers are as efficient as the  $E_T^{\text{miss}}$  and jet triggers for the case of GMSB1 signal events. The efficiency for the g55 photon trigger after the event filter as a function of the reconstructed  $p_T$  of the leading photon is shown in Figure 2. As expected, after a steep turn on around 55 GeV a plateau is reached. The integrated efficiency above the threshold of 55 GeV is  $\sim 98\%$ .

Table 4: Trigger efficiencies and statistical errors for the GMSB1 event sample for ( $\mathcal{L} = 10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ ).

Trigger item	Efficiency	Trigger item	Efficiency
2EM13	$98.71 \pm 0.11$	XE70	$81.39 \pm 0.39$
EM100	$83.00 \pm 0.38$	J70+XE30	$93.64 \pm 0.25$
EM18+XE15	$98.79 \pm 0.12$	2J42+XE30	$93.98 \pm 0.24$
J100	$91.43 \pm 0.28$	4J23	$92.27 \pm 0.27$

Table 5: Trigger efficiencies and statistical errors for the GMSB1 event sample for ( $\mathcal{L} = 10^{33} \text{ cm}^{-2} \text{ s}^{-1}$ ).

Trigger item	L1	L1+L2	L1+L2+EF
g55	$97.18 \pm 0.60$	$84.47 \pm 1.32$	$80.47 \pm 1.44$
2g17i	$71.13 \pm 1.65$	$55.07 \pm 1.81$	$47.91 \pm 1.81$
j65+xE70	$80.66 \pm 0.40$	$80.63 \pm 0.40$	$69.53 \pm 0.46$
3j65	$83.63 \pm 0.37$	$83.55 \pm 0.37$	$83.37 \pm 0.37$

In summary it can be said that in the GMSB1 scenario the use of photon triggers is possible for initial running conditions, as well as at a higher luminosity. The efficiencies are as high as for the triggers based on jets and  $E_T^{\text{miss}}$  and can thus provide good redundancy.

### 3.1.2 Signal selection

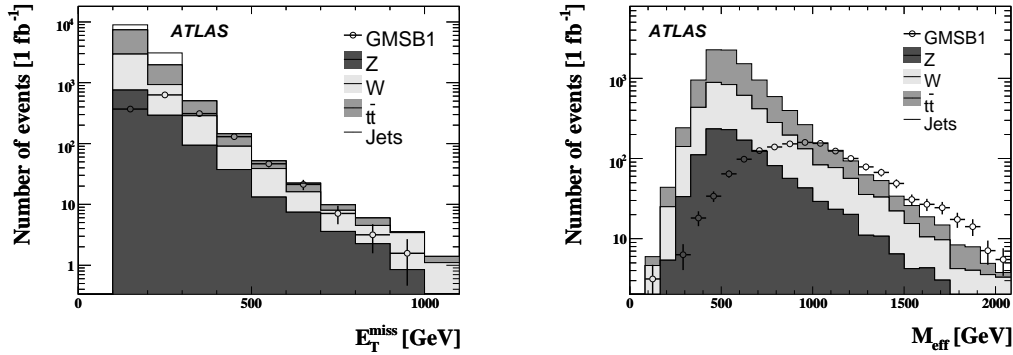

At the benchmark point GMSB1, 48.9% (16.4%) of the signal events have one (two) photons with  $p_T > 20 \text{ GeV}$  in the fiducial acceptance ( $|\eta| < 2.5$ ) used for photon identification. For the reconstruction of photons a standard cut-based photon selection [43] is used. This is mainly based on variables using information of the first and second samplings of the electromagnetic calorimeter. The photons are required to be isolated and those located in the transition regions between barrel and endcap calorimeters are excluded. No track veto is applied. After a full GEANT4 simulation of the ATLAS detector, the selection efficiency for photons with  $p_T > 20 \text{ GeV}$  is about 65%.

Table 6: ALPGEN Background samples used in this section. The corresponding integrated luminosities is shown.

Process		Integrated luminosity ( $\text{fb}^{-1}$ )
Top	leptonic	$\sim 13.4$
	semi-leptonic	$\sim 3.5$
	hadronic	$\sim 17.1$
Electroweak + jets	$Z \rightarrow e^+e^-$	$\sim 4.8$
	$Z \rightarrow \mu^+\mu^-$	$\sim 8.3$
	$Z \rightarrow \tau^+\tau^-$	$\sim 21.6$
	$Z \rightarrow \nu\nu$	$\sim 9.1$
	$W \rightarrow e\nu$	$\sim 3.4$
	$W \rightarrow \mu\nu$	$\sim 4.7$
	$W \rightarrow \tau\nu$	$\sim 3.9$
QCD	multiple jet production	$\sim 0.03$

As background to the signal, events with QCD jets, single gauge boson (W and Z) production and  $t\bar{t}$  production are simulated using the ALPGEN generator. The specific processes are listed in Table 6 and the corresponding integrated luminosities are given for each process. In order to separate the signal from the Standard Model background a standard preselection for SUSY-like signatures is first performed:

- At least four jets must be found with  $p_T > 50$  GeV ( $p_T > 100$  GeV for the leading jet).
- Missing transverse energy  $E_T^{\text{miss}} > 100$  GeV and  $E_T^{\text{miss}} > 20\% \cdot M_{\text{eff}}$ , where the effective mass  $M_{\text{eff}}$  is defined as the scalar sum of  $E_T^{\text{miss}}$  and the transverse momenta of the four leading jets.

 Figure 3: Distributions after preselection for  $1 \text{ fb}^{-1}$ . Left: Missing transverse energy. Right: Effective mass for signal and Standard Model background.

The distributions of  $E_T^{\text{miss}}$  and  $M_{\text{eff}}$  after this selection are shown in Figure 3 for the Standard Model background (histograms) and the signal (open symbols) for an integrated luminosity of  $1 \text{ fb}^{-1}$ . No large excess of events is seen over the Standard Model background. However, as shown in Figure 4, a cut on the number of reconstructed photons with  $p_T > 20$  GeV and  $|\eta| < 2.5$  provides an effective way to further suppress the backgrounds. Figure 3.1.2 shows the  $p_T$  distribution of the leading photon after the initial preselection. Table 7 shows the number of selected events for signal ( $S$ ) and background ( $B$ ) after requiring 0, 1 or 2 photons passing the cuts described above and either the g55 or the 2g17i trigger. This combination of triggers has a combined efficiency for the signal of  $\sim 85\%$  ( $\sim 99\%$ ) before (after) applying these selection cuts. The number of events is normalized to an integrated luminosity of  $1 \text{ fb}^{-1}$ .

In addition, the signal significance defined as  $Sig = S/\sqrt{B}$  is given in the table. In the calculation of  $Sig$  it is assumed, that there is at least one background event left. With the requirement of two high-energy photons the selection is mainly free from Standard Model background and the significance becomes very large.

In addition to the selection criteria listed above, checks were made to see whether a better signal significance can be achieved by requiring an opposite sign same flavour (OSSF) lepton pair, which originates in the squark/gluino decay cascade from a  $\tilde{\chi}_2^0$  to  $\tilde{\chi}_1^0$  decay via a slepton, as depicted in Figure 1. Here, only electrons and muons are accepted as leptons. The requirement of at least one OSSF lepton pair reduces the number of selected signal and background events. The suppression factor for the signal for the combination of one photon and one OSSF pair is larger than for the combination of two photons. Hence, although the background is reduced to a very low level, just using the requirement of two photons gives the largest significance. Requiring an OSSF pair in addition to two photons just reduces the signal, because the background is already very low.

Figure 4: Distributions after preselection for  $1 \text{ fb}^{-1}$ : Number of reconstructed photons with  $p_T > 20 \text{ GeV}$  and  $|\eta| < 2.5$  (left) and transverse momentum of the leading photon for signal and Standard Model background. (right)

### 3.2 GMSB parameter scan with fast simulation

To investigate the discovery potential of the selection described above, over a wider range of the GMSB parameter space, it is necessary to make use of a fast detector simulation to obtain adequate statistics for signal event reconstruction at various points in the parameter space. The computing requirements of the full simulation make it impractical for this study, so for this part of the analysis the fast simulation package ATLFAST [44] has been used instead. ATLFAST performs no detailed simulation of particle interactions with the detector material, but instead parameterizes the detector response. It has two main features relevant to the analysis discussed here:

- every generated particle is reconstructed.
- there is no distinction between electromagnetic and hadronic calorimeter compartments and the energy of a particle is obtained by smearing the energy of the generated particle with a resolution function. No shower development is simulated.

Note that ATLFAST does not simulate either reconstruction inefficiencies nor particle misidentification for any particles.

Figure 5(a) shows the  $M_{\text{eff}}$  distributions of the GMSB1 event sample for full and fast simulation. In the low energy region a small deviation of the fast simulation with respect to the full simulation can be

Table 7: Number of selected signal and background events for  $1 \text{ fb}^{-1}$  for different cuts on the number of photons and opposite sign same flavour (OSSF) lepton pairs.

$N_\gamma$	$N_{\text{OSSF}}$	Signal	$\Sigma$ Background	Sig	$N_W$	$N_Z$	$N_{t\bar{t}}$

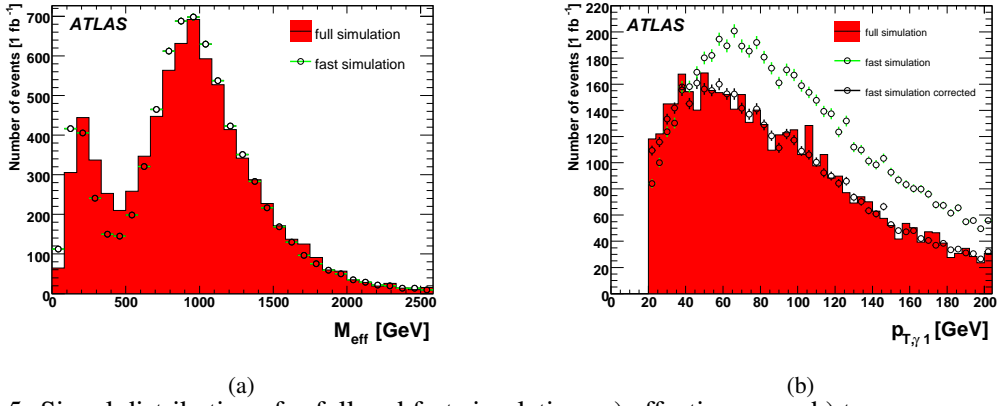

Figure 5: Signal distributions for full and fast simulation: a) effective mass, b) transverse momentum of the leading photon.

observed, which is due to a slightly higher jet momentum in ATLFast in the low energy region. However, of more importance for this analysis is the simulation of the photon identification and it is important that the fast simulation provides a reliable modelling. The transverse momentum of the leading photon is shown in Figure 5(b) for full and fast simulation. It can clearly be seen that some significant discrepancies between both simulation approaches exist. This is a result of the photon detection efficiency, which is not included in the fast simulation. The fast simulation assumes a 100% detection efficiency for all truth photons which pass a certain isolation criterion. This effect is taken into account in the analysis by imposing a realistic reconstruction probability on each photon by hand, depending on the transverse momentum of the photon. The corrected  $p_T$  distribution is also shown in Figure 5(b).

In Table 8 the numbers of selected signal events for full and fast simulation are shown and good agreement can be observed after each step of the selection. The level of agreement of the fast simulation with the full simulation is of the order of 10% which is considered to be sufficient for a rough estimation of the discovery potential via a scan of the GMSB model parameters using ATLFast.

 Table 8: Number of selected signal events normalised to  $\mathcal{L} = 1 \text{ fb}^{-1}$  for full and fast simulation for GMSB1.

$N_\gamma$	$N_{\text{OSSF}}$	Signal (full)	Signal (fast)
0	0	1287.4	1597.7
1	0	902.9	1029.5
2	0	252.9	275.3

In order to estimate the selection efficiency and the discovery potential of the two photon channel in a more model independent way, a scan of some GMSB model parameters has been performed. The mass spectrum and branching fractions of the different GMSB model points have been calculated using ISASUGRA 7.74 [36]. For each point 12500 signal events have been generated using the HERWIG/JIMMY [40,41]. As discussed above, ATLFAST is used for the detector simulation of the signal with a correction applied to the photon reconstruction efficiency. The estimates for the Standard Model background are taken from the full simulation as described in Section 3.1.2.

For the scan, the SUSY breaking scale parameter  $\Lambda$  has been varied from 60 to 200 TeV in steps of 10 TeV and  $\tan\beta$  has been varied from 2 to 50 in steps of 2. The other model parameters are fixed to  $N_5 = 1$ ,  $M_{\text{mes}} = 500$  TeV,  $\text{sgn}\mu = +1$  and  $C_{\text{grav}} = 1$ , as for the GMSB1 model point. In this part of the parameter space the neutralino is usually the NLSP, which is most often not the case for larger  $N_5$  or larger  $\tan\beta$ . For these regions, other channels need to be used to discover GMSB SUSY. These are discussed in Section 5. The discovery potential for the case of different  $C_{\text{grav}}$  and hence non-pointing photons is briefly discussed in Section 3.3.

Figure 6 shows the contour lines where the significance reaches  $\text{Sig} = 5\sigma$  for the default selection cuts as described above for different integrated luminosities. Since it is assumed that there is 1 background event left, these contour lines represent the lines with 5 signal events. In the regions below and left of the lines a  $5\sigma$  discovery can be made with the corresponding amount of data. In the high  $\tan\beta$  region above the solid line no sensitivity is quoted for the two photon channel, since in this region the  $\tilde{\tau}$  is the NLSP and so no significant excess of photons is expected from the SUSY decay chains. Due to the fact that the SUSY cross section decreases with increasing  $\Lambda$ , the significance decreases as a function of  $\Lambda$  for a given integrated luminosity. In general the discovery potential in most parts of the GMSB model parameter space is high, giving confidence that GMSB SUSY can be discovered in the two photon channel with early data, if it is realised in nature.

Figure 6:  $5\sigma$  discovery potential contour lines for GMSB SUSY in the  $\Lambda$  -  $\tan\beta$  plane for different integrated luminosities.

### 3.3 GMSB3 (non-pointing photon) full simulation studies

If the gravitino mass parameter  $C_{\text{grav}}$  is larger than unity, the NLSP will not decay promptly. In the case where the NLSP is a light neutralino, the resulting photons in the final state will not point back to the interaction point and may therefore be reconstructed and triggered with lower efficiency. The reconstruction efficiency is discussed in greater detail in Section 4.1. Here, the standard photon selection will be used to estimate the discovery potential.

Table 9: Trigger efficiencies and statistical errors for the GMSB3 event sample for ( $\mathcal{L} = 10^{33} \text{ cm}^{-2} \text{ s}^{-1}$ ).

Trigger item	L1	L1+L2	L1+L2+EF
g55	90.19 $\pm$ 1.08	46.04 $\pm$ 1.81	36.88 $\pm$ 1.75
2g17i	34.13 $\pm$ 1.72	17.77 $\pm$ 1.39	12.87 $\pm$ 1.22
j65+xE70	80.38 $\pm$ 0.56	80.24 $\pm$ 0.56	71.18 $\pm$ 0.64
3j65	79.80 $\pm$ 0.57	79.66 $\pm$ 0.57	79.62 $\pm$ 0.57

 Table 10: Number of selected signal (GMSB3) and background events for  $1 \text{ fb}^{-1}$  for different cuts on the number of photons and opposite sign same flavour (OSSF) lepton pairs.

$N_\gamma$	$N_{\text{OSSF}}$	Signal	$\Sigma$ Background	Sig	$N_W$	$N_Z$	$N_{\tilde{t}\tilde{t}}$
0	0	825.2	929.6	27.1	274.4	21.0	632.8
0	1	265.2	73.0	33.2	8.7	1.4	63.0
1	0	255.8	51.7	35.7	19.5	2.0	30.1
1	1	68.6	1.4	58.6	0.2	0.0	1.2
2	0	12.5	0.1	12.5	0.0	0.0	0.1
2	1	4.7	0.0	4.7	0.0	0.0	0.0

A suitable model point to study is the GMSB3 point, which has the same parameters as GMSB1, but with  $C_{\text{grav}} = 55$ . The  $\tilde{\chi}_1^0$  decay length in this point is therefore  $\gamma\beta c\tau \approx 3 \text{ m}$ . Although only 12.4% (0.6%) of the reconstructed events contain one (two) photons with  $p_T > 20 \text{ GeV}$  in the detector acceptance region, this well exceeds the number of background photons. This suggests that one could also use the above defined selection, which is based on the requirement of two hard photons.

Table 9 shows the trigger efficiencies for the same items listed in Table 5. For the L1 trigger, the main source of inefficiency for the g55 trigger is from neutralino decaying to photons outside the inner-detector volume. The larger the  $C_{\text{grav}}$  parameter is, the greater is the number of neutralinos that will decay outside the inner-detector. This effect is more pronounced for the 2g17i trigger, which is optimized for the production of both photons within the inner-detector volume. At L2 trigger and at the event filter, cuts are placed on the shape of the electromagnetic showers, which are less efficient for non-pointing photons due to their wider shower shape in the  $\eta$  direction compared to prompt photons. The small difference in jet trigger efficiencies between GMSB1 and GMSB3 is again due to the difference in the number of photons produced within the inner-detector volume. Photons in the event are treated as jets up to the event filter, so that GMSB1 has effectively a larger number of jets, compared to the GMSB3 sample, which makes a small but significant difference in jet trigger efficiency.

The resulting numbers of selected events for  $1 \text{ fb}^{-1}$  are shown in Table 10. It can clearly be seen that, although the significance, again defined as  $\text{Sig} = S/\sqrt{B}$ , is smaller than in the GMSB1 case, there are enough photons to select a large number of signal events. The difference to the prompt photon case is that with the requirement of an OSSF lepton pair one could obtain a larger significance, which is largest for a combination of one hard photon and one OSSF pair.

### 3.4 Conclusion of GMSB SUSY with photon signatures

In certain regions of the GMSB parameter space the NLSP is a light neutralino, decaying to a gravitino via the emission of hard photons. These photons can be used to efficiently reject the Standard Model background and to discover GMSB SUSY, if it is realized in nature. Attention must be paid to the fact that the photons might not point back to the interaction point leading to losses in reconstruction and

Figure 7: Schematic diagram of a non-pointing photon in the barrel section of the electromagnetic calorimeter. A long lived neutralino can travel a significant distance before decaying into a photon and a gravitino. The gravitino will escape the detector without interacting. A photon produced in this manner can enter the calorimeter at a significantly different angle ( $\eta_\gamma$ ) than a photon produced at the primary vertex ( $\eta_1$ ).

trigger efficiencies.

## 4 Prospects for neutralino lifetime determination

If GMSB SUSY is discovered, the ATLAS calorimeter can be used to first establish whether the neutralino has a long mean lifetime, and then to quantify it. The calorimeter can be used to both measure the direction and the time of the electromagnetic shower. Both the capabilities can be utilised to determine the mean lifetime of the neutralino.

If the neutralino has a significant decay length, a photon can be observed<sup>3</sup> that will not “point-back” to the primary interaction point. This is shown schematically in Figure 7. The neutralino ( $\tilde{\chi}_1^0$ ) travels a significant distance before decaying into a photon ( $\gamma$ ) and a gravitino ( $\tilde{G}$ ). Due to the finite opening angle between the photon and  $\tilde{G}$ , the path taken by the photon does not extrapolate back to the primary interaction point.

The first sampling layer can measure the  $\eta$  position (Cluster 1 in Figure 7) whereas the second sampling layer can measure both  $\eta$  and  $\phi$  (Cluster 2 in Figure 7). A vector corresponding to the path of the photon can therefore be constructed in the  $r-z$  plane. Although we can not measure the exact decay point of the neutralino based on these two measurements, we can extrapolate the path of the photon back to the beam axis, and measure the distance between this point and the primary vertex ( $Z'$  in Figure 7).

Since the ATLAS calorimeter has a pointing geometry, if a photon enters the calorimeter at a significant angle, the resulting electromagnetic shower can be spread out over a larger number of calorimeter cells. This wider shower-shape can result in issues for photon reconstruction algorithms and identification criteria. The effects of the reconstruction and identification of the non-pointing photons are discussed in Section 4.1.

If the neutralino has a mean lifetime greater than  $0.05 \text{ ns}$ <sup>4</sup>, the  $Z'$  value associated with the photon can be used to establish that the neutralino has a “long” lifetime. Once this observation has been made, the  $Z'$  distance can also be used to measure the mean lifetime. This is discussed in Section 4.2.

The neutralino is a massive particle. This means that photons produced from long-lived neutralinos will arrive at the calorimeter later than prompt photons from the primary vertex. A method which uses the calorimeter timing information to calculate the mean neutralino lifetime is discussed in Section 4.3.

<sup>3</sup>As long as the neutralino decays before the calorimeter.

<sup>4</sup>For typical values assumed for the neutralino energy and mass of 200 and 100 GeV respectively, photons with a  $Z'$  of at least 1cm from the primary vertex were observed.

Figure 8: Left: The distributions of the decaylength of the neutralino in the  $z$  direction. Right: The transverse momentum of the photons they produce.

## 4.1 Reconstruction and identification of non-pointing photons

### 4.1.1 $\eta$ definitions

Due to the nature of the non-pointing photons, two definitions of  $\eta$  are used in this section. The ‘truth  $\eta$ ’ refers to the  $\eta$  from the particle vector from the Monte Carlo event record (shown as  $\eta_\gamma$  in Figure 7). The term ‘detector  $\eta$ ’ refers to the  $\eta$  as measured by constructing a vector from (0,0,0) to the barycenter of the electromagnetic shower (shown as  $\eta_2$  in Figure 7).

### 4.1.2 Photon reconstruction efficiency

The photon reconstruction efficiency is defined as the fraction of photons, produced from the decay of a neutralino, that are reconstructed as a photon candidate. Using information from the Monte Carlo event record, photons are selected to be used in the efficiency calculation if they satisfy the following criteria:

- originate from a neutralino decay occurring inside the outer envelope of the inner detector,
- $p_T > 20$  GeV,
- $|\text{detector } \eta| < 2.5$ .

Photons are declared as successfully reconstructed if a photon candidate is found within  $\Delta R < 0.2$  of the position of the truth photon in the calorimeter.

The  $z$ -component of the decay length and the momentum of the photon in the GMSB samples, as shown in Figure 8 and 8, depend upon the  $C_{\text{grav}}$  parameter of the sample.

The overall efficiency for a photon to be reconstructed in the long-lived neutralino data samples, GMSB2 and GMSB3, is  $88.3 \pm 0.2\%$  and  $83.3 \pm 0.4\%$  respectively. This efficiency includes the reconstruction of photons which have converted to an electron-position pair. This occurs approximately 30% of the time and is dependent on how much material the photon travels through the inner-detector. This means that a photon from a long-lived neutralino will have a smaller probability of converting than a photon produced at the primary vertex. The reconstruction efficiency of a photon which does not convert, is  $89.3 \pm 0.2\%$  for the GMSB2 sample and  $84.2 \pm 0.5\%$  for the GMSB3 sample.

The difference in overall reconstruction efficiency measured between the GMSB2 and GMSB3 samples is due to the distribution of neutralino lifetimes in the sample, and hence the proportion of photons which are significantly “non-pointing”.

Figure 9: Reconstruction efficiency as a function of  $\Delta\eta$  for the GMSB2 and GMSB3 samples.

The reconstruction efficiency is measured independently from the sample parameters as a function of the variable  $\Delta\eta = \text{detector } \eta - \text{truth } \eta$  as shown in Figure 9.

There is excellent agreement between the two cases. The efficiency is approximately 90% for  $\Delta\eta < 0.25$ , and falls steadily to 75% for  $\Delta\eta \approx 0.5$ . It is clear that the reconstruction efficiency could bias any measured neutralino lifetime distribution. This efficiency distribution is parameterised with an approximation to the top-hat function:

$$R_{\text{eff}}(\Delta\eta) = \frac{b}{1 + e^{\frac{|\Delta\eta| + a}{c}}} + d \quad (1)$$

with  $a = 4.7(6.9)$ ,  $b = 174(229)$ ,  $c = 0.779(1.16)$  and  $d = 0.545(0.351)$  for GMSB2 (GMSB3). The GMSB2 fit result is used in Sections 4.2 and 4.3 (due to greater statistics) to account for any bias in the neutralino lifetime determination due to inefficiency.

#### 4.1.3 Study of photon identification efficiency

The dependence of the photon efficiency on the neutralino decay length has been studied for all of the standard photon selection variables [43]. The efficiency for each cut is defined as the fraction of reconstructed photons with  $p_T > 20$  GeV and  $|\text{detector } \eta| < 2.5$  that pass the standard select requirement for the given variable. Only photons that are successfully identified with true photons that come from the decay of a SUSY particle are used.

Figure 10 shows the efficiency of these cuts as a function of the component of the neutralino decay length parallel to the beam axis. From this figure it can be seen that the hadronic leakage (Had/Em) is independent of the neutralino decay length. Of the cuts forming the standard selection from the second sampling layer of the electromagnetic calorimeter, only the ratio of energy in the  $3 \times 3 / 3 \times 7$  cells (R33) is shown to be flat with respect to the neutralino decay length. The efficiency of the cuts on the ratio of energy in the  $3 \times 7 / 7 \times 7$  cells (R37) and the lateral width of the shower (weta2) are shown to have a clear dependence on the decay length. These two cuts are removed to form an ‘unbiased photon selection’ in the second sampling layer.

For the cuts forming the standard cut selection in the first sampling layer of the electromagnetic calorimeter, the fraction of energy (f1) and the cuts on the search for a second minima in the first sampling layer (DeltaE and DeltaEmax2) are shown to be relatively stable with respect to the neutralino decay length. There is however, a significant dependence of the efficiency on the decay length for the fraction of energy outside the shower core (fracm), the shower width in three strips (weta1) and the total width of the shower (wtot). These three cuts are removed to form an ‘unbiased photon selection’ in the first sampling layer.

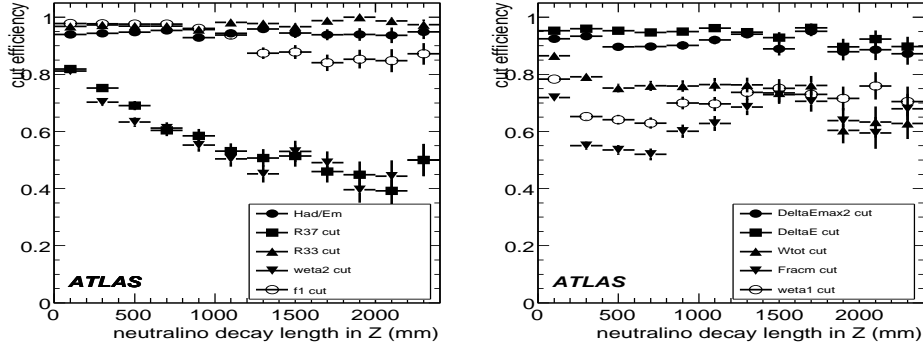

Figure 10: Photon identification cut efficiencies as a function of neutralino decay length in Z

Table 11 shows the effect on the overall efficiency as the five cuts which have been shown to be dependent on the neutralino decay length cuts are excluded from the standard photon selection to form an ‘unbiased photon selection’. For simplicity the cuts are separated according to which calorimeter sampling layer they are based upon.

Table 11: Summary of photons identification efficiencies for the three different signal samples. The hadronic, second sampling and first sampling cuts are applied sequentially.

Standard photon selection			
	hadronic	2 <sup>nd</sup> sampling	1 <sup>st</sup> sampling
GMSB1	$(94.1 \pm 0.2)\%$	$(75.7 \pm 0.4)\%$	$(64.1 \pm 0.4)\%$
GMSB2	$(94.2 \pm 0.1)\%$	$(56.4 \pm 0.3)\%$	$(41.9 \pm 0.3)\%$
GMSB3	$(94.4 \pm 0.3)\%$	$(49.8 \pm 0.6)\%$	$(36.1 \pm 0.6)\%$
Unbiased selection			
	hadronic	2 <sup>nd</sup> sampling	1 <sup>st</sup> sampling
GMSB1	$(94.1 \pm 0.2)\%$	$(93.4 \pm 0.2)\%$	$(85.7 \pm 0.3)\%$
GMSB2	$(94.2 \pm 0.1)\%$	$(92.2 \pm 0.1)\%$	$(82.5 \pm 0.1)\%$
GMSB3	$(94.4 \pm 0.3)\%$	$(92.1 \pm 0.3)\%$	$(80.7 \pm 0.5)\%$

The relative effect of loosening cuts on the background is shown in Table 12, which shows the fraction of jets, from a di-jet Monte Carlo data sample, that are reconstructed as photons, that also pass the two different photon selections.

Table 12: The fraction of jets reconstructed as photons and passing all photon criteria. The hadronic, second sampling and first sampling cuts are applied sequentially.

	Hadronic	2 <sup>nd</sup> sampling	1 <sup>st</sup> sampling
Default photon selection	$(3.4 \pm 0.1)\%$	$(0.57 \pm 0.06)\%$	$(0.19 \pm 0.03)\%$
Unbiased selection	$(3.4 \pm 0.1)\%$	$(2.7 \pm 0.1)\%$	$(0.70 \pm 0.07)\%$

## 4.2 Projected impact-parameter method for neutralino mean lifetime measurement

The distribution of the photon’s projected longitudinal impact parameter  $Z'$  arising from GMSB signal events can be used to estimate the mean neutralino lifetime.

Figure 11: Fitted slope parameters of the projected intersection distributions versus mean neutralino lifetime from the custom-built Monte Carlo simulation for an integrated luminosity of  $30 \text{ fb}^{-1}$ .

A distribution of the intersection points of the  $z$ -axis with the projected photon path is then created for all reconstructed photons. Each intersection point is corrected for the vertex displacement. An exponential function is fitted to the intersection distribution in order to extract the slope parameter which is sensitive to the mean neutralino lifetime. The range for the fit was chosen to be 50 to 500 mm, to remove any possible vertex effects, and to ensure that the decay occurred within the volume of the inner-detector.

Plotting the resulting slope parameters versus the mean neutralino lifetime reveals a clear correlation (Figure 11) between the slope parameter and the neutralino lifetime. These results were obtained using a custom-built Monte Carlo program which provides a detailed parameterisation of the response of the transition radiation tracker and the electromagnetic calorimeter. It is envisaged that a calibration curve such as this, created using full simulation, could be used to determine the mean neutralino lifetime from a measurement of the slope of the  $Z'$  distribution. In reality this slope will also be a function of the  $\beta$  of the neutralino.

For the GMSB2 data set, a slope of  $-4.35(6) \times 10^{-3}$  was measured and for the GMSB3 data set, a slope of  $-3.8(2) \times 10^{-3}$  was measured. These slopes were obtained before any photon identification cuts were applied. To estimate the effect of bias due to the reconstruction efficiency, a weight ( $= \frac{1}{R_{\text{eff}}(\Delta\eta)}$ ) is applied to the events, see Section 4.1.2. By comparing the effect of applying this correction on the resultant  $Z'$  slope, a  $-5 \times 10^{-5}$  systematic error was obtained. Table 13 shows the values obtained when different photon identification cuts are used.

The results from the GMSB2 and GMSB3 samples shown in Table 13 demonstrate very clearly how the slope of the  $Z'$  distribution can be affected by photon identification cuts which are based on width measurements of the electromagnetic shower.

### 4.3 Calorimeter timing

A comparison has been made of the timing of the electromagnetic shower in the calorimeter, compared to the lifetime of the generated neutralino (in its rest frame). A Gaussian is fitted to this distribution for different bins of true lifetime, and the resultant mean cluster-time per generated neutralino mean lifetime

Table 13: The slope of the projected-impact-parameter ( $Z'$ ) distributions of the photon, fitted from 50 to 500 mm and measured in two different fully simulated Monte Carlo samples with different photon identification cuts.

GMSB2: Generated mean lifetime of 3.17 ns			
dataset	hadronic	2 <sup>nd</sup> Sampling	1 <sup>st</sup> Sampling
default photon selection	$-4.35(6) \times 10^{-3}$	$-7.00(9) \times 10^{-3}$	$-8.3(1) \times 10^{-3}$
unbiased selection	$-4.35(6) \times 10^{-3}$	$-4.39(6) \times 10^{-3}$	$-4.54(7) \times 10^{-3}$
GMSB3: Generated mean lifetime of 10.7ns			
dataset	hadronic	2 <sup>nd</sup> Sampling	1 <sup>st</sup> Sampling
default photon selection	$-3.8(2) \times 10^{-3}$	$-6.6(2) \times 10^{-3}$	$-7.7(3) \times 10^{-3}$
unbiased selection	$-3.8(2) \times 10^{-3}$	$-3.9(2) \times 10^{-3}$	$-4.1(2) \times 10^{-3}$

Table 14: The mean lifetimes, measured using the calibrated calorimeter time, in two different full simulation Monte Carlo samples with different photon identification cuts. Also shown is the generated mean lifetime of the samples used.

GMSB2: Generated mean lifetime of 3.17ns			
dataset	hadronic	2 <sup>nd</sup> Sampling	1 <sup>st</sup> Sampling
default photon selection	$2.9 \pm 0.2$ ns	$1.1 \pm 0.07$ ns	$1.33 \pm 0.05$ ns
unbiased selection	$2.9 \pm 0.2$ ns	$2.9 \pm 0.2$ ns	$3.0 \pm 0.2$ ns
GMSB3: Generated mean lifetime of 10.7ns			
dataset	hadronic	2 <sup>nd</sup> Sampling	1 <sup>st</sup> Sampling
default photon selection	$9 \pm 4$ ns	$3.4 \pm 0.7$ ns	$2.9 \pm 0.6$ ns
unbiased selection	$9 \pm 4$ ns	$8 \pm 3$ ns	$19 \pm 19$ ns

is plotted in Figure 12. This fit to this plot is used to calibrate the calorimeter time. It has been shown that this method is robust against photon reconstruction or identification efficiency biases. This is because it is independent of the angle of incidence of the photon on the calorimeter. The arrival time of the photon at the calorimeter is a function of the  $\beta = v/c$  of the neutralino as well as its lifetime.

Using this calibrated calorimeter time, the neutralino lifetime is plotted for each photon. This distribution has the expected exponential shape modified by acceptance and resolution effects. In order to remove these effects, an exponential is fitted between 0.2 and 1 ns. The mean lifetime of the sample ( $\tau$ ) was calculated from  $\tau = \frac{1}{slope}$  where *slope* is the slope of the exponential fitted.

To calculate the effect of bias due to the reconstruction efficiency, a weight ( $= \frac{1}{R_{eff}(\Delta\eta)}$ ) was applied to the events (see Section 4.1.2). The systematic error on the lifetime determination due to uncertainties on the reconstruction efficiency was determined to be 2%.

To study the effect of the photon identification on this method, the mean lifetime deduced from the slope of the exponential is measured after different identification cuts are applied to the photon sample. These mean lifetimes are shown in Table 14. The large errors on the calculated lifetimes from the GMSB3 sample are due to lack of statistics available for the fit, over the limited range.

In order to obtain estimates for the systematic uncertainty due to the predicted  $\beta$  distribution of the GMSB sample (or an error in the timing calibration), the calibration curve (Figure 12) was scaled up and down by 5% corresponding to the difference in mean  $\beta$  value between the GMSB2 and GMSB3 samples. The effect on the measured mean lifetime determination corresponds to a systematic error of 0.4(2) ns

Figure 12: The measured cluster time as a function of the generated neutralino lifetime, for individual neutralinos in the Monte Carlo samples.

for the GMSB2(3) samples.

In order to obtain estimates for the systematic uncertainty in the mean lifetime determination from the choice of fitting region or a global shift in the timing calibration, the fit range of the exponential distributions was shifted by 100 ps. A systematic error of 1(10) ns was obtained for the GMSB2(3) samples.

The shape of the observed neutralino lifetime distribution is strongly affected by geometric acceptance and event kinematics. To obtain a lifetime measurement unaffected by these issues, a very limited fitting range has been used. A more accurate fit could be achieved by fitting the entire distribution. A full acceptance correction, including model dependent effects, would then be required to relate this distribution to the mean neutralino lifetime. This work, beyond the scope of this publication, should produce a more accurate measurement of the mean neutralino lifetime.

#### 4.4 Conclusion of the neutralino lifetime determination

Two independent methods for determining the mean neutralino lifetime have been discussed. The two methods are independent with different issues. For the  $Z'$  method of Section 4.2, a study using a simple custom-built Monte Carlo program shows that there is a good correlation between the  $Z'$  parameter and the mean neutralino lifetime. However, full simulation of a range of lifetime samples will be required to get the correct parameterisation of the relationship. The calorimeter timing study (Section 4.3), shows there is a good correlation between the calorimeter time and lifetime of the associated neutralino. The largest errors from this studies are due to the limited statistics in the range of the measured neutralino lifetime distribution, used for the exponential fit.

In both methods, one has to take care that the biases introduced by the reconstruction and identification of the photons are both measured and reduced, in order to prevent a distortion of the lifetime distribution.

Both of these methods are signal dependent and rely on simulation calibration, either to produce the  $Z'$  calibration curve, or the timing calibration. This is because both the  $Z'$  value and the arrival time of the photon in the calorimeter are functions of the  $\beta$  of the neutralino as well as its lifetime. One can assume a distribution of  $\beta$  from Monte Carlo simulation (as has been done here), but constraints on the both parameters can in principle be achieved by combining the methods. It is proposed that, if non-pointing photons are observed, a multivariate analysis method could be used to combine information from the calorimeter timing and  $Z'$  together with information from the primary vertex and cluster positions and energy to place model-independent constraints on the  $\beta$  and lifetime of the parent of the non-pointing photon.

## 5 Trigger and reconstruction for searches of long-lived heavy particles

Heavy, charged, long-lived particles are predicted in many models of physics beyond the Standard Model. One example is GMSB where for high  $\tan\beta$  the  $\tilde{\ell}$  is the NLSP which couples weakly to the gravitino. The signal is a heavy long-lived charged particle with velocity significantly smaller than the speed of light,  $\beta < 1$ . The momentum (and therefore  $\beta$ ) spectrum of these particles is model dependent. Those which have  $\beta$  close to unity are indistinguishable from ordinary muons. Those with  $\beta$  significantly lower than 1 could be identified and their mass determined.

In ATLAS event fragments from different parts of the detector are assigned to a particular bunch crossing (BC) using the BC identifier (BCID). The usual assumption is that the particles traverse the detector at nearly at the speed of light ( $\beta \approx 1$ ). Hits from a slower particle may be lost during data collection, or may be marked with the wrong BCID. The implications of low particle speed in the ATLAS trigger and data acquisition design are considered below.

This note does not address the case where the decay length of heavy charged NLSP is such that a significant number of particles will decay inside the tracking volume.

### 5.1 Datasets used

This analysis is based on a data sample of 10,000 events from the CSC production generated with the characteristics of GMSB point 5:  $\Lambda = 30$  TeV,  $M_m = 250$  TeV,  $N_5 = 3$ ,  $\tan\beta = 5$ ,  $\text{sgn}(\mu) = +$ ,  $C_{\text{grav}} = 5000$ . At this point the squarks and gluinos have masses around 700 GeV, the neutralino has a mass of 114 GeV and the  $\tilde{\tau}$  and  $\tilde{\ell}$  have masses of 102 and 100 GeV respectively. The cross-section for this point is 23 pb and the  $\tilde{\tau}$ ,  $\tilde{e}$  and  $\tilde{\mu}$  are co-NLSPs and are produced in the decay  $\tilde{\chi}^0 \rightarrow \tilde{\ell}^\pm \ell^\mp$ . Because of the small mass difference between the neutralino and the slepton, the  $\tilde{\ell}$  and lepton are nearly collinear. The  $p_T$  and  $\beta$  spectra of the sleptons and accompanying leptons are shown in Figure 13.

Figure 13: Transverse momentum and velocity spectra for sleptons and accompanying leptons from the GMSB5 sample.

GMSB5 is a single benchmark point and cannot be taken to represent all the possibilities of long-lived particle production. Some issues that impact our ability to discover long-lived new particles, if they exist, depend on the mass and  $\beta$  spectrum of these particles. In order to make our study less model dependent we also used for this study additional samples of events containing a single  $\tilde{\tau}$  each, generated at different  $\beta$  with a uniform  $\eta$  distribution between  $\eta = -3$  and  $\eta = +3$ .

Split-SUSY events containing long-lived gluinos with masses of 300 GeV and 1000 GeV were also used to assess the efficiency of the slow particle trigger, as discussed below. The generation and simula-

tion of these Split-SUSY events is described in Section 6.

For the background study we used single muon events from the CSC production. They were produced at constant  $p_T$  with a uniform  $\eta$  distribution, like the single  $\tilde{\tau}$  samples. We used cross-section estimates of 1000 pb (200 pb) for muons with  $p_T > 40$  GeV ( $> 100$  GeV) inside the ATLAS acceptance of  $|\eta| < 2.5$  [45].

The simulation of a long-lived heavy sleptons in the ATLAS detector required a special patch to GEANT4 [46].

## 5.2 Trigger and DAQ issues

When trying to identify slow particles [47, 48] one must pay special attention to the dimensions of ATLAS. Since the detector extends over 20m in length from the interaction point to each detector side and the bunch crossing period is 25ns, this means that particles from three separate bunch crossings can co-exist in the detector at the same time.

As described above, the matching of event fragments from different subdetectors is achieved using the BCID. This is calibrated so that particles originating together at the interaction point and traveling at the speed of light will have the same BCID assigned to them in all detector elements.

When  $\beta$  is sufficiently small, the particle will take longer to reach the detectors (especially those far from the interaction point) and hits may be assigned a wrong BCID and thus not be read-out. Figure 14 shows the efficiency with which slepton hits in the muon trigger chambers are associated to the correct bunch crossing as a function of  $\beta$ . This figure was produced using the single  $\tilde{\tau}$  events described above. It can be seen that efficiency drops sharply below  $\beta = 0.8(0.7)$  in the endcap (barrel). In order to find particles with  $\beta < 0.7$  ( $\beta < 0.6$ ) in the endcap (barrel), ATLAS must collect hits from the following bunch crossing (BC). Fortunately the MDT chambers collect data over a 700 ns interval, and thus hits from many BCs will be present. The RPC and TGC data acquisition can be set up to read out data from  $\pm 7$  and  $\pm 1$  BCs around the triggered BC respectively. The option to read out the information about extra BC, which was originally intended for debugging, must be switched on during routine ATLAS operation if we want to increase our efficiency for long-lived charged particles.

Figure 14: The efficiency, as a function of  $\beta$ , for all slepton hits in the muon trigger chambers to be included in the same BC with fast particles, for the barrel (right) and the endcap (left).

The hits from a slow particle may fall outside the correct BC, either for all trigger stations (e.g. if the particle is very slow and the trigger was produced by another feature in the event) or hits in the low- $p_T$  stations in the barrel may arrive in the correct BC, but the hits in the outer station may be late. In such a case, even if the  $p_T$  of the particle was high, it would produce a low  $p_T$  trigger.

Table 15: The L1 trigger efficiencies for GMSB5 simulated events for items from the trigger menu for  $\mathcal{L} = 10^{33} \text{cm}^{-2} \text{s}^{-1}$ . The description of the trigger items is in [42]

Trigger label	Description & Efficiency in GMSB5
MU40	95%
xE200	63%
EM25i	46%

In GMSB5 the two sleptons are produced with different  $\beta$ 's, and since most of the sleptons have high  $\beta$ , at least one of the two produced sleptons will have  $\beta > 0.7$  in 99% of the events. The level-1 [49] muon trigger efficiency in the correct BC is very high, either from a slepton with high  $\beta$ , or from one of the accompanying leptons. Table 15 shows the level-1 trigger efficiencies for GMSB5 events, based on the Level-1 thresholds defined in the standard ATLAS menu for a luminosity of  $10^{33}$ .

Nevertheless, a low  $\beta$  slepton, one with good potential for a mass measurement, could arrive to the muon spectrometer, or more likely the outer muon station, in the next BC. In such a case the slow slepton will not be found by the trigger, or be identified as a low  $p_T$  muon. In order to identify such a slow particle muon trigger chamber data from the next BC has to be collected.

In Split SUSY, the gluinos are produced directly, and there are few other features in the event. Therefore the  $R$  hadrons themselves must trigger the event. Since both of the  $R$  hadrons may be slow, the muon trigger may correspond to the wrong BC for the central parts of the detector. As a result, other event information such as that from the inner detector may be lost in the previous BC. This problem may be solved by also collecting data from the previous BC in the inner detector, but the feasibility of doing this, from the point of view of increased data volume, has not been investigated in this work. Additional data from the calorimeter is not required in order to find long lived heavy charged particles.

### 5.3 A L2 trigger for heavy sleptons

Figure 15: The  $\beta$  measured for sleptons in the barrel at L2 for different values of true  $\beta$ . The error bar represents the fitted sigma of the measured  $\beta$  distribution.

At L2 [50], algorithms are activated based on the Region of Interest (RoI) identified at L1. Each algorithm has a reconstruction stage which processes the data from the relevant parts of the subdetectors,

and a hypothesis stage which makes the decision to keep or reject the reconstructed feature. L2 and the Event Filter run in "trigger chains" which define the order in which algorithms are called and the input and output of each processing stage.

The role of the L2 muon trigger is to confirm muon candidates flagged by the L1 and to give more precise physics quantities of the muon candidate.

The L2 muon selection is performed in two stages. The first stage is performed by the muFast algorithm [51], which starts from a L1 muon RoI and reconstructs the muon in the spectrometer, giving a new  $p_T$  estimate. The hypothesis cuts on the estimated  $p_T$  are set so that 90% of the muons with  $p_T$  above the nominal threshold would pass the selection. The resulting trigger element is then passed to the next algorithm.

Track finding in the inner-detector is performed based on the region of interest found by muFast. The muFast candidate and inner-detector tracks then pass to the next algorithm, muComb, which matches an inner-detector track to the muon spectrometer track and refines the  $p_T$  estimate [50].

In the muon barrel, the excellent time resolution (about 3 ns) of the RPC allows measurements of the time of flight (TOF). A method for finding the slepton and measuring its mass at L2 has been developed. We will show that, in the barrel, a slow particle may already be selected effectively at L2. Figure 15 shows the mean value and error of the  $\beta$  reconstructed at the L2 as a function of generated  $\beta$ . This figure was produced using the single  $\tilde{\tau}$  events described above.

A selection based only on the  $\beta$  measurement would leave too many muons in the sample. At the hypothesis stage, we select using  $p_T(\text{candidate}) > 40$  GeV,  $\beta(\text{candidate}) < 0.97$  and  $m(\text{candidate}) > 40$  GeV. The mass is calculated from the measured  $\beta$  and the candidate's  $p_T$  and  $\eta$  estimated by muFast. Figure 16 show the mass distribution of signal and background resulting from the selection for an integrated luminosity of  $500 \text{ pb}^{-1}$ . It can be seen that the signal to background ratio is already good at the L2.

At a luminosity of  $10^{33}$ , a slow particle trigger without further trigger selection would produce a rate lower than 1 Hz coming from muons. Further refinement of the slow particle selection using subsequent muon trigger stages can reduce this rate to 0.2 Hz. The measurement of  $\beta$  for high  $p_T$  muon candidates is

Figure 16: Mass distribution of signal and background resulting from the L2 selection for an integrated luminosity of  $500 \text{ pb}^{-1}$ . The shaded area is the GMSB5 signal, the dashed line is the muon background, and the full line is the sum.

already part of the standard ATLAS L2 program MuFast, and a program to make the selection described above is part of the ATLAS L2 trigger.

Measuring  $\beta$  in the muon spectrometer at the second level trigger could be particularly useful for  $R$  hadrons, which have a L2 trigger efficiency of about 50% for a mass of 300 GeV. The efficiency loss comes mainly from events where the  $R$  hadron is neutral in the inner detector (and undergoes charge exchange before the muon spectrometer), which then fail the second stage of the L2 trigger requiring matching between the candidate found in the muon spectrometer and a track in the inner detector. An-

Figure 17: The efficiency to reconstruct sleptons as muons as a function of  $\beta$  for two ATLAS muon reconstruction packages.

other source of loss (probably less well simulated) is the assignment of inner detector hits from the charged  $R$  hadron to the incorrect bunch crossing.

If the  $R$  hadron is identified in the muon spectrometer as a slow particle candidate, it could be accepted without the requirement of a matching inner detector track. The slow particle selection at L2 results in an efficiency of 92% to select events with  $R$  hadrons in the barrel. The corresponding muon rate is expected to be completely negligible since all muons have an inner detector track.

The limitations of the L2 slow particle trigger should be noted. Firstly, this selection is performed only in the barrel of the muon spectrometer, where the RPCs are the trigger chambers. The timing information from the endcap is in BC granularity and cannot be used to measure  $\beta$ . Secondly, a slow particle which does not produce a RoI in the correct BC will not cause the muFast algorithm to be called, and the selection will not be performed. Therefore, slow particles in the endcap, as well as very slow sleptons in events triggered by other objects such as high  $p_T$  leptons, can only be identified offline.

The final trigger decision in ATLAS is made in the event filter, which uses algorithms adapted from the offline reconstruction. As will be shown in the next section, the standard muon reconstruction is not efficient for slow particles; therefore many would be rejected at this stage. The combined trigger efficiency of L2 and the event filter for sleptons with velocity  $\beta = 0.6$  is 39%.

To avoid the efficiency loss at the event filter, a specific reconstruction algorithm for slow particles, like the one we describe below for reconstruction, is being implemented at the event filter.

Slow particle candidates found at L2 that do not have a matching inner-detector track (such as charge flipped  $R$ -hadron candidates) should be accepted without further event filter selection. This will increase the combined trigger efficiency of the L2 and the event filter for  $R$  hadrons with a mass of 300 GeV from 25% to 92% in the barrel. The muon rate for this selection is completely negligible since all muons have an inner-detector track, but the effect of cavern background on this selection has not been studied yet.

#### 5.4 Reconstruction of heavy sleptons with the current muon reconstruction packages

In the standard ATLAS reconstruction [52], stable sleptons are expected to be reconstructed as muons. The efficiency to reconstruct slow sleptons is compromised due to the following issues: muons are reconstructed by forming track segments in the three stations of the Muon Spectrometer. Segments in the  $\phi$  direction are found using the trigger chamber data. The data may not be collected if the hits from a slepton are in the next bunch crossing instead of the collision BC. The lack of a  $\phi$  segment hinders the reconstruction of the precision segment in  $\eta$  using the MDT data. Furthermore, the radii of MDT hits

are distorted by late arrival of the slepton and may not fit well to a segment.

The efficiency of reconstructing the slepton as a muon depends on the reconstruction technique. Figure 17 shows the reconstruction efficiency for sleptons with the two ATLAS combined reconstruction packages, Staco and Muid which are based on the muon standalone packages MuonBoy and MOORE respectively. It can be seen that reconstruction efficiency starts dropping sharply for  $\beta < 0.8$ . This indicates that special reconstruction techniques will be required for the slow particles. This is discussed in the next subsection.

### 5.5 Identifying heavy long-lived particles at reconstruction

Estimating the velocity and mass in the event reconstruction allows us to identify heavy long lived charged particles, as well as to avoid the efficiency losses suffered when reconstructing them as muons. We do this with the MuGirl package [53], which enables us to select candidates also when the segment reconstruction is imperfect. Offline, the velocity can be also determined using the MDTs, the ATLAS precision muon chambers. In the MDT detectors, the hit position is obtained from the particle drift time. The drift distance is calculated assuming the particle passed the chamber with  $\beta = 1$ , which is wrong for the slow slepton. Minimizing the  $\chi^2$  of fit with respect to the time of arrival to the muon detectors yields an estimate of  $\beta$  and of the particle mass. This information is combined with estimates of  $\beta$  from the muon trigger chambers. Figure 18 shows the  $\beta$  resolution and reconstructed mass of sleptons from GMSB5 obtained from the reconstruction with MuGirl.

Figure 18:  $\beta$  resolution and reconstructed mass for sleptons from the GMSB5 sample.

### 5.6 Conclusion of strategies for the long-lived heavy particle search

Heavy, long-lived charged particles can be discovered in ATLAS, should they exist. However, this cannot be done effectively using the standard ATLAS muon reconstruction tools. Furthermore, much of the discovery must be done before the analysis stage, in the data acquisition, high level trigger and reconstruction. We have added to the standard ATLAS software components which can identify sleptons effectively.

The efficiency to discover slow long-lived charged particles depends on collecting extra data from the bunch crossing following the one in which the interaction occurred. This is most important for data from the muon trigger chambers, where this possibility is included in the data acquisition design.

For the GMSB5 model, discovery would assured with low integrated luminosity, once the MDT and RPC time calibrations are established. The discovery methods are largely independent of the model

characteristics, with discovery for a given integrated luminosity depending primarily on the production cross-section of the slow particles.

## 6 Search strategies for $R$ hadrons at ATLAS

### 6.1 Introduction

The presence (or absence) of massive exotic stable hadrons will be an important observable in the search for and quantification of any new physics processes seen at the LHC. Stable exotic coloured particles are predicted in a range of SUSY scenarios (see, for example, Refs. [22–26, 31]). Such particles could be copiously produced at the LHC and sensitivity to particle masses substantially beyond those excluded by earlier collider searches ( $\lesssim 200$  GeV) [31] could be achieved at ATLAS even with rather modest amounts of integrated luminosity ( $\sim 1\text{fb}^{-1}$ ). This section outlines a strategy for the detection of exotic massive, long-lived hadrons (so-called  $R$  hadrons) formed from either stable gluinos or stops ( $R_{\tilde{g}}$  and  $R_{\tilde{t}}$  hadrons, respectively). As described in section 2.1, the  $R_{\tilde{g}}$  hadrons ( $R_{\tilde{t}}$  hadrons) are considered in the context of a Split-SUSY (stop NLSP/gravitino LSP) scenario. Although this work is performed in the framework of SUSY, the techniques presented here may be used in generic searches for stable heavy exotic hadrons. As in the heavy lepton studies presented in section 4, this work relies on a signature of high- $p_T$  muon-like track, although the distributions presented in this section provide a means of discriminating between lepton and hadron hypotheses for any observed stable massive particle.

This section is organised as follows. First a description is given of the simulation of  $R$  hadrons at ATLAS, including both the event generation and scattering of  $R$  hadrons in matter. Final state observables associated with  $R_{\tilde{g}}$  and  $R_{\tilde{t}}$  hadrons are then presented and it is shown how it may be possible to experimentally distinguish between these two types of particles should a discovery be made of stable massive exotic hadrons. Finally, the discovery potential for  $R_{\tilde{g}}$  and  $R_{\tilde{t}}$  hadrons is presented.

### 6.2 Physics and detector simulation

#### 6.2.1 Event generation

The leading-order event generator PYTHIA [54] was used to produce samples of pair-produced gluino and stop-antistop events for a range of gluino and stop masses, as summarised in Table 16. Production mechanisms of stops and gluinos are illustrated in Figure 19, which shows leading-order Feynman diagrams. The effects of higher orders, which are important for the jet selection used later in section 6.3.3, are computed within PYTHIA using the parton shower technique.

The processes studied were selected such that they provide conservative estimates of likely rates at the LHC, which depend principally on the mass of the heavy object under study and not other free SUSY parameters.

For the gluino generation a Split-SUSY scenario was used in which squarks masses were set to 4 TeV. To ensure the results presented here are as model-independent as possible, only the PYTHIA sub-process  $gg \rightarrow \tilde{g}\tilde{g}$  was considered whilst neglecting the quark annihilation process  $q\bar{q} \rightarrow \tilde{g}\tilde{g}$ , which is sensitive to the squark mass. The former process is anyway the dominant production channel for gluino masses up to  $\sim 1.5$  TeV.

For the stable stop sample, the diagonal production of pairs of the lighter stop state ( $\tilde{t}_1$ ) were assumed and the following sub-processes modelled:  $gg \rightarrow \tilde{t}_1\tilde{t}_1$   $q\bar{q} \rightarrow \tilde{t}_1\tilde{t}_1$ . All sparticle masses except that of the  $\tilde{t}_1$  quark were set to 4 TeV although, at leading-order, the masses of other sparticles are not relevant for the cross-section calculations [55].

Table 16: Expected number of gluino and stop pair-production events for  $1\text{fb}^{-1}$  of integrated luminosity and the equivalent luminosity of signal samples.

sparticle	Mass (GeV)	Events/ $\text{fb}^{-1}$	$\mathcal{L} (\text{fb}^{-1})$
$\tilde{g}$	300	$2.69 \times 10^5$	$3.72 \times 10^{-2}$
$\tilde{g}$	600	$4.84 \times 10^3$	2.07
$\tilde{g}$	1000	138	72.5
$\tilde{g}$	1300	16.4	610
$\tilde{g}$	1600	2.12	$4.72 \times 10^3$
$\tilde{g}$	2000	0.230	$4.35 \times 10^4$
$\tilde{t}$	300	$7.82 \times 10^3$	1.12
$\tilde{t}$	600	$1.76 \times 10^2$	35.2
$\tilde{t}$	1000	6.4	$1.5 \times 10^3$

Figure 19: Selection of leading-order processes illustrating the production of gluino and stop particles.

String fragmentation [56] was used to model the momenta of the  $R$  hadrons. A Peterson fragmentation function [57],

$$D(z) \propto \frac{1}{z} \left( 1 - \frac{1}{z} - \frac{\epsilon_{q\tilde{g}}}{1-z} \right)^{-2}, \quad (2)$$

for which the  $\epsilon$  parameter for the heavy coloured object ( $\epsilon_{q\tilde{g}}$ ) has a value extrapolated from its value for  $b$ -quarks ( $\epsilon_{q\tilde{g}}/\epsilon_b = m_b^2/m_{q\tilde{g}}^2$ ) [58] was used to model the momentum distribution of the  $R$  hadron.

Following hadronisation, and based on calculations of the mass hierarchy of the lowest-lying  $R$ -hadron states [59], around 55% (40%) of the stable  $R_{\tilde{g}}$  ( $R_{\tilde{t}}$ ) hadrons are predicted to have zero electric charge. This difference arises principally due to the possible existence of gluino-gluon states, for which the production probability is set to 10% here, and which are treated as mesons when propagating through matter (Section 6.2.2).

To complement the signal samples, various background samples were used, each corresponding to an integrated luminosity of at least  $\sim 1 \text{fb}^{-1}$ . The generated and reconstructed number of events, and the equivalent luminosity of each sample is given in Table 17. As the simulated trigger used for this analysis requires a hard muon-like track, only events which could give rise to a high  $p_T$ -muon ( $p_T > 150 \text{GeV}$ ) were simulated. The following processes were considered. Leading-order 2-to-2 QCD processes, which include all quark flavours except top, and which differ in the values of the internal matrix element cut-offs ( $\hat{p}_T$ ) were generated with PYTHIA, the predictions of which are denoted QCD when discussed in section 6.3.2. In addition, backgrounds arising from diboson (HERWIG [40]) and single boson (PYTHIA) production, denoted electroweak, were produced, again with matrix element cut-offs in order to produce hard muons. A sample of  $t\bar{t}$  pair-production events, termed top, was also prepared using the MC@NLO [60] program.

Table 17: Background samples used in this work. The number of generated and reconstructed events are shown along with the equivalent integrated luminosity. Event weighting accounts for the non-integer number of generated and reconstructed  $t\bar{t}$  events.

### 6.2.2 Simulation of $R$ -hadron scattering in matter

A model of  $R$ -hadron scattering [61,62] recently implemented in Geant4 [63] is used in this work. This is an update of earlier work [59] which, in view of the inherent uncertainties associated with modelling such processes, adopts a pragmatic approach in which the scattering rate is estimated with the geometric cross-section and phase space arguments are used to predict the different 2-to-2 and 2-to-3 reactions. Other approaches to modelling  $R$ -hadron scattering have been proposed, based on Regge phenomenology [24, 25, 64]. These yield predictions of energy loss and scattering cross-sections which are qualitatively similar to those given by the model used here and any differences would not be expected to change the conclusions of this paper.

The typical energy loss per interaction is predicted to be low (around several GeV [61]) since only the light quarks within the  $R$  hadron should participate in interactions with matter, leaving the heavy squark or gluino as a spectator. This implies that the fraction of  $R$  hadrons which would be triggered ( $\beta \gtrsim 0.6$ , see Section 6.3.1) and which would then be stopped during their traversal of the detector is negligible<sup>5</sup>.

In addition to energy loss, another feature of  $R$ -hadron scattering, which has implications for experimental searches, is the possibility of charge and baryon number exchange. Following repeated scattering  $R_{\bar{g}}$  hadrons and  $R_{\bar{t}}$  hadrons not containing an anti-stop should enter the muon system predominantly as baryons. This is due to the occurrence of meson-to-baryon conversion processes for which the inverse reaction is suppressed [59]. Anti-baryons, however, would be expected to quickly annihilate in matter and  $R_{\bar{t}}$  hadrons containing anti-stops would thus largely remain as mesons.

The material budget of the part of the ATLAS detector enclosed by the muon system varies as a function of pseudorapidity between 11 and 21 interaction lengths [5,29], with the calorimeters providing the largest contribution. It is estimated that a  $R_{\bar{g}}$  hadron ( $R_{\bar{t}}$  hadron) will typically undergo 10-20 (7-15)

<sup>5</sup>Although it does not form a part of this work, the possibility of observing the decay of  $R$  hadrons which would be stopped offers a promising and complementary means of searching for  $R$  hadrons at the LHC [65,66].

nuclear interactions before reaching the muon system [62]. The difference in scattering rates is due to the smaller number of light valence quarks present in  $R_{\bar{t}}$  hadrons. Owing to the large number of interactions a substantial rate of events is thus expected in which a  $R$  hadron appears to possess different values of the electric charge in the inner detector and muon system.

While such topologies represent a challenge for track reconstruction software, they also provide observables useful for the discovery and characterisation of  $R$  hadrons, something which is explored in section 6.3. For example, a  $R_{\bar{g}}$  hadron can reverse the sign of its charge.  $R_{\bar{t}}$  hadrons [31] can only show this behaviour in the case where an intermediate neutral state oscillates into its anti-particle [67,68]. Since the expected rates of such are processes are essentially unconstrained by experimental limits on SUSY scenarios, they are not included in the simulation used here. Instead, a conservative, zero oscillation scenario is considered.

### 6.3 Event selection

#### 6.3.1 Trigger

The selected level 1 trigger is the *mu6* trigger [29], which has been considered in previous studies of  $R$  hadrons at ATLAS as the most promising trigger for this type of work [69]. This trigger is sensitive to the ‘classic’ stable massive particle signature of a high transverse momentum muon-like track. The trigger efficiency after the level 2 selection for both  $R_{\bar{g}}$  and  $R_{\bar{t}}$  hadrons falls from around 30% at masses of several hundred GeV to around 20% at 2 TeV. The variation of efficiency with mass is due to the slowness of the  $R$  hadron. Here, we consider events in which a  $R$ -hadron track in the muon system must be associated with the correct bunch crossing<sup>6</sup>. This leads to a rapid fall in efficiency for  $\beta \lesssim 0.6$ . A gradual decrease in efficiency would therefore naively be expected for increasing  $R$ -hadron mass. After including requirements that the event filter is passed and the muon-like track is well-reconstructed, there is little mass-dependence in the overall efficiency for  $R_{\bar{g}}$  hadrons (around 10-15%) or  $R_{\bar{t}}$  hadrons (20-30%). This difference arises due to the stringent track cuts in the event filter which, at low masses ( $\sim 300$  GeV) reject a substantial proportion of tracks which have reversed the sign of their charge, which, as explained in section 6.2.2, occurs only for  $R_{\bar{g}}$  hadrons. At higher masses, corresponding to higher transverse momentum, the poorer momentum resolution allows more ‘charge flippers’ to pass. As shown in section 6.3.3 this source of inefficiency has little effect on the discovery potential owing to the large predicted cross-section for low mass  $R_{\bar{g}}$  hadrons. However, future work could involve the development of triggers which do not rely on linked inner detector-muon chamber tracks. Should such a trigger configuration be introduced which is based on the *mu40* [29] trigger at level 1, this could potentially improve the overall efficiency by a factor of 2 – 3 for  $\beta \gtrsim 0.6$ .

#### 6.3.2 $R$ -hadron final state observables

Following the trigger selection, reconstructed final state quantities were used to select  $R$ -hadron events and suppress background. A number of variables are presented which were found to provide discrimination between  $R$ -hadron and Standard Model background processes. Since observables associated with  $R_{\bar{g}}$  hadrons and  $R_{\bar{t}}$  hadrons are mostly very similar, generally only the  $R_{\bar{g}}$ -hadron spectra are presented in this section. Where there is a substantial difference in the spectra of the two particle species, separate distributions are shown.

Figure 20 shows the expected transverse momenta distributions,  $\frac{dn}{dp_T}$ , of muon-like tracks in  $R_{\bar{g}}$  and  $R_{\bar{t}}$ -hadron events, for an integrated luminosity of  $1\text{fb}^{-1}$ . Distributions from background events are also shown. As expected, the  $R$ -hadron spectra become harder with larger mass, extending up to  $\sim 1$  TeV at the largest mass values, while the background events are comparatively softer.

<sup>6</sup>Section 5 explores possibilities of probing the lower  $\beta$  region

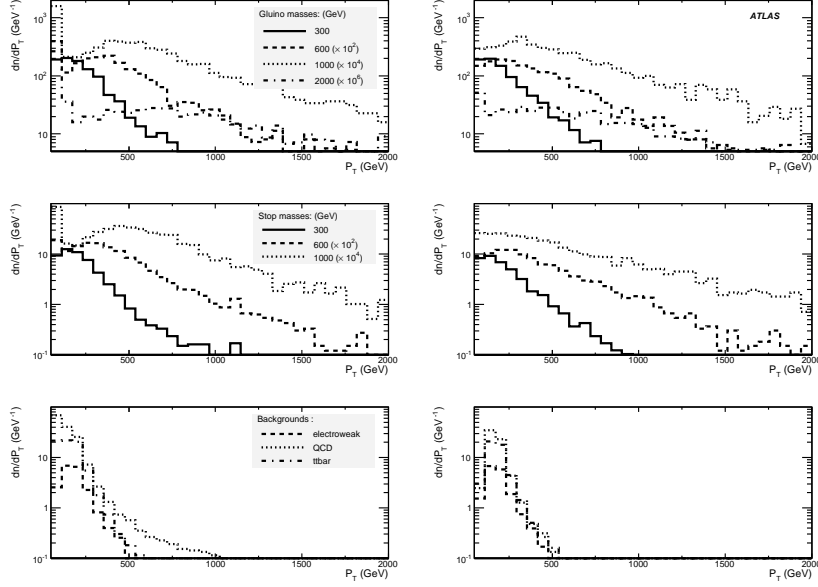

Figure 20: Distributions of transverse momenta  $\frac{dn}{dp_T}$  of hard tracks ( $p_T > 50$  GeV) as reconstructed in the ID (left) and muon (right) system. The top, middle, and bottom plots show tracks from  $R_{\tilde{g}}$ ,  $R_{\tilde{l}}$ , and background events, respectively. As labelled,  $R$ -hadron spectra are scaled according to  $R$ -hadron mass. The spectra correspond to an equivalent integrated luminosity of  $1\text{fb}^{-1}$ .

The ratio of high and low threshold  $HT/LT$  TRT hit multiplicities is shown in Fig 21 (top left) for  $R_{\tilde{g}}$  hadrons of mass 1000 GeV and muon candidates from background events. The different thresholds correspond to low ( $\sim 200$  eV) and high ( $\sim 6.5$  keV) amounts recorded of ionisation energy for a hit. Owing to the large mass and restricted  $\beta$  range the simulated  $R$ -hadron data peak at lower values of  $HT/LT$  than the background tracks.

Since  $R$  hadrons will typically suffer only several GeV energy loss per interaction through scattering in the calorimeter, it is unlikely they will be associated with a hard calorimeter jet. Figure 21 (top right) shows the distance  $R = (\Delta\eta^2 + \Delta\phi^2)^{1/2}$  between a  $R_{\tilde{g}}$ -hadron track and a jet (defined with the  $k_T$  algorithm) with  $p_T > 100$  GeV. Clearly for the  $R$  hadrons, the spectrum is typically larger than around 1, unlike the background sources which peak at lower values. The QCD background peaks around zero since a large proportion of muons in this sample are produced in the decay of heavy quarks. The top distribution peaks at values around 0.4 reflecting the higher jet multiplicity in such events compared to  $R$ -hadron events. The distribution is not shown for the electroweak backgrounds owing to the statistical imprecision of the Monte Sample sample (very few events with high  $p_T$  jets arise in the selected kinematic region under study here).

In a leading-order picture,  $R$  hadrons will be produced approximately back-to-back, unlike a number of background sources, as can be seen in Figure 21 (bottom left), which shows the cosine of the angle between two  $R_{\tilde{g}}$ -hadron candidates which both leave hard tracks in the muon system ( $\cos\Delta\Phi_{\mu,\mu}$ ); the  $R_{\tilde{g}}$ -hadron sample peaks strongly at  $(\cos\Delta\Phi_{\mu,\mu}) \sim -1$ . Figure 21 (bottom right) shows the distribution of the cosine of the angle between hard tracks in the inner detector and muon system ( $\cos\Delta\Phi_{ID,\mu}$ ), which, for pair production events, would be expected to display peaks at  $\sim \pm 1$ .

As described in section 6.2.2, charge exchange processes can give rise to events in which a linked track is assigned different values of electric charge in the inner detector and muon systems. This is shown in Figure 22 which shows the variable  $\frac{q_{ID} p_{T,ID}}{q_{\mu} p_{T,\mu}}$ , where  $q_{ID}$ ,  $q_{\mu}$ ,  $p_{T,ID}$ , and  $p_{T,\mu}$  are the charge as reconstructed in the inner detector and muon system, and the reconstructed transverse momentum in

Figure 21: Ratio of the number of high to low threshold hits in the TRT (top left); distance between a  $R$ -hadron candidate and a jet (top right); cosine of the angle between two high  $p_T$  tracks in the muon system (bottom left); and cosine of the angle between high  $p_T$  tracks in the ID and muon systems (bottom right). Distributions are shown for  $R_{\tilde{g}}$  hadrons of mass 1000 GeV and three background sources.

the inner detector and muon system, respectively. The gluino distributions show a two peak structure, with the peak at negative values of  $\frac{q_{ID}^{pT,ID}}{q_{\mu}^{pT,\mu}}$  arising from charge ‘flipping’ processes.  $R_{\tilde{t}}$ -hadron spectra indicate a very small rate (several per cent) of candidates with oppositely signed charge in the muon and ID systems which is due to charge misidentification in the muon and ID systems. Both the stop and gluino distributions become broader with increasing mass; this reflects the commensurate increase in  $p_T$  and hence degraded resolution of the tracking systems, which has the effect of allowing a greater proportion of charge-‘flipping’  $R_{\tilde{g}}$  hadrons to satisfy the event filter.

Figure 22: Distributions of  $\frac{q_{ID}^{pT,ID}}{q_{\mu}^{pT,\mu}}$  for  $R_{\tilde{g}}$  (left) and  $R_{\tilde{t}}$  hadrons (right). Predictions for a range of  $R$ -hadron masses are shown.

### 6.3.3 $R$ -hadron selection criteria

Using the information presented in section 6.3.2  $R$ -hadron selection criteria were developed following an optimisation procedure [62]. First, no hard muon-like track ( $p_T > 250$  GeV) can come within a distance  $R < 0.36$  of a hard jet ( $p_T > 100$  GeV). Furthermore a candidate  $R$  hadron must satisfy at least one of the following conditions listed below. For consistency the same selection is applied both for  $R_{\tilde{g}}$  and  $R_{\tilde{t}}$  hadrons though criteria 3-4 are only relevant for  $R_{\tilde{g}}$  hadrons. However, these have a negligible impact

on the study of the stop discovery potential.

1. The event contains at least one hard muon track with no linked inner detector track. A linked track is defined such that the distance  $R = (\Delta\eta^2 + \Delta\phi^2)^{1/2}$  between the measurements in the ID and muon systems is less than 0.1.
2. The event contains two hard back-to-back ID tracks with the TRT hit distribution satisfying  $HT/LT < 0.05$ . A back-to-back configuration is defined such that the cosine of the angle between the two muon tracks is less than -0.85.
3. The event contains two hard back-to-back (as defined above) like-sign muon tracks.
4. The event contains at least one hard muon track with a hard matching ID track of opposite charge fulfilling the condition  $p_{T,ID} > 0.5p_{T,\mu}$ .

Table 18 shows the acceptance numbers and rates for the various samples. It can be seen that for  $R$ -hadron masses below 1 TeV ATLAS opens up a discovery window with integrated luminosity of the order of  $1 \text{ fb}^{-1}$ . For masses above 1 TeV the rate of signal events is small, and is comparable to the expected background rate, so even discovery would be challenging even with larger data-sets.

Table 18: Number of events selected for the given samples. Background samples not mentioned here are rejected by the selection.

Sample	Accepted events	Rate (Events / $\text{fb}^{-1}$ )
300 GeV gluino	235	$6.44 \times 10^3$
600 GeV gluino	551	$2.70 \times 10^3$
1000 GeV gluino	774	10.7
1300 GeV gluino	732	1.20
1600 GeV gluino	685	0.147
2000 GeV gluino	546	$1.26 \times 10^{-2}$
300 GeV stop	78	70.0
600 GeV stop	134	3.9
1000 GeV stop	170	0.1
J5	1	0.893
J8	1	$2.26 \times 10^{-3}$
$Z \rightarrow \mu\mu$	1	0.776

## 6.4 Conclusion of $R$ -hadron search strategies

Stable massive exotic hadrons ( $R$  hadrons) are predicted in a number of SUSY scenarios. By exploiting the signature of a hard penetrating particle which may undergo charge exchange in the calorimeter and seemingly does not fall within a jet, ATLAS will be able to discover  $R$  hadrons for masses below 1 TeV with relatively low amounts of integrated luminosity ( $\sim 1 \text{ fb}^{-1}$ ).

## 7 Conclusion

Search strategies at ATLAS have been developed for a range of signatures of new physics processes expected within SUSY models. Studies were made of high transverse momentum photons, which may or

may not have been produced at the primary collision point, and of slow moving stable massive interacting particles (sleptons and  $R$ -hadrons).

It was shown that with early LHC data, corresponding to an integrated luminosity of around  $1\text{fb}^{-1}$ , ATLAS opens up a discovery window for those SUSY scenarios giving rise to the aforementioned signatures. Although the studies were performed within the framework of SUSY, the techniques used can be applied to generic searches for physics beyond the Standard Model.

# Dilepton Resonances at High Mass

## Abstract

We present the discovery potential of a heavy new resonance decaying into a pair of leptons with early LHC data with the ATLAS detector. The dilepton final states are robust channels to analyze because of the simplicity of the event topology. The unprecedented available center-of-mass energy will allow one to probe regions that are inaccessible at previous experiments even with modest amounts of data. After studying the Standard Model predictions and the associated uncertainties one can then look for significant deviations as indication of beyond the Standard Model physics (BSM). The focus of the note is to study the prospects for discovering BSM physics in the dilepton final states with an integrated luminosity ranging from 100 pb<sup>-1</sup> to 10 fb<sup>-1</sup>.

## 1 Introduction

New heavy states forming a narrow resonance decaying into opposite sign dileptons are predicted in many extensions of the Standard Model: grand unified theories, Technicolor, little Higgs models, and models including extra dimensions [1–4]. The discovery of a new heavy resonance would open a new era in our understanding of elementary particles and their interactions. Because of the historic importance of the dilepton channel as a discovery channel and the simplicity of the final state, these channels will be very important to study with early ATLAS data. The strictest direct limits on the existence of heavy neutral particles are from direct searches at the Tevatron [5–7]; the highest excluded mass is currently almost 1 TeV. The LHC will have a center-of-mass energy of 14 TeV which should ultimately increase the search reach for new heavy particles to the 5 - 6 TeV range. Many exotic models can be tested at the LHC, but analyzing all the existing models is impossible. Instead we choose to take a different approach, grouping the early-data analysis by their final state topologies. There have been several other ATLAS studies evaluating the potential for discovery of a heavy resonance [8]. However, this is the first study to include full trigger simulation, misalignments, and data driven methods. Including these experimental issues is important to realistically estimate the analysis potential. We focus on the early data phase of the experiment, defined roughly to include the accumulation of up to 10 fb<sup>-1</sup> of ATLAS data.

In the remaining of this introduction, the investigated models are reviewed. In sections 2 and 3, we explore the detector performance concerning the electron, muon and tau reconstruction abilities at high energies and the corresponding trigger efficiencies. In section 4 we investigate the Standard Model predictions and associated uncertainties, as well as the signal cross-section. In section 5, we proceed to search for Exotic resonances.

### 1.1 Models Predicting a $Z'$

Several models [1,3] predict the existence of additional neutral gauge bosons. In particular, grand unified theories, as well as “little Higgs” models, predict their existence as a manifestation of an extended symmetry group. Generically, there are no predictions for the mass of these particles. Since the experimental consequences are very similar in the dilepton final state, we examine only some representative models: the Sequential Standard Model (SSM)<sup>1</sup>, the  $E_6$  and the Left-Right Symmetric models [9]. The partial width of the  $Z'$  boson is given by  $\Gamma(Z' \rightarrow \ell^+ \ell^-) \approx [(g_\ell^R)^2 + (g_\ell^L)^2] \frac{m_{Z'}}{24\pi}$  where  $g_\ell^R$  and  $g_\ell^L$  are the right and left handed couplings of the charged leptons to the  $Z'$  boson and  $m_{Z'}$  is the mass of the  $Z'$  boson. For

---

<sup>1</sup>The Sequential Standard Model includes a new heavy gauge boson with exactly the same couplings to the quarks and leptons as the Standard Model  $Z$  boson.

$Z'$ Model	Indirect Searches (GeV)	Direct Searches (GeV)	
		$e^+e^-$ Colliders	$p^+p^-$ Colliders
$Z'_\chi$	680	781	864
$Z'_\psi$	481	366	853
$Z'_\eta$	619	515	933
$Z'_{LRSM}$	804	518	–
$Z'_{SSM}$	1787	1018	966

Table 1: 95% C.L. limits on various  $Z'$  models.

the masses and couplings considered here the natural width is typically around 1% of the mass of the resonance.

The strictest limits from direct searches come from the D0 and CDF experiments at the Tevatron [5–7]. Indirect searches have also been undertaken by the LEP experiments [10]. The direct limits range from several hundred GeV to approximately 1 TeV and are shown in Table 1. These limits are not expected to improve much beyond 1 TeV [11]. It should be noted that for models where the  $Z'$  couples preferentially to the third generation the limits are lower, therefore we consider it important to look at a lower invariant mass region in this channel.

## 1.2 Randall-Sundrum Graviton

The Randall-Sundrum model [4] addresses the hierarchy problem by adding one extra-dimension linking two branes, the Standard Model brane and the Planck brane. The hierarchy is solved by assuming for the fifth dimension a warped geometry in which the size of the ordinary coordinates decreases exponentially from the Planck scale to the TeV scale. The Randall-Sundrum model predicts the existence of a tower of Kaluza-Klein excitations of the graviton. These should be observable as resonances which decay into lepton pairs at the LHC. The current limits depend on the parameters of the model, and range from several hundred GeV to one TeV [5]. We consider the observability of a Randall-Sundrum graviton decaying into electron pairs. The width of the graviton resonance would be very small. For the parameters considered here it ranges from  $10^{-4}$  to a few  $10^{-3}$  times the mass.

## 1.3 Technicolor

Strongly interacting theories, like Technicolor and Extended Technicolor, provide a dynamical solution to the problem of Electroweak Symmetry Breaking. Many new technifermions which are bound together by a QCD-like force are predicted. One of the most promising search channels is the dilepton decay of the  $\rho_{TC}$  and  $\omega_{TC}$ . We study the “Technicolor Strawman Model” or TCSM [12, 13] as a benchmark model for generic strongly interacting theories. The most stringent limits on technihadrons in the TCSM framework come from the CDF collaboration, who rules out  $\rho_{TC}$  and  $\omega_{TC}$  with masses below 280 GeV for a particular choice of the TCSM parameters [14]. The width of the techni-mesons depends on the number of technicolors, but is generally assumed to be small, of the order of a few percent of their mass. More details on the exact values of the parameters considered are discussed in a later section.

## 2 Object Identification and Performance

This section describes the requirements used to select objects for the analyses and summarizes findings on the performance using Monte Carlo simulations of the production and decay of new dilepton resonances.

## 2.1 Electron Identification

The electron identification and performance is described in detail elsewhere [15]; here we summarize the results concerning very high transverse momentum<sup>2</sup> ( $p_T$ ). electron identification and reconstruction. The background to very high  $p_T$  electron pairs is expected to be low, therefore only minimal selection criteria need to be applied, in order to maximize efficiency. These minimal criteria are called *loose*. On the other hand, when trying to select very high  $p_T$   $\tau$  lepton pairs, where one  $\tau$  decays hadronically, a tighter selection on the electron from the other  $\tau$  decay is needed.

On top of the minimal requirements that the reconstructed clusters should have an absolute pseudo-rapidity ( $\eta$ ) less than 2.5 and should be associated with a track reconstructed in the inner detector, two electron selections were studied (both described in detail in [15]):

- A *loose* selection based on hadronic leakage and shower shape variables. This selection achieves very high efficiency while maintaining rejection against highly energetic pions with wide showers.
- A *medium* selection, which makes further requirements to obtain better rejection against  $\pi^0 \rightarrow \gamma\gamma$  background by exploiting the very fine granularity of the first compartment of the electromagnetic calorimeter, and tighter requirements on the associated track.

Figure 1 shows the reconstruction efficiency together with the efficiency of the two selections in a sample  $Z' \rightarrow e^+e^-$  events with  $m_{Z'} = 1$  TeV as a function of transverse momentum and pseudo-rapidity, normalized to truth electrons with  $p_T$  greater than 50 GeV and  $|\eta|$  smaller than 2.5. The efficiency of the reconstruction is dominated by the efficiency of the cluster to track association and is on average slightly below 80%. It must be noted that this efficiency has improved in the more recent software version used in [15]. The *loose* selection criteria have a relative efficiency close to 1, whereas the *medium* selection leads to an overall average efficiency between 65% and 70%.

The energy resolution for electrons at high  $p_T$  is about 1% except in the crack region between the forward and central calorimeters where the resolution is about 5%. The probability to assign the wrong charge to an electron ranges from 1% to at most 5% as the transverse momentum goes from 100 GeV to 1 TeV [16]. For a 1 TeV  $Z'$  a dielectron mass resolution of  $(0.80 \pm 0.02)\%$  is obtained.

## 2.2 Muon Identification

Here we discuss the requirements used to select muons, as well as a method to extract the identification efficiency from data. The ATLAS detector has an excellent standalone muon spectrometer: muon tracks can be found both in the inner detector and the muon spectrometer. A “combined” muon track consists in matched tracks from both the muon spectrometer and inner detector. We require that a muon, with  $p_T \geq 30$  GeV,

- forms a combined track (inner detector and muon spectrometer) with  $|\eta| \leq 2.5$ ,
- has a match  $\chi^2 < 100.0$  (5 D.O.F) between the parameters of the inner detector and muon spectrometer tracks.

The muons in the 1 TeV  $Z'$  sample have a most probable  $p_T$  of about 500 GeV. An efficiency of  $(95 \pm 0.2)\%$  with a resolution of approximately 5% is found with this selection. The results are consistent with previous studies [17, 18].

The muon identification efficiency as a function of  $p_T$  has been determined using two methods. The first method is the ‘tag and probe’ method, which has been used successfully at the Tevatron. In this method one uses a ‘standard candle’ as an in situ calibration point. It involves selecting  $Z \rightarrow \mu\mu$  events

<sup>2</sup>The transverse momentum is defined as the momentum projected on the plane transverse to the beam axis.

Figure 1: Efficiency of the *loose* and *medium* selection criteria in  $Z' \rightarrow e^+e^-$  events with  $m_{Z'} = 1$  TeV as a function of  $p_T$  (left) and  $\eta$  (right). The reconstruction efficiency is normalized to truth electrons inside the geometrical acceptance  $|\eta| < 2.5$  and with  $p_T > 50$  GeV.

and evaluating the reconstruction efficiency from data on these events. One combined muon is used as the tag while an inner detector track is used as a probe track. One can then study how often the probe muon also has a combined track to get an unbiased measurement of the combined muon reconstruction efficiency. The reconstruction efficiency was measured by fitting to the dimuon invariant mass spectrum and finding the fraction of events where the probe track was found as a combined track. A comparison between this tag and probe method and Monte Carlo truth is shown in Fig. 2. The Monte Carlo truth efficiency is determined by counting the number of generated muons with successfully reconstructed inner detector tracks that also have a combined muon track. This study demonstrates that we should be able to use this method to extrapolate into the very high  $p_T$  range.

### 2.3 Tau Identification

The algorithm to reconstruct hadronically decaying  $\tau$  lepton candidates is described in [19]. It is calorimeter based; it starts from a reconstructed cluster with a transverse energy<sup>3</sup>  $E_T > 15$  GeV and then builds identification variables based on information both from the electromagnetic and hadronic calorimeters, as well as the inner tracker. Finally, an electron and a muon veto are applied, which means that hadronically decaying  $\tau$  candidates which are matched (which “overlap”) with an identified electron or muon are removed.

The reconstruction efficiency, defined as the probability of a true hadronically decaying  $\tau$  to be reconstructed as a cluster, and normalized to all true hadronically decaying  $\tau$  leptons with  $E_T > 15$  GeV inside the  $\eta$  acceptance, is flat as a function of  $\eta$  and  $\phi$ . The average efficiencies are summarized in Table 2. Efficiencies for electron and muon vetoes are given with respect to all reconstructed  $\tau$  leptons.

A likelihood is computed for each  $\tau$  candidate. The  $\tau$  likelihood combines information from the calorimeter describing the shower shape and tracking information in a multivariate likelihood to maximize the discrimination from background. Detailed studies were done to optimize the  $\tau$  lepton efficiency

<sup>3</sup>The transverse energy is defined as the energy multiplied by  $\sin \theta$ , where  $\theta$  is the angle between the beam axis and the direction from the interaction point to the cluster.

Figure 2: Efficiency of muon reconstruction and identification as a function of  $p_T$  from two different methods (see text).

Events in $ \eta  \leq 2.5$	$(87.1 \pm 0.1) \%$
Events in $ \eta  \leq 2.5$ AND $E_T > 15$ GeV	$(85.6 \pm 0.2) \%$
Reconstruction	$(98.8 \pm 0.1) \%$
Electron veto	$(99.3 \pm 0.1) \%$
Muon veto	$(99.9 \pm 0.0) \%$

Table 2: Reconstruction efficiency, efficiency of  $e/\mu$ - $\tau$ -jet overlap removal for hadronically decaying  $\tau$  leptons from  $Z'$  boson decays. The efficiencies for kinematic requirements are also given.

Requirement	Efficiency (%)
$E_T > 60 \text{ GeV}$	$89.8 \pm 0.2$
AND $1 \leq N_{\text{trk}} \leq 3$	$79.2 \pm 0.3$
AND likelihood requirement	$51.0 \pm 0.3$

Table 3: Preselection and identification efficiency for  $Z' \rightarrow \tau\tau$  ( $m = 600 \text{ GeV}$ ). Efficiency is given with respect to reconstructed hadronically decaying  $\tau$  leptons (after removal of overlap with electrons or muons).

and jet rejection for the  $Z'$  boson search. The result (shown in Table 3) was to impose a  $p_T$ -dependent likelihood requirement, a requirement on the number of tracks, and a requirement on the transverse energy.

### 3 Trigger

The aim of the trigger system is to reduce the rate of events flowing through the data acquisition to 200 Hz while maintaining a highly efficient selection for rare signal processes. Even at the initial luminosity of  $\mathcal{L} = 10^{31} \text{ cm}^{-2}\text{s}^{-1}$ , it will be a challenge to keep the trigger highly efficient for all important final states. Several detailed trigger studies were undertaken for the dilepton final state. In this section we summarize those results.

#### 3.1 Electron Triggers

There are several proposed triggers which in principle can be used for the dielectron analysis. We studied four triggers: e55 - requiring one electron with  $p_T \geq 60 \text{ GeV}$ , e22i - requiring one isolated electron with  $p_T \geq 25 \text{ GeV}$ , 2e12 - requiring two electrons with  $p_T \geq 15 \text{ GeV}$ , and 2e12i - requiring two isolated electrons with  $p_T \geq 15 \text{ GeV}$ .

Table 4 shows the efficiency at the three ATLAS trigger levels [20]: level 1 (L1), level 2 (L2), and the event filter (EF) for a sample of graviton events. As can be seen in this table, the most efficient triggers are the high  $p_T$  triggers that do not require isolation. The low  $p_T$  triggers (2e12, 2e12i) will not be considered any further.

Signature	Efficiency (L1/L2/EF) (%)			Total Trigger Efficiency (%)
e55	$99.9 \pm 0.0$	$95.9 \pm 0.2$	$94.6 \pm 0.3$	$90.8 \pm 0.3$
e22i	$85.9 \pm 0.3$	$96.4 \pm 0.4$	$83.9 \pm 0.3$	$80.9 \pm 0.4$
2e12	$99.9 \pm 0.1$	$84.9 \pm 0.5$	$85.5 \pm 0.3$	$72.6 \pm 0.6$
2e12i	$59.1 \pm 0.7$	$86.1 \pm 0.7$	$86.2 \pm 0.3$	$43.9 \pm 0.7$

Table 4: Trigger level efficiencies on  $G \rightarrow e^+e^-$  ( $m = 500 \text{ GeV}$ ) events with respect to *loose* electron offline selection. The last column shows the overall trigger efficiency after all levels.

#### 3.2 Muon Triggers

For the dimuon channel we investigated the trigger efficiency for dimuon events using the single muon 20 GeV  $p_T$  trigger mu20 [20]. Results for various signal samples are shown in Table 5. Detailed studies on ways to estimate the trigger efficiency were carried out and presented in [21]. It was found that a tag and probe method, similar to the method described for the offline muon reconstruction, could be used to

<i>Sample</i>	mu20 Efficiency (L1/L2/EF) (%)			Total Trigger Efficiency (%)
$m = 400 \text{ GeV } \rho_T/\omega_T$	$97.6 \pm 0.1$	$98.8 \pm 0.1$	$99.5 \pm 0.1$	$96.0 \pm 0.1$
$m = 600 \text{ GeV } \rho_T/\omega_T$	$98.1 \pm 0.1$	$98.5 \pm 0.1$	$99.2 \pm 0.1$	$95.9 \pm 0.1$
$m = 800 \text{ GeV } \rho_T/\omega_T$	$97.6 \pm 0.1$	$98.7 \pm 0.1$	$99.2 \pm 0.1$	$95.6 \pm 0.1$
$m = 1 \text{ TeV } \rho_T/\omega_T$	$97.6 \pm 0.1$	$98.7 \pm 0.1$	$99.2 \pm 0.1$	$95.6 \pm 0.1$
$m = 1 \text{ TeV } Z'_\chi$	$97.8 \pm 0.1$	$98.9 \pm 0.1$	$99.5 \pm 0.0$	$96.3 \pm 0.1$
$m = 2 \text{ TeV } Z'_{SSM}$	$97.6 \pm 0.1$	$98.7 \pm 0.1$	$98.9 \pm 0.1$	$95.3 \pm 0.2$

Table 5: Simulated trigger level efficiencies of dimuon resonance samples with respect to offline selection. The last column shows the overall trigger efficiency after all levels.

extrapolate  $Z \rightarrow \mu\mu$  results to high  $p_T$ . In addition, efficiencies were obtained using orthogonal triggers, giving a sample which was minimally biased with respect to the muon triggers. It was found in [21] that these estimates agreed with both the tag and probe method and the results from the simulated samples shown here. As can be seen from Table 5 the single muon triggers are highly efficient for any of our signal samples with a total trigger efficiency around 95%.

### 3.3 Triggers for Taus

The  $\tau$  lepton decays to hadronic states in 65% of the cases, and the rest of the time to lighter leptons ( $e$  or  $\mu$ ). In our studies of ditau final states we select events triggered with a single lepton ( $e/\mu$ ) trigger. Thus, we consider two true final states, which we denote  $e\tau_h$  and  $\mu\tau_h$ .

For the  $e\tau_h$  channel we consider two triggers: e22i and e55, as studied in section 3.1. The  $\mu\tau_h$  events are selected using the mu20 trigger already used in section 3.2. Note that the efficiencies shown here are lower than for the dimuon or dielectron channel. This arises because there is only one electron or muon in the final state considered here while in the dielectron or dimuon final state either electron/muon can satisfy trigger requirements. Table 6 summarizes the trigger efficiencies.

<i>Signature</i>	Efficiency (L1/L2/EF) (%)			Total Trigger Efficiency (%)
e22i	$85.2 \pm 0.5$	$89.8 \pm 0.4$	$90.2 \pm 0.3$	$69.1 \pm 0.6$
e55	$90.0 \pm 0.3$	$74.2 \pm 0.4$	$78.7 \pm 0.6$	$52.6 \pm 0.8$
e22i or e55	$96.7 \pm 0.1$	$88.7 \pm 0.4$	$88.9 \pm 0.3$	$75.5 \pm 0.5$
mu20	$79.8 \pm 0.6$	$90.7 \pm 0.4$	$97.5 \pm 0.4$	$70.6 \pm 0.5$

Table 6: Trigger level efficiencies for different triggers for  $\tau$  leptons from  $m = 600 \text{ GeV } Z'$  bosons decaying to  $e\tau_h$  and  $\mu\tau_h$  final states with respect to offline selection. The last column shows the overall trigger efficiency after all levels.

## 4 Standard Model Predictions and Other Sources of Systematic Uncertainties

In this section, we investigate the main background sources and we show the dominance of the neutral Drell-Yan process. Then we investigate the uncertainties in the Standard Model predictions for Drell-Yan production, as well as for an extra neutral gauge boson. Finally, we discuss the experimental sources of uncertainties, including a dedicated study of the effect of the muon spectrometer alignment.

#### 4.1 Background Sources

The neutral Drell-Yan (DY) process constitutes the irreducible background in the search for new heavy dilepton resonances.

The dielectron reducible background results from events in which one or two electrons come from the jet→electron or photon→electron contamination. In addition, true isolated electrons can be produced by  $W \rightarrow e\nu$  or  $Z \rightarrow ee$  decays. By combining these effects in the dielectron case, one can list the reducible background sources: inclusive jets, W+jets, W+photon, Z+jets, Z+photon, photon+jet and photon+photon. For a first estimation of these backgrounds, we have used the event generator PYTHIA [22] to compute the differential cross-sections as a function of the invariant mass of the object pair. The results are shown on the left of Fig. 3. The neutral Drell-Yan process has a much lower cross-section than most of the backgrounds. For each electron-candidate leg originating from a jet (photon), we then apply a rejection factor<sup>4</sup> of  $R_{e-jet} = 4 \times 10^3$  ( $R_{e-\gamma} = 10$ ) [15]. We apply an additional requirement to take into account the geometrical acceptance in which the electrons are identified, i.e.  $|\eta| < 2.5$ , and require at least one object with  $p_T \geq 65$  GeV. The resulting differential cross-sections are shown on the right of Fig. 3. One can see that each contribution represents at most 25% of the neutral Drell-Yan process. The sum of all contributions does not exceed 30%. Both the transverse momentum and the rapidity requirements play an important role in reducing the QCD-jet background because it is produced mainly in the  $t$ -channel resulting in jets with high rapidities. Further reduction of these backgrounds may be obtained by requiring opposite electric charges.

The WW, WZ, ZZ and top pair processes can also produce two opposite sign electrons. Whereas the cross-sections of the diboson processes are of the same order as the smallest backgrounds above, the top pair cross-section is not negligible. As the topology of the events is not as simple as in the above backgrounds, no conclusion can be drawn without a full simulation study. Using a sample of fully leptonic and semi-leptonic  $t\bar{t}$  events, it was checked that the  $t\bar{t}$  background was of the order of 10% of the Drell-Yan contribution for di-object masses above 500 GeV after applying electron identification and the same rejection factor as above to the most energetic jet.

Figure 3: Background contribution to the  $e^+e^-$  invariant mass spectrum: before selection requirements (left) and after selection requirements (right).

<sup>4</sup>This number is given for the *medium* selection while the *loose* selection was used here. However, this corresponds to an efficiency of  $(80.6 \pm 0.2)\%$ , which is higher than our average efficiency using *loose* criteria, due to the better performance of the more recent release used in [15].

The rejection factors  $\mu$ -jet and  $\mu$ -photon are higher than the ones corresponding to the electrons and the resulting reducible backgrounds are lower.

All these assumptions will have to be checked with the real data. One can use for instance electron-muon or same charge samples, in which no signal is expected.

In the following, only the neutral Drell-Yan is considered as a source of background in the dilepton channel. The ditau case is treated later.

## 4.2 Controlling the Dilepton Cross-Section

The background estimations in the last section were performed with the PYTHIA event generator which uses tree-level calculations of the cross-sections. The tree-level dilepton cross-sections are subject to large higher order electroweak and QCD corrections. These are known at least to next-to-leading order (NLO) of perturbation theory, not only for the Standard Model Drell-Yan process, but also for a number of new physics processes. They have the additional benefit of reducing the uncertainty induced by the *a priori* unknown renormalization and factorization scales  $\mu_{R,F}$ . In the following, we discuss in detail the various known radiative corrections and the remaining theoretical uncertainties, focusing on the Standard Model Drell-Yan process and the corrections to the tree-level cross-section.

### 4.2.1 NLO Electroweak Corrections

The electroweak corrections to the Drell-Yan process are known to NLO in the fine-structure constant  $\alpha$  [23, 24]. Initial-state photon radiation must be factorized into the parton density functions (PDFs), which in principle modifies the DGLAP evolution of quarks and gluons, but has in practice little effect on the quality of the global fit [25]. Only at very large  $x$  and  $\mu_F^2$  can the correction become of the order of 1%. Multiple initial-state photon emission can also be resummed, leading to a 0.3% modification of the cross-section [26], or matched to parton showers [27]. The remaining initial-state QED contributions are also small, whereas the photon radiation emitted by the final state leptons can have a significant impact on their mass ( $M$ ) and transverse momentum spectra as well as the forward-backward asymmetry  $A_{FB}$  [28].

In the vector-boson resonance region(s) these and the universal parts of the weak corrections, which can amount to +80 (+40) % for muon (electron) pairs below and  $-18$  ( $-10$ ) % above the resonance, can be taken into account by using a running value of  $\alpha(M^2)$  or, more generally, effective vector and axial vector couplings in the Effective Born Approximation. The corrections are then reduced to +6 (+2) % for muon (electron) pairs below and +1 ( $< +1$ ) % above the resonance. While the presence of new physics can modify the running of the weak parameters, the QED corrections remain unaffected.

The electroweak corrections coming from non-factorisable box diagrams with double-boson exchange are small in the  $Z$  (and  $Z'$ ) resonance region(s), but they can be quite large away from these resonances ( $-4$  to  $-16$  % for electron pairs,  $-12$  to  $-38$  % for muon pairs of invariant mass 300 GeV to 2 TeV at the LHC, see Fig. 4).

### 4.2.2 NLO QCD Corrections

The QCD corrections to the Standard Model Drell-Yan process are known at NLO [29] and next-to-next-to-leading order (NNLO) [30, 31] in the strong coupling constant  $\alpha_s$ . The latter include in principle non-factorisable corrections through  $qq$  and  $gg$  initial states, which remain, however, smaller than 1% in practice, even at small values of  $x$ , where the gluon density is large. The effects of multiple soft-gluon radiation have been resummed simultaneously in the low- $p_T$  and high-mass (above 500 GeV) regions at next-to-leading logarithmic (NLL) accuracy not only for Standard Model  $Z$ -bosons [32], but also for  $Z'$  bosons [33]. They were shown to be in good agreement with the NNLO result as well as the one

Figure 4: NLO electroweak corrections in the high-mass region for Standard Model electron and muon pair production at the LHC [23]. In the presence of a new resonance, these relative corrections would be largely reduced (see text).

obtained by matching NLO QCD to parton showers in MC@NLO [33, 34]. In contrast, the matching of tree-level matrix elements to parton showers in PYTHIA [22] requires the *ad hoc* application of a (slightly) mass-dependent correction ( $K$ ) factor and leads to an unsatisfactory description of the  $p_T$  spectrum. For resonant spin-2 graviton production, which involves not only color-triplet quark, but also color-octet gluon initial states, the NLO QCD corrections are substantially larger ( $K \simeq 1.6$ ) [35, 36] than those for Standard Model or extra neutral gauge bosons ( $K \simeq 1.26$ , see Fig. 5). In this case, the matching of matrix elements to parton showers has only been performed at the tree-level [37], and resummation has only been performed in the low- $p_T$  region [36].

While the NLO total cross-sections for vector bosons and gravitons still change substantially when the renormalization and factorization scales are varied simultaneously around the resonance mass  $M$  by a factor of two ( $\pm 9\%$ ) [33, 36], the scale uncertainty is reduced to the percent-level at NNLO [30, 31] or, alternatively, to  $+6$  and  $-3\%$  after joint resummation at the NLL order [33].

The theoretical uncertainty coming from different parameterizations of parton densities is estimated in Fig. 5 [33] for invariant masses above 500 GeV. Since the invariant mass of the lepton pair is correlated with the momentum fractions of the partons in the external protons, the normalized mass spectra (left) are indicative of the different shapes of the quark and gluon densities in the CTEQ6M<sup>5</sup> parameterization [38]. The latter also influence the transverse-momentum spectra (right). The shaded bands show the uncertainty induced by variations, added in quadrature, along the 20 independent directions that span the 90% confidence level of the data sets entering the CTEQ6 global fit [39]. With about  $\pm 5\%$  at 1 TeV ( $\pm 11\%$  at 3 TeV), the PDF uncertainty is slightly larger than the scale uncertainty [33, 40].

<sup>5</sup>CTEQ collaboration has recently proposed new sets of PDFs. Using them, both the central values and uncertainties may change by several percents.

Figure 5: Mass (left) and transverse-momentum (right) spectra after matching the NLO QCD corrections to joint resummation with CTEQ6M parton densities. The mass spectra have been normalized to the LO QCD prediction using CTEQ6L parton densities. The shaded bands indicate the deviations allowed by the up and down variations along the 20 independent directions that span the 90% confidence level of the data sets entering the CTEQ6 global fit.

The uncertainty at low transverse momenta coming from non-perturbative effects in the PDFs is usually parameterized with a Gaussian form factor describing the intrinsic transverse momentum of partons in the proton. Three different parameterizations of this form factor have been proposed [41–43]. In all three cases the transverse-momentum distribution is changed by less than +3 and −6 % for  $p_T > 5$  GeV [33].

Combining the three contributions (from the scales, the PDFs and the non-perturbative form factor), the total theoretical QCD uncertainty is  $\pm 8.5\%$  at 1 TeV,  $\pm 14\%$  at 3 TeV. It must be noted that these uncertainties are common to the signal (heavy resonance) and background (Standard Model Drell-Yan).

### 4.3 Effect of Muon Spectrometer Misalignment

At large  $p_T$  ( $\geq 100$  GeV), an important contribution to the muon momentum resolution is the alignment of the muon spectrometer. In the early data period, the resolution is expected to be dominated by the alignment. The ultimate goal of the alignment system is to determine the position of the chambers in the muon spectrometer to about  $40 \mu\text{m}$  and  $\sigma_{rot}(mrad) = 0.5\sigma_{trans}(mm)$ .

A detailed study was carried out in order to determine the effect of possible larger uncertainties in the position of the chambers to the  $Z'$  search. For the analysis, in addition to the ideal case of no misalignment at all, we have chosen 7 different hypotheses of misalignment:  $(40\mu\text{m}, 20\mu\text{rad})$ , corresponding to the target value of the alignment system,  $(100 \mu\text{m}, 50 \mu\text{rad})$ ,  $(200 \mu\text{m}, 100 \mu\text{rad})$ ,  $(300 \mu\text{m}, 150 \mu\text{rad})$ ,  $(500 \mu\text{m}, 250 \mu\text{rad})$ ,  $(700 \mu\text{m}, 350 \mu\text{rad})$  and  $(1000 \mu\text{m}, 500 \mu\text{rad})$ . In the last two cases, the alignment resolution is of the same order or greater than the track sagitta we want to measure.

As shown in Fig. 6, the dominant effect leading to a wash out of the signal is the resolution loss<sup>6</sup>. The

<sup>6</sup>The slight excess of events around 600 GeV is due to mis-reconstructed Z bosons. In later versions of the software, this effect is not present anymore.

loss of resolution due to misalignment will deteriorate our ability to determine the charge of the muon. This was also studied as a function of the misalignment and is summarized in Table 7.

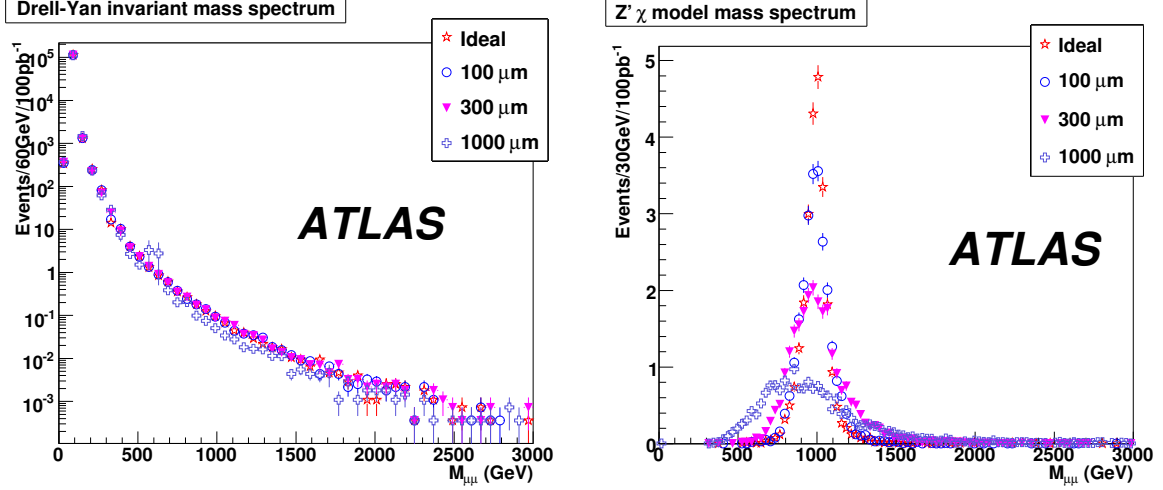

Figure 6: Left: reconstructed invariant mass distribution of Drell-Yan events for different misalignment hypotheses. The numbers corresponds to an integrated luminosity of 100 pb<sup>-1</sup>. Right: reconstructed invariant mass of the Z' χ model for the seven misalignment scenarios.

Misalignment (μm)	Ideal	40	100	200	300	500	700	1000
Relative efficiency	0.984	0.984	0.984	0.98	0.973	0.948	0.918	0.877

Table 7: Loss in signal efficiency due to the charge misidentification for seven misalignment hypotheses.

#### 4.4 Other Systematic Uncertainties

Additional experimental systematic uncertainties must be taken into account, listed as follows:

- the uncertainty in the efficiency of object identification was assumed to be 5% for muons, 1% for electrons, and 5% for τ leptons;
- the uncertainty in the energy scale was assumed to be 1% for muons, 1% for electrons, and 5% for τ leptons;
- the uncertainty in the resolution of the objects is as follows:  $\sigma(\frac{1}{p_T}) = \frac{0.011}{p_T} \oplus 0.00017$  for muons, 20 % for electrons, and 45% for τ leptons.
- the uncertainty in the luminosity was assumed to be 20% with an integrated luminosity of 100 pb<sup>-1</sup> of data and 3% for 10 fb<sup>-1</sup>.

The effect of all the above on the discovery potential is discussed in the next section for individual channels.

## 5 Search for Exotic Physics

In this section we present the discovery potential for several resonant signatures in the early running of ATLAS. We focus on the reach with an integrated luminosity of up to  $10 \text{ fb}^{-1}$  of data.

The statistical significance of an expected signal can be evaluated in several ways. The simplest approach, “number counting” is based on the expected rate of events for the signal and background processes. From these rates, and assuming Poisson statistics, one can determine the probability that background fluctuations produce a signal-like result according to some estimator; e.g. the likelihood ratio. In the “shape analysis” approach, a detailed knowledge of the expected spectrum of the signal and background for one observable (like the invariant mass distribution for example) can be used to improve the sensitivity of the search by treating each mass bin as an independent search channel, and combining them accordingly.

The resulting sensitivity is in general higher in the shape analysis than the estimation given in the number counting approach. In the shape analysis, the data is fitted or compared to two models: a background-only model and a signal-plus-background model. These are also called “null hypothesis”, noted  $H_0$  and “test hypothesis”, noted  $H_1$ , respectively. The input signal and background shapes are given to the fitting algorithms either as histograms in the non-parameterized approach [44] or as functions in the parameterized approach. For each of the models, a likelihood or a  $\chi^2$  distribution is computed and the log of the ratio of the two likelihoods (LLR) or the difference of two  $\chi^2$ s are estimated and used to compute the confidence levels. Either  $CL_b = CL_{H_0}$  alone, or  $CL_s = CL_{H_1}/CL_{H_0}$  (in the “modified frequentist approach” [44]) can then be used to compute the significance  $S$ :

$$S = \sqrt{2} \times \text{Erf}^{-1}(1 - CL_b) \quad \text{or} \quad S = \sqrt{2} \times \text{Erf}^{-1}\left(1 - \frac{1}{CL_s}\right) \quad (1)$$

in the *double tail* convention<sup>7</sup>.

A convenient way to compute the LLR is to use the Fast Fourier Transform (FFT) method presented in [45]. The advantage of this method is that it does not require the generation of millions of pseudo-experiments needed for high significances and which can be time consuming. The sources of systematic uncertainties can then be incorporated as nuisance parameters.

The above methods have been used to investigate the discovery potential of the  $Z'$  boson in the dilepton ( $e, \mu, \tau$ ) channels, of the graviton in the dielectron channel, and of Technicolor in the dimuon channel. This is presented in the following sections.

### 5.1 Background Estimation

As discussed in the previous section, neutral Drell-Yan production of lepton pairs is expected to be the dominant background for all the analyses (but  $\tau^+\tau^-$ ) and other contribution will be neglected here. Since different techniques are used to estimate the signal significance we also treat the Drell-Yan background in a few different but entirely consistent ways:

- In the “number counting” approach, we simply count the expected number of events under the resonance peak from various background sources, including the Drell-Yan process.
- In the non-parameterized  $CL_s$  method, we use the number and shape of the mass distribution by producing a histogram for the background.
- For several analyses, we perform a fit to the Drell-Yan background parameterizing the shape which allows to estimate the number of background events and extrapolate it to higher masses.

---

<sup>7</sup>In this convention,  $1 - CL_b$  has to be lower than  $2.87 \times 10^{-7}$  to correspond to a  $5\sigma$  significance.

Each of these methods produces a complementary and consistent approach to estimating the main background. When the Drell-Yan fit is needed, we parametrize the shape of the background by the formula  $ae^{-bM^c}$ , where  $M$  is the invariant mass of the lepton pair and  $a, b, c$  are parameters of the fit. Fits to the Drell-Yan spectrum presented in section 4.2 suggest that the parameterization  $\exp(-2.2M^{0.3})$  used by [46] describes the background shape well. It is this one which is used in the  $Z' \rightarrow \mu\mu$ ,  $G \rightarrow ee$  and technicolor analyses. In the  $Z' \rightarrow ee$  analysis, these parameters are allowed to vary in the individual ensemble tests. The fit to the entire spectrum letting all parameters float is consistent with this prescription.

## 5.2 $Z' \rightarrow ee$ Using a Parameterized Fit Approach

### 5.2.1 Event Selection

The selection of events with two electrons coming from a  $Z'$  has been studied in samples of fully simulated  $Z'_\chi \rightarrow e^+e^-$  events with  $Z'$  boson masses of 1, 2 and 3 TeV, corresponding respectively to integrated luminosities of  $21 \text{ fb}^{-1}$ ,  $204 \text{ fb}^{-1}$  and  $2392 \text{ fb}^{-1}$ .

The first requirement is that the two highest  $p_T$  clusters in the event be in the geometrical acceptance. The next requirement is that these clusters be associated with a track; its efficiency is 67% at 1 TeV and decreases for higher masses. The third requirement is that these two reconstructed electron candidates be identified as *loose* electrons. The relative efficiency of such a selection is at least 94% and increases with invariant mass. The trigger studies have been normalized to events with two *loose* electrons. As shown in section 3.1, the highest trigger efficiency is obtained with a non-isolated single electron trigger (e55). Its efficiency is 90.8% per event. The last requirement is that the two electrons have opposite electric charges. The requirement flow is presented in Table 8, where the events are counted in a window of  $\pm 4 \Gamma_{Z'}$  around the center of the resonance. Although the opposite charge requirement is optional in the absence of a large background, especially at very high invariant mass, it allows to have a control sample (made of same sign dielectrons) for the background. The resulting overall efficiency is 48% at  $m = 1 \text{ TeV}$ , 42% at  $m = 2 \text{ TeV}$  and about 34% at  $m = 3 \text{ TeV}$ .

Selection	Signal at 1 TeV	DY at 1 TeV	Signal at 2 TeV	DY at 2 TeV	Signal at 3 TeV	DY at 3 TeV
	347.	3.56	14.7	0.16	1.22	0.015
2 generated $e^\pm$ , $ \eta  < 2.5$	299.	3.07	13.7	0.15	1.16	0.013
2 clusters with a track	201.	2.06	8.0	0.09	0.62	0.009
2 <i>loose</i> electrons	190.	1.96	7.2	0.08	0.52	0.008
At least one $p_T > 65 \text{ GeV}$	190.	1.96	7.2	0.08	0.52	0.008
Event triggered	173.	1.77	6.6	0.07	0.47	0.007
2 opposite charges	166.	1.70	6.2	0.07	0.43	0.007

Table 8: Requirement flow table for the  $Z' \rightarrow e^+e^-$  analysis: cross-sections in fb. The events are counted in a window of  $\pm 4 \Gamma_{Z'}$  around the resonance.

The above efficiencies, normalized to events in the geometrical acceptance ( $|\eta| < 2.5$ ), are shown in Fig. 7 (left) as a function of the invariant mass of the electrons. They do not depend on the model used to generate the  $Z'$  samples. Only the requirement that the two electrons be in the geometrical acceptance depend on the model. Indeed, the relative proportions of initial quark flavors depend on the couplings of the  $Z'$  to the quarks. The PDF of the up quarks being harder than that of the down quarks,  $Z'$  produced by a  $u\bar{u}$  pair tend to be slightly more boosted, and therefore the electrons stemming from their decay tend to be produced at slightly higher pseudo-rapidities. This effect is visible in Fig. 7 (right) showing

Figure 7:  $Z'_\chi \rightarrow e^+e^-$  selection efficiency as a function of the generated invariant mass. Left: all selections, normalized to events in the geometrical acceptance; right:  $|\eta| < 2.5$  criteria for  $u\bar{u}$  and  $d\bar{d}$  events separately and for different  $Z'$  models (generator level).

the efficiency of the  $|\eta|$  selection for  $u\bar{u}$  and  $d\bar{d}$  events separately, and for a number of benchmark  $Z'$  models: the Sequential Standard Model ( $Z'_{SSM}$ ), the  $E_6$  models  $Z'_\psi$ ,  $Z'_\chi$ ,  $Z'_\eta$ , and the left-right symmetric model ( $Z'_{LR}$ ). It is therefore possible to generalize the efficiencies that have been measured in the fully simulated samples to models which haven't been simulated as well as to intermediate masses.

### 5.2.2 Discovery Potential

**Modeling of the dilepton invariant mass spectrum.** In order to compute the significance for several  $Z'$  models, a parameterization of the mass spectrum of the signal and of the background has been used. The differential cross-section can be factorized with a good precision in a parton-level term  $\frac{d\hat{\sigma}}{dm}$  and a PDF-dependent term  $G_{PDF}(m)$ :

$$\frac{d\sigma}{dm}(m) = \frac{d\hat{\sigma}}{dm}(m) \times G_{PDF}(m) \quad (2)$$

Using this factorization, one can write:

$$\left. \frac{d\sigma}{dm} \right|_{DY}(m) = \frac{1}{m^2} \times G_{PDF}(m) \quad (3)$$

$$\begin{aligned} \left. \frac{d\sigma}{dm} \right|_{\text{Signal}}(m) &= \frac{1}{m^2} \times G_{PDF}(m) \\ &+ \mathcal{A}_{\text{peak}} \times \frac{\Gamma_{Z'}^2}{m_{Z'}^2} \frac{m^2}{(m^2 - m_{Z'}^2)^2 + m_{Z'}^2 \Gamma_{Z'}^2} \times G_{PDF}(m) \\ &+ \mathcal{A}_{\text{interf}} \times \frac{\Gamma_{Z'}^2}{m_{Z'}^2} \frac{m^2 - m_{Z'}^2}{(m^2 - m_{Z'}^2)^2 + m_{Z'}^2 \Gamma_{Z'}^2} \times G_{PDF}(m) \end{aligned} \quad (4)$$

where  $\mathcal{A}_{\text{peak}}$  is the amplitude of the  $Z'$  process and  $\mathcal{A}_{\text{interf}}$  is the amplitude of the interference  $Z'/Z$  and  $Z'/\gamma$ , both normalized to the Drell-Yan process. This parameterization only depends on four parameters:

$m_{Z'}$ ,  $\Gamma_{Z'}$ ,  $\mathcal{A}_{\text{peak}}$  and  $\mathcal{A}_{\text{interf.}}$ . The differential cross-section is then multiplied by the appropriate  $K$ -factor (see section 4.2). The detector performance is accounted for as follows: the differential cross-section is multiplied by the efficiency computed above and convoluted by the invariant mass resolution (see section 2.1). The agreement between this parameterization and the full simulation is shown in Fig. 8 (left) for a  $Z'_\chi$  at 1 TeV.

Figure 8: Left: mass spectrum for a  $m = 1 \text{ TeV } Z'_\chi \rightarrow e^+e^-$  obtained with ATLAS full simulation (histogram) and the parameterization (solid line). The dashed line corresponds to the parameterization of the Drell-Yan process (irreducible background). Right: Log-likelihood ratio densities with  $1 \text{ fb}^{-1}$  for a  $m = 2 \text{ TeV } Z'_\chi$  for the signal and background hypotheses. The vertical line is the median experiment in the H1 hypothesis.

**Results** Using the parameterization presented above to generate mass spectra for signal ( $\gamma/Z/Z' \rightarrow e^+e^-$ ) and background ( $\gamma/Z \rightarrow e^+e^-$ ), one can compute the distributions of the log-likelihood ratio of the signal (H1) and background (H0) hypotheses.

Figure 8 (right) shows the LLR distributions obtained for a  $2 \text{ TeV } Z'_\chi$  with  $1 \text{ fb}^{-1}$  as well as the median signal experiment used to calculate  $CL_s$ . The FFT method [45] was used in the computation of the LLR distributions. It is important to note that the mass window used to perform the analysis does not affect the result.

Figure 9 (left) shows the integrated luminosity needed for a  $5\sigma$  discovery of the usual benchmark  $Z'$  models as a function of the  $Z'$  mass. Only statistical uncertainties were taken into account. The systematic uncertainties are discussed in the next paragraph. A fixed mass window of  $[500 \text{ GeV} - 4 \text{ TeV}]$  was used to compute the significance. Roughly speaking, less than  $100 \text{ pb}^{-1}$  are needed to discover a  $1 \text{ TeV } Z'$ , about  $1 \text{ fb}^{-1}$  are needed to discover a  $2 \text{ TeV } Z'$ , and about  $10 \text{ fb}^{-1}$  are needed to discover a  $3 \text{ TeV } Z'$ .

**Systematic Uncertainties** The sources of systematic uncertainties were listed in section 4. Since the main background is the Drell-Yan process, the systematic uncertainties from both the efficiencies and the theoretical predictions on the cross-section will affect the number of signal and background events in the same way, and can be added in quadrature. The uncertainties in the event selection efficiency mainly come from the electron identification and the geometrical acceptance. The former amounts to  $2 \times \pm 1\% = \pm 2\%$  for two electrons. Taking the extreme efficiencies for pure  $u\bar{u}$  and  $d\bar{d}$  events as a conservative estimate, the latter goes from  $\pm 3$  to  $\pm 0.5\%$ . Overall, this represents a systematic uncertainty

Figure 9: Integrated luminosity needed for a  $5\sigma$  discovery of  $Z' \rightarrow e^+e^-$  as a function of the  $Z'$  mass. Left: for various benchmark models with statistical uncertainties only; right: for the  $Z'_\chi$  with systematic uncertainties included.

of  $\pm 3.6\%$  to  $\pm 0.6\%$  from the event selection. This is small as compared to the theoretical uncertainties, which range from  $\pm 8.5\%$  to  $\pm 14\%$ . The effect of these combined uncertainties on the luminosity needed to discover 1, 2 and 3 TeV  $Z'$ s is  $^{+9}_{-10}\%$ ,  $^{+14}_{-10}\%$ ,  $^{+15}_{-13}\%$  (respectively).

The uncertainty in backgrounds other than the Drell-Yan process is another type of uncertainty. However, given that the Drell-Yan contribution is at the level of about 1% of the signal, any variation of the level of non-Drell-Yan background, which is more than ten times smaller, is negligible.

The uncertainty in the electron energy resolution is another type of uncertainty. In addition to the expected uncertainties in the energy resolution as measured in the calorimeter (see section 4), we have conservatively assumed that there was no increase in precision on the measured dielectron invariant mass coming from the angle measurement provided by the tracker. In this case, the resolution of invariant mass increases from about 1% (see section 2.1) to about 1.5%. The effect of these uncertainties on the luminosity needed for a discovery is  $^{+5}_{-2}\%$ , independent of the  $Z'$  mass.

The last type of uncertainty which has been considered is the electron energy scale. When varied within the expected uncertainties, the discovery luminosity varies by  $^{+2.5}_{-0}\%$ , independent of the  $Z'$  mass.

Combining all the above systematic uncertainties, the luminosity needed to discover, for example, a  $Z'_\chi$  is shown in Fig. 9 (right). It must be noted that the systematic effect coming from the fact that we do not know a priori the mass of the signal was not taken into account. This is addressed separately in appendix A.

### 5.3 $Z' \rightarrow \mu\mu$ Using a Parameterized Fit Approach

The dimuon channel represents an important complement to the dielectron channel. Although the resolution is expected to be up to an order of magnitude worse in the kinematic regime of interest, reducible backgrounds are expected to be considerably lower as discussed in Section 4.1. This feature makes the dimuon channel competitive, especially with early data where the design background rejection may not be achieved. In this section we consider two signal models decaying into dimuons - the  $Z'_{SSM}$  and the  $Z'_\chi$  boson.

### 5.3.1 Event Selection

To select events from the  $Z' \rightarrow \mu\mu$  process we require two muons of opposite charge. The muons are required to fulfill the muon identification criteria studied in Section 2.2, including  $p_T \geq 30$  GeV and  $|\eta| \leq 2.5$ . Events are triggered using the mu20 trigger described in Section 3.2. As seen in Section 4.1, this should select a sample which consists mainly of  $Z/\gamma \rightarrow \mu\mu$  with limited contamination from other sources of the order of a few percent. Table 9 indicates the effects of the various requirements on both the signal and background samples.

Sample	$Z'_{SSM}$ (1 TeV)	$Z'_\chi$ (1 TeV)	Drell-Yan
Generated	508.6	380.6	13.5
$ \eta  \leq 2.5$	366.8	271.5	10.8
$p_T \geq 30$ GeV	364.0	270.1	10.7
Muon identification	342.3	256.0	10.0
Trigger	325.2	243.2	9.5
Opposite charge	324.8	243.0	9.5

Table 9: Selection requirement flow for the  $Z' \rightarrow \mu\mu$  analysis - cross-sections in fb. Events are counted in a mass window of  $\pm 50$  GeV of the resonance mass (signal) and for  $m_{\mu\mu} > 800$  GeV (background).

### 5.3.2 Discovery Potential

To evaluate the discovery potential, we use the FFT method [45], as in section 5.2. The amount of data required to discover a  $Z'$  boson is computed from the log-likelihood ratio (LLR) of the signal (H1) and background (H0) hypotheses. Figure 10 shows the  $1 - CL_b$  obtained as a function of the integrated luminosity for the two studied  $Z'$  boson models at  $m = 1$  TeV. The largest expected systematic uncertainty (from misalignment of the muon spectrometer) is shown separately. One can see that the amount of luminosity needed for a  $5\sigma$  discovery ranges from 20 to 40  $\text{pb}^{-1}$ , which is competitive with the dielectron channel.

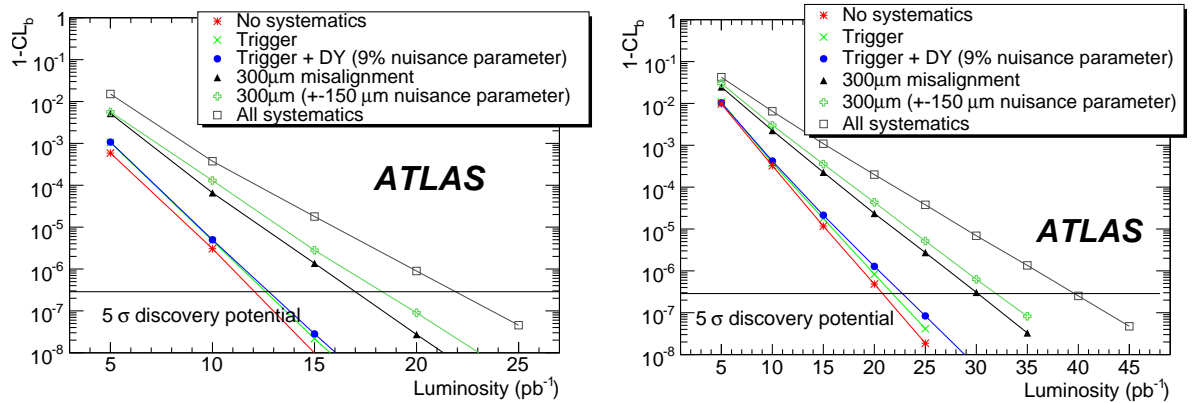

Figure 10: Results of the FFT computation of  $1 - CL_b$  for  $m = 1$  TeV  $Z'_{SSM}$  (left) and  $Z'_\chi$  (right) bosons. The horizontal line indicates the  $1 - CL_b$  value corresponding to  $5\sigma$ .

**Systematic Uncertainties** Section 4 describes the systematic uncertainties that were considered. As can be seen from Fig. 10 the effect of the nominal systematic uncertainties is modest in this channel. The largest theoretical uncertainty entering this study is the knowledge of the Standard Model Drell-Yan cross-section. In the dimuon channel, the largest experimental uncertainty is the resolution for high  $p_T$  muons which will be initially dominated by the alignment of the muon spectrometer. As already discussed, the nominal alignment precision may not be achievable with the integrated luminosities presented here and hence could significantly alter the conclusions. Figure 10 shows that the integrated luminosity needed to reach  $5\sigma$  increases from 13 to 20  $\text{pb}^{-1}$  if the muon spectrometer is aligned with a precision of 300  $\mu\text{m}$ . This takes into account an uncertainty of 150  $\mu\text{m}$  on the alignment precision estimate, which will have to be measured in data (e.g. from the  $Z \rightarrow \mu\mu$  sample) and which is treated as a nuisance parameter in the sensitivity computation.

#### 5.4 $Z' \rightarrow \tau\tau$ Using a Number Counting Approach

The ditau signature is an important component to the high mass resonance search. In particular, there are models in which a hypothetical new resonance couples preferentially to the third generation [47]. For these models the branching ratios are such that the dielectron and dimuon channels are not viable - hence it is critical that we consider all possible channels including ditaus. In this section we discuss the discovery potential for such a resonance. Because of finite resources we restrict ourselves to the process  $Z' \rightarrow \tau\tau$  with a single mass point  $m = 600 \text{ GeV}$  although much of the discussion generalizes to a generic ditau resonance search. The ditau final state can be divided into three final states: hadron-hadron (where both  $\tau$  leptons decay hadronically), hadron-lepton (where one  $\tau$  lepton decays hadronically and one decays leptonically), and lepton-lepton (where both decay leptonically). Here we consider the hadron-lepton ( $h - \ell$ ) final state. The possibility of observing the hadron-hadron final state using a hadronic  $\tau$  trigger will be examined later.

##### 5.4.1 Event Selection

To select events in the hadron-lepton final state, we select events with a “hadronic  $\tau$ ” candidate, a charged lepton (muon or electron), and missing transverse energy<sup>8</sup> ( $\cancel{E}_T$ ). As opposed to the dielectron or dimuon channel, the backgrounds to the ditau channel are considerably larger and include Drell-Yan production,  $W$ +jets,  $t\bar{t}$  and dijet events. After the initial object selection several additional requirements are needed to maximize the expected signal significance.

We consider hadronic  $\tau$  candidates with  $p_T > 60 \text{ GeV}$  and impose a requirement on the likelihood as a function the  $\tau$  transverse energy as described in Section 2.3. Candidates which overlap with an electron or muon are removed.

For electron candidates we require *medium* electron selection criteria in this analysis (see Section 2.1). The initial muon selection is the same as described in Section 2.2. Since this channel only requires one high  $p_T$  lepton the backgrounds are considerably higher than for the dielectron or dimuon final states. To address this we impose additional requirements on the isolation of the lepton. The isolation requirement imposed on electron candidates is  $\sum E_{T_{EM}}^{\Delta R < 0.2} / p_T < 0.1$  where  $\sum E_{T_{EM}}^{\Delta R < 0.2}$  is the sum of the energy deposits in the electromagnetic calorimeter within a cone of  $\Delta R = 0.2$  from the location in  $\eta$ - $\phi$  of the electron, less the electron candidate energy. Isolated electrons are required to have  $p_T > 27 \text{ GeV}$ . We impose an isolation requirement similar to that of electrons on muon candidates:  $\sum E_{T_{EM}}^{\Delta R < 0.2} < 0.1$ . For isolated muons we require that the  $\chi^2$  lie between 0 and 20 and to be considered by the analysis muons must have  $p_T > 22 \text{ GeV}$ .

<sup>8</sup>The missing transverse energy was reconstructed using the cell based algorithm described in [48].

Selection	Signal	$t\bar{t}$	Drell-Yan	Multijet	W+jet
Trigger	1356.	213600.	$2.3950 \cdot 10^7$	$4.19000 \cdot 10^6$	$6.69400 \cdot 10^6$
Lepton	905.	150900.	$1.2600 \cdot 10^7$	$1.08230 \cdot 10^6$	120400.
$\tau$ selection	368.	7818.	145680	40080	4587.
Opposite charge	315.	2498.	5306	23240	771.
$\cancel{E}_T > 30$ GeV	270.	2040.	2562	835	162.
$m_T < 35$ GeV	203.2	302.4	388.0	436.4	83.8
$p_T^{tot} < 70$ GeV	155.0	106.7	331.5	221.6	28.4
$m_{vis} > 300$ GeV	132.5	26.2	105.6	33.8	15.0
$\cos\Delta\phi_{\ell h} > -0.99$	13.3	2.1	5.5	2.3	2.7

Table 10: Requirement flow table for the  $m = 600$  GeV  $Z'_{SSM} \rightarrow \tau\tau \rightarrow \ell h$  analysis - cross-sections given in fb. The Drell-Yan process includes all flavors of leptons ( $e^+e^-$ ,  $\mu^+\mu^-$ ,  $\tau^+\tau^-$ ) with an invariant mass of at least 60 GeV.

After making the  $\tau$  candidate selection we make several further requirements to maximize the signal significance. First, we require that  $\cancel{E}_T \geq 30$  GeV. To greatly help with the rejection of the  $t\bar{t}$  backgrounds we employ a requirement on the total event  $p_T$  which is defined as the sum of  $\cancel{E}_T$  and the vector sum of the hadronic  $\tau$  with the lepton transverse momentum. We require  $p_T^{tot} < 70$  GeV.

The transverse mass of the event is determined by using the lepton kinematics and the event  $\cancel{E}_T$ . Defining a four-vector for the missing energy:  $\cancel{p}_T = (\cancel{E}_{Tx}, \cancel{E}_{Ty}, 0, |\cancel{E}_T|)$ , the transverse mass is calculated as:

$$m_T = \sqrt{2p_{T,\ell}\cancel{p}_T(1 - \cos\Delta\phi_{\ell,\cancel{p}_T})}.$$

We require that  $m_T < 35$  GeV.

In the case of the lepton-hadron channel one cannot simply reconstruct the invariant mass of the resonance as energy is taken away from the event by the neutrinos. However, two quantities can be constructed

- A visible mass variable is calculated as defined by CDF [49] using the hadronic  $\tau$  and the lepton four-vector information:

$$m_{vis} = \sqrt{(\underline{p}_\ell + \underline{p}_h + \cancel{p}_T)^2}$$

- The collinear approximation is used to build up the event-by-event invariant mass. The fraction of the  $\tau$  momentum carried by the visible decay daughters,  $x_\ell$  and  $x_h$ , are calculated with the following formulas:

$$x_\ell = \frac{p_{x,\ell}p_{y,h} - p_{x,h}p_{y,\ell}}{p_{y,h}p_{x,\ell} + p_{y,h}\cancel{p}_x - p_{x,h}p_{y,\ell} - p_{x,h}\cancel{p}_y}, \quad x_h = \frac{p_{x,\ell}p_{y,h} - p_{x,h}p_{y,\ell}}{p_{y,h}p_{x,\ell} + p_{x,\ell}\cancel{p}_y - p_{x,h}p_{y,\ell} - p_{y,\ell}\cancel{p}_x}.$$

The reconstructed mass is then calculated as  $m_{\tau\tau} = \frac{m_{\ell,h}}{\sqrt{x_\ell x_h}}$ .

To greatly help the background rejection and to restrict our search to the region of interest we require  $m_{vis} > 300$  GeV. Since the collinear approximation breaks down when the two  $\tau$  leptons are back-to-back, we impose the requirement that  $\cos\Delta\phi_{\ell h} > -0.99$ . Of course, since a very heavy particle tends to be produced at rest, the decay objects are mostly back-to-back, leading to a highly inefficient mass reconstruction.

Figure 11: Left: the visible mass distribution in the  $Z' \rightarrow \tau\tau \rightarrow \ell h$  analysis for signal and background processes (1 fb<sup>-1</sup> of data is assumed). Right: the reconstructed invariant mass obtained using the collinear approximation.

#### 5.4.2 Discovery Potential for 1 fb<sup>-1</sup> of Data

Table 10 shows the effect of the various selection requirements for the signal as well as all background processes considered. Distributions of the visible and reconstructed masses for signal and background are shown in Fig. 11. Here we assume a 600 GeV  $Z'$  and the SSM cross-section. In 1 fb<sup>-1</sup> of ATLAS data we estimate 132. signal events and 181. background events after imposing the event selection up to the requirement on visible mass. Using  $S/\sqrt{B}$  we estimate the signal significance to be 9.9. The collinear approximation breaks down when the two  $\tau$  leptons are back-to-back, so that even a loose requirement (such as  $\cos\Delta\phi_{\ell h} > -0.99$ ) reduces the signal by a large factor. Hence, we expect that the search will proceed by looking at the visible mass. If a significant excess over background is seen, the collinear approximation will then be used to help establish the presence of a new resonance.

**Systematic uncertainties** The systematic uncertainties that were considered are described in Section 4. For an analysis of 1 fb<sup>-1</sup> of data the dominant systematic source on the signal, just over  $\pm 18\%$ , comes from the uncertainty in the luminosity. The second most dominant systematic, the hadronic  $\tau$  energy scale, affects the signal at the  $\pm 10\%$  level. Summing in quadrature the effect of all systematic uncertainties on the signal Monte Carlo sample results in a total systematic uncertainty of about  $\pm 20\%$ . The current Monte Carlo samples available for the backgrounds to the ditau analysis are statistically limited and hence prevent a rigorous evaluation of the systematics at this time. As a conservative estimate, we assume that the total systematic uncertainty in the backgrounds is identical to that observed in the signal Monte Carlo. This is a conservative estimate because the majority of the backgrounds in the data have very large cross-sections (dijets, W+jets, etc.) and in principle the evaluation of systematic uncertainties there should be less sensitive to statistical fluctuations than for the signal events. Summing these systematic uncertainties in quadrature and using the formula  $S/\sqrt{B + \delta B^2}$  gives a significance of 3.4 in 1 fb<sup>-1</sup>.

### 5.5 $G \rightarrow e^+e^-$ in a Parameterized Fit Approach

In this section we present a sensitivity study for the Randall-Sundrum  $G \rightarrow ee$  final state. In this channel, it is assumed that there is no interference between the  $G$  and the dilepton background. Table 11 shows the parameters of the different  $G$  samples used in this analysis.  $\Gamma_G$  is the simulated graviton resonance width and  $\sigma_m$  stands for the width of the observed resonance after convolution with detector resolutions. For  $k/\bar{M}_{pl} < 0.06$  the resonance is narrow compared to the experimental resolution.

The main Standard Model background is neutral Drell-Yan production. Other backgrounds such as dijets with both jets misidentified as electrons are expected to be small and neglected at this time.

Model Parameters		$\Gamma_G$	$\sigma_m$	$\sigma \cdot BR(G \rightarrow e^+e^-)$
$m_G$	$k/\bar{M}_{pl}$	[GeV]	[GeV]	[fb]
500 GeV	0.01	0.08	4.6	187.4
750 GeV	0.01	0.10	6.4	27.7
1.0 TeV	0.02	0.57	7.9	26.0
1.2 TeV	0.03	1.62	10.3	22.4
1.3 TeV	0.04	2.98	11.4	25.3
1.4 TeV	0.05	5.02	13.1	26.8

Table 11: Parameters of the  $G \rightarrow ee$  samples used: natural width ( $\Gamma_G$ ), Gaussian width after detector effects ( $\sigma_m$ ) and leading order cross-section.

#### 5.5.1 Event Selection

In reconstructing the resonance mass, we require a pair of electrons – we do not make any charge requirements – with  $p_T \geq 65$  GeV using the *loose* electron selection criteria described in Section 2.1. We require that the events pass the e55 single electron trigger (see section 3.1). Finally we require that the two electrons are roughly back-to-back in  $\phi$  with  $\cos\Delta\phi_{ee} < 0$  between the two electrons. Table 12 shows the remaining cross-section at each stage of the selection and the total efficiency for different mass points. The efficiency decreases at high graviton masses, due to the track match requirement, which is consistent with the  $Z'$  boson analysis (see section 5.2). Table 13 shows the same requirement flow for the Drell-Yan.

The Drell-Yan background distribution after this event selection is shown in Fig. 12 along with signal at  $m_G = 1$  TeV and coupling  $k/\bar{M}_{pl} = 0.02$ . The exponential described in Section 5.1 has been used to model the shape of the background.

#### 5.5.2 Discovery Potential

We search for an excess of events in the mass range from 300 GeV up to 2 TeV and study the signal sensitivity by use of “extended maximum likelihood” fitting. We consider two hypotheses. The null hypothesis, H0, is the hypothesis that the data are described by the Standard Model. The test hypothesis, H1, is that the data are described by the sum of the background and a narrow Gaussian resonance.

To investigate the potential for discovery pseudo-experiments are generated from both the null and test hypothesis. Each pseudo-experiment is fit twice. The first fit assumes the data are described by

Selection / Sample	500 GeV	750 GeV	1.0 TeV	1.2 TeV	1.3 TeV	1.4 TeV
Generated	187.4	27.7	26.0	22.4	25.3	26.8
Acceptance	172.4	25.9	24.7	21.2	24.0	25.4
Trigger	168.7	25.0	22.6	19.1	21.4	22.3
Electron Id.	127.9	18.3	16.4	12.8	14.6	14.7
$p_T \geq 65$ GeV	125.7	18.2	16.3	12.7	14.5	14.6
$\cos\Delta\phi_{ee} < 0$	123.0	17.8	16.0	12.6	14.3	14.4
Selection efficiency (%)	$65.6 \pm 1.1$	$64.4 \pm 1.1$	$61.7 \pm 1.1$	$56.3 \pm 1.1$	$56.4 \pm 1.1$	$53.9 \pm 1.1$

Table 12: Requirement flow for the  $G \rightarrow ee$  analysis. The remaining cross-section (in fb) is given at each stage. The mass window is chosen as  $\pm 4\sigma_m$  around the signal peak.

Selection/Sample	500 GeV	750 GeV	1.0 TeV	1.2 TeV	1.3 TeV	1.4 TeV
Generated	20.33	4.91	1.43	0.90	0.51	0.51
Acceptance	18.53	4.50	1.36	0.87	0.48	0.49
Trigger	18.45	4.25	1.16	0.80	0.45	0.44
Electron Id.	14.13	3.18	0.88	0.58	0.38	0.33
$p_T \geq 65$ GeV	13.85	3.15	0.88	0.57	0.38	0.33
$\cos\Delta\phi_{ee} < 0$	13.41	3.09	0.85	0.56	0.36	0.33

Table 13: Remaining Drell-Yan cross-section (in fb) at each stage of the  $G \rightarrow ee$  analysis. The mass window is chosen as  $\pm 4\sigma_m$  around the signal peak.

Figure 12: Left: expected (histogram) and “observed” (filled circles) Drell-Yan spectrum from full simulation. The observed distribution includes a graviton with mass of 1 TeV and coupling  $k/\bar{M}_{pl} = 0.02$ . Note that for the purposes of this plot the vertical axis has been rescaled: the error bars correspond to an integrated luminosity of 100 fb<sup>-1</sup>. Right: Log likelihood ratio curves for one million pseudo-experiments generated with background only (filled circles), and signal plus background (empty circles) for the same  $m = 1$  TeV signal point.

the Standard Model using the function described in Section 5.1. The second fit assumes the data are described by the sum of a Gaussian and the shape describing the Drell-Yan background. During this second fit the mean of the Gaussian is allowed to float throughout the entire mass region considered, and the width is fixed to the detector resolution.

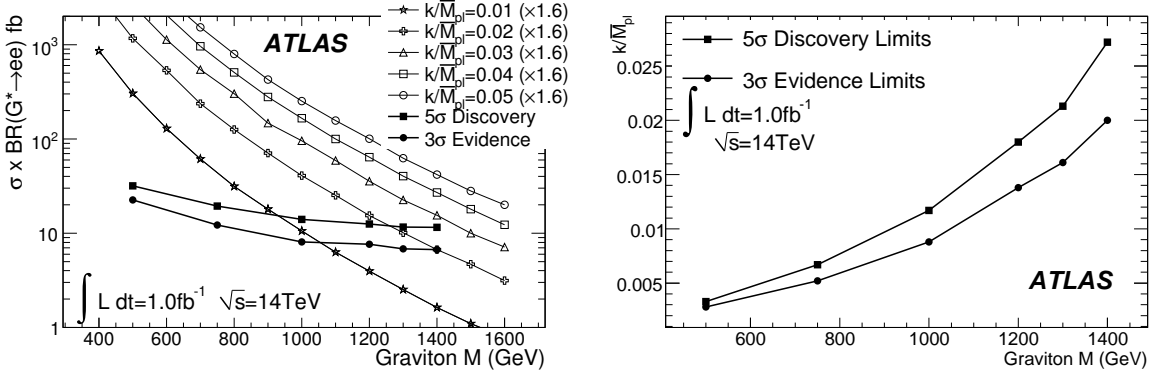

Figure 13: 5σ discovery potential (full squares) as a function of the graviton mass. The 3σ evidence potential is also shown (full circles). Left: shown with cross-sections as calculated by PYTHIA (LO) and multiplied by a  $K$  factor of 1.6 for several values of the coupling; right: dependence of the discovery potential on the coupling.

We can then compare the likelihood of the signal and background hypotheses. The distribution of the logarithm of the likelihood ratio between H<sub>0</sub> and H<sub>1</sub> is constructed, and shown for one signal point in Fig. 12. Based on this, we calculate the average expected discovery potential from the fraction of the likelihood ratio distribution for background-only pseudo-experiments that extends beyond the mean of the distribution for signal plus background experiments. Figure 13 shows the 5σ discovery and 3σ evidence reach in cross-section and  $k/\bar{M}_{pl}$  coupling constant as a function of graviton mass, estimated

for an integrated luminosity of  $1 \text{ fb}^{-1}$ .

The LO cross-sections are multiplied by the  $K$ -factors discussed in section 4.2.2 for both signal and Drell-Yan background. Various sources of systematic uncertainties for signal and background are considered in the evaluation of the experimental sensitivity, including luminosity, energy scale, energy resolution, electron identification efficiency and Drell-Yan background uncertainties as listed in section 4.4. The combined effect of the systematic uncertainties is to increase the amount of integrated luminosity needed for discovery between 10 and 15 percent for the different parameter sets.

## 5.6 Technicolor Using a Non-Parameterized Approach

Topcolor-assisted Technicolor models with walking gauge coupling predict new technihadron states that would be copiously produced at the LHC. The lowest mass states are the scalar technipions ( $\pi_T^{\pm,0}$ ) and the vector technirho and techniomega ( $\rho_T^{\pm,0}$  and  $\omega_T^0$ ). The vector mesons decay into a gauge boson plus technipion ( $\gamma\pi_T$ ,  $W\pi_T$  or  $Z\pi_T$ ), and fermion-antifermion pairs. This analysis searches for the decays  $\rho_T \rightarrow \mu^+\mu^-$  and  $\omega_T \rightarrow \mu^+\mu^-$ . The dimuon mode has a lower branching fraction than the modes involving technipions but the signal is clean, straightforward to trigger on, and can be readily observed with early ATLAS data.

The particular model studied here is the “Technicolor Strawman Model” or TCSM [12, 13]. In the TCSM, it is expected that techni-isospin is an approximate good symmetry and therefore the isotriplet  $\rho_T$  and isosinglet  $\omega_T$  will be nearly degenerate. We will assume for what follows that  $m_{\rho_T} = m_{\omega_T}$ . The technipions are also expected to be nearly degenerate. In the TCSM, the technipion masses are generically not small. In particular, if  $m_{\pi_T} > m_{\rho_T}/2$  the decays of the  $\rho_T$  and  $\omega_T$  to technipions would be kinematically forbidden [50]. The dimuon rate is expected to come dominantly from the  $\omega_T$  with a smaller contribution from the  $\rho_T$ .

The event selection is summarized in Table 14. The technivector meson natural widths are less than a GeV, so the observed width  $\sigma(m)$  is entirely due to detector resolution.

In principle, the best search sensitivity is not obtained by examining the entire dimuon mass distribution for a bump all at once but by using an optimized mass window that maximizes the signal significance for a given assumed signal mass. A prescription for the optimal window size is taken from an analytic calculation in Ref. [51]. Assuming a narrow Gaussian peak on a linear background, the optimal window was found to be  $\pm 1.4\sigma$  about the peak mass. Since we are not really in the narrow resonance regime, we did a study using full-simulation ATLAS Monte Carlo for a Technicolor signal on a Drell-Yan background. Taking  $S/\sqrt{B}$  as our measure of significance, Fig. 14 (left) shows that a window size of  $\pm \sim 1.5\sigma$  or a bit larger is optimal. For this study, a window size of  $\pm 1.5\sigma$  about the peak mass is used.

Figure 14 (right) shows the integrated luminosity necessary to observe either  $3\sigma$  evidence or a  $5\sigma$  discovery, using the modified frequentist approach [44], of technimesons in this channel. The systematic uncertainties summarized in section 4.4 were included in this calculation of technimeson search sensitivity. It should be noted that the integrated luminosity needed for  $5\sigma$  discovery will be affected by the level of misalignment of the muon spectrometer. The contours in Fig. 14 were computed assuming the level of alignment we expect to achieve. The studies in sections 4.3 and 5.3 show that for an initial precision of  $300 \mu\text{m}$  with an uncertainty of  $150 \mu\text{m}$  the amount of data needed to reach  $5\sigma$  would increase by approximately 50%.

$m_{\rho_T, \omega_T}$ (GeV)	400	600	800	1000
Peak mass (GeV)	403	603	804	1004
$\sigma(m)$ (GeV)	13	22	34	46
Requirement				
Generated	201	60.8	23.0	10.1
$ \eta  < 2.5$	116	39.8	15.8	7.3
$p_T > 30$ GeV	114	39.5	15.7	7.2
L1_MU20	112	38.7	15.3	7.0

Match $\chi^2 < 100$	104	35.7	14.0	6.4
Opposite charge	104	35.7	14.0	6.4
Mass window	78.2	26.3	10.3	4.7
Drell-Yan background	46.9	14.1	6.1	2.8
Selection efficiency (%)	$38.9 \pm 0.5$	$43.2 \pm 0.5$	$44.8 \pm 0.5$	$46.8 \pm 0.5$

Table 14: Selection requirement flow for the analysis - cross-section in fb.

Figure 14: Left: for two different  $\rho_T, \omega_T$  signal masses,  $S/\sqrt{B}$  is plotted as a function of mass-window size for windows centered on the peak mass. Right: integrated luminosity needed for  $3\sigma$  evidence or  $5\sigma$  discovery as a function of  $\rho_T, \omega_T$  mass. The dashed lines include only statistical uncertainties while the solid lines contain the systematic uncertainties as well.

## 6 Summary and Conclusions

Several models which lead to resonances in the dilepton final state have been studied. Various systematic studies have been undertaken which estimate the effect of uncertainties from both theoretical knowledge of Standard Model processes as well as expected and assumed early detector performance. Data-driven methods have been developed to evaluate efficiencies, backgrounds, and uncertainties. It has been shown that even with early data the discovery potential can be dramatically increased from current limits. The discovery potential with an integrated luminosity of  $10 \text{ fb}^{-1}$  depends on the particular model and varies in the  $m = 1.0$  to  $3.5 \text{ TeV}$  range. It should be noted that resonance masses above  $1 \text{ TeV}$  which are unreachable by the Tevatron experiments could be discovered with  $100 \text{ pb}^{-1}$  of data already.

### A Effect of the Unknown Location and Rate

When estimating the significance of a local excess of events, the size of the region considered and uncertainties in the shape of the background can significantly reduce the sensitivity of the search. This appendix presents an assessment of the size of this effect for the  $Z'$  boson to dilepton searches. If an excess is found in the dilepton invariant mass, its significance needs to be evaluated in a way that takes into account the possibility of background fluctuations of different masses, cross-sections and widths. One possible way to do this is through the use of maximum likelihood fits, where these quantities are free parameters.

To estimate the effect on the sensitivity of the unknown rate and location of a dilepton resonance, the decay  $Z'_{SSM} \rightarrow ee$  and  $Z'_{SSM} \rightarrow \mu\mu$  were both generated for 16 true  $Z'$  masses between 1 and 4 TeV (evenly spaced every 200 GeV), with a lower cut on the true dilepton mass of 0.5 TeV in all cases. Each sample was simulated and reconstructed using fast simulation, and events were required to have two back-to-back ( $\Delta\phi > 2.9$ ) leptons of opposite charge with  $p_T > 20 \text{ GeV}$  and within  $|\eta| < 2.5$ . For an estimation of the expected background, Standard Model Drell-Yan production was used.

The dilepton resonance was modeled using an ad-hoc parameterization that models appropriately the shapes of both the  $Z' \rightarrow ee$  and  $Z' \rightarrow \mu\mu$  modes, consisting of a product between a Breit-Wigner and a Landau distribution with a common mean, and where the width of the Landau was parameterized as a function of the width of the Breit-Wigner<sup>9</sup>. The common mean, the width parameter and the amplitude of the signal are allowed to float in the fits.

Figure 15 shows the likelihood ratio distributions for an  $m = 3 \text{ TeV}$   $Z'_{SSM} \rightarrow ee$  fit-based significance, where the signal rate, the peak's width and the mean mass all float in the fit, corresponding to an integrated luminosity of  $4 \text{ fb}^{-1}$ . The distributions of the log-likelihood ratio for fits to H0 pseudo-experiments and for fits to H1 pseudo-experiments are shown. The fraction  $p$  of the H0 distribution that has a likelihood ratio larger than the mean of the H1 distribution is shaded. The value of  $p$  is then transformed into a significance following the convention under which  $p = 2.87 \times 10^{-7}$  corresponds to  $5\sigma$  (see section 5). The fraction shown in the plot corresponds to a significance of  $4.29\sigma$ .

Several million pseudo-experiments were generated and fit, covering different masses and luminosities. Figure 16 shows the significance for different approaches in the case of an  $m = 3 \text{ TeV}$   $Z'_{SSM}$  for both the dielectron (left) and the dimuon (right) cases. The plots compare the significance as obtained from number counting (circles), fixed mass fits (dots) and floating mass fits (squares). The floating-mass significances are on average 20% lower than the fixed-mass calculations for  $Z' \rightarrow ee$ , and about 15% lower in the dimuon case (in obtaining these numbers, we exclude the region below  $2.25 \text{ fb}^{-1}$ , which is affected by low statistics effects).

<sup>9</sup>The best motivated shape is a Breit-Wigner convoluted with a Gaussian resolution. Unfortunately, the convolution fit is very time consuming and for this study millions of fits were performed. Empirically the combination of a Breit-Wigner and a Landau were found to give essentially identical results.

Figure 15: Likelihood ratio distribution for an  $m = 3 \text{ TeV } Z'_{SSM} \rightarrow ee$ ; the distribution on the left corresponds to background-only pseudo-experiments; the one on the right, to signal plus background.

Figure 16: Comparison of the fit-based significance for fixed-mass (dots) and floating-mass (squares) fits for both cases,  $Z' \rightarrow ee$  (left) and  $Z' \rightarrow \mu\mu$  (right). Circles show the estimation from number counting.

# Lepton plus Missing Transverse Energy Signals at High Mass

## Abstract

The prospects for the discovery of heavy lepton-neutrino resonances with the ATLAS detector are evaluated using full detector simulation. The performance of large missing transverse momentum measurement is studied. Its impact on the lepton-neutrino transverse mass reconstruction, and on the backgrounds rejection, is then discussed. As benchmark, the sensitivity to a Standard Model like  $W'$  is evaluated. Emphasis is put on the discovery potential of ATLAS with early data, namely with an integrated luminosity of  $10 \text{ pb}^{-1}$  to  $10 \text{ fb}^{-1}$ .

## 1 Introduction

The Standard Model of particle physics has been able to predict or describe, within errors, almost all measurements performed within its domain. However, several fundamental questions remain unresolved. Its mechanism for electroweak symmetry breaking has not been experimentally confirmed. The model parameters still lack a theoretical explanation. There are indications, therefore, that the Standard Model is not a fundamental theory, but a good approximation of nature at the energy ranges that have been so far accessible to experiment. Thus, the search for physics beyond the Standard Model is an important part of the ATLAS physics program. In this document, a study is presented of the potential for the search of final states comprised of one electron or muon (*lepton*, in what follows) plus missing transverse energy.

A large variety of theories beyond the Standard Model, predict additional gauge bosons. Any charged, spin 1 gauge boson which is not included in the Standard Model is called  $W'$  boson and according to several predictions there is at least one  $W'$  boson detectable at the LHC. These theories and models which predict new charged gauge bosons range from the Grand Unified Theories [1–3], the various Left-Right Symmetric Models [1, 4–10], Kaluza-Klein theories [11–15], Little Higgs models [16–18], dynamical symmetry breaking models [19] and even models inspired from superstrings [20–22]. As an example, the 45 decompositions of the  $SO(10)$  gauge group, which is a candidate for large GUT symmetries, under the  $SU(3)_C \times SU(2)_L \times SU(2)_R \times U(1)_{B-L}$  gives rise to a  $(1,1,3,0)$  triplet coming from the  $SU(2)_R$  group. That is, a triplet of right-handed  $W^{\pm,0}$  fields, which carry weak (V+A) interactions. A theoretical model, based on the gauge group  $SU(3)_C \times SU(2)_L \times SU(2)_R \times U(1)_{B-L}$  which is called a Left-Right Symmetric Model (LRSM), after spontaneous symmetry breaking, predicts a right-handed  $W_R$  gauge boson mixes with the left-handed  $W_L$  boson of the Standard Model. The  $W_R$  gauge boson is a very attractive  $W'$  boson candidate. The search for these particles is an important part of the studies for new physics to be performed at LHC. Studies presented here are based on predictions of a “Standard Model-like”  $W'$  boson from so-called extended gauge models [23]. This  $W'$  boson has Standard Model-like couplings to fermions and its decays to  $WZ$  bosons are suppressed.

The D0 experiment, at Fermilab, has set the present lower limit for the  $W'$  boson mass [24] to  $m_{W'} > 1 \text{ TeV}$  at 95% C.L. The LHC, with a centre-of-mass energy of 14 TeV, is expected to increase the search reach even at early stages of data taking. Other ATLAS studies have evaluated the potential for discovery of  $W' \rightarrow \ell \nu_\ell$  where  $\ell = \mu, e$  [25]. This study is based on the most recent realistic detector description, including a complete simulation of the trigger chain.

The remaining of this paper is organized as follows. The Monte Carlo samples which were used are summarized in section 2. Section 3 discusses the expected performance on lepton reconstruction, as well as on missing transverse energy. Section 4 briefly describes the triggers which were used in this study. The event selection is discussed in section 5. The discovery potential of a  $W'$  with Standard Model couplings is assessed in section 7, after examining the systematic uncertainties in section 6.

## 2 Monte Carlo Samples

Table 1 summarizes the samples used in this study; a detailed account of the procedures, generators and settings used is given in [26]. Signal samples for masses other than 1 and 2 TeV were produced locally and validated against central production samples.

For the signal, samples of  $W' \rightarrow \ell \nu$  events were generated with PYTHIA v6.403 [27], based on the leading order cross sections and the parton distribution functions CTEQ6 [28], where  $\ell$  can be any type of lepton ( $\tau$  included), for true  $W'$  boson masses ranging from 1 to 4 TeV.

The main background for a  $W'$ -type state is the high-mass tail of Standard Model  $W$  boson production; in order to provide enough background to study also the higher  $W'$  boson masses, two samples of Standard Model  $W$  boson events were produced, with different requirements on the true invariant mass of the  $W$  boson: one with  $200 \text{ GeV} < m_W < 500 \text{ GeV}$ , and one with  $m_W > 500 \text{ GeV}$ . In these studies, the alignment and calibration of the detector is assumed to be well described in the reconstruction algorithms.

Table 1: Monte Carlo samples used for the study of  $W'$  bosons.  $\hat{p}_T$  represents the transverse momentum of the partons in their rest frame. The  $t\bar{t}$  sample includes only fully leptonic and semi-leptonic channels.

## 3 Reconstruction Performance

### 3.1 Muon Reconstruction

Muon reconstruction in ATLAS uses all main detector subsystems. The Muon Spectrometer (MS) is designed to provide efficient and precise stand-alone momentum measurement for muons of transverse momentum up to  $O(p_T = 1 \text{ TeV})$ . During the back-tracking of the muon to the production vertex, energy loss fluctuations can be measured with the use of the calorimeters, which can also provide independent

Figure 1: Inverse  $p_T$  resolution for muons from  $W'$  boson decays; left:  $p_T < 400$  GeV (muons from  $m = 1$  TeV  $W'$  bosons), right:  $p_T > 800$  GeV (muons from  $m = 2$  TeV  $W'$  bosons).

Figure 2: Muon transverse momentum resolution as a function of  $\eta$  (left) and  $p_T$  (right) in  $W'$  boson decays. Filled circles represent muons from  $m = 1$  TeV  $W'$  bosons, while open circles correspond to muons from  $m = 2$  TeV  $W'$  bosons.

muon tagging to increase the identification efficiency. For optimum performance in momentum resolution, the MS information is combined with the track information obtained in the Inner Detector (ID). A full description of the algorithms for muon performance and identification can be found in [29] and [30].

Figure 1 shows the inverse transverse momentum ( $1/p_T$ ) resolution for muons from decays of a  $W'$  boson for muons below  $p_T = 400$  GeV and above  $p_T = 800$  GeV. Especially relevant for the analysis are the negative tails in these plots, since they correspond to reconstructed muon candidates that have a  $p_T$  larger than that of the true particle. The relative contribution of these tails can be assessed by the fraction of muon candidates separated by more than  $2\sigma$  from the mean of the distribution (which in both cases is consistent with zero, as it should). The fraction in that negative tail is  $(4.9 \pm 0.3)\%$  for muons with  $p_T < 400$  GeV, and  $(3.8 \pm 0.4)\%$  for  $p_T > 800$  GeV (to be compared with 2.275% for a gaussian distribution). The transverse momentum resolution achieved is shown as a function of the pseudo-rapidity  $\eta$  and  $p_T$  in Fig. 2. On average a resolution of 4.5 and 5.5% is recorded for muons from  $W'$  bosons of  $m = 1$  TeV and 2 TeV respectively.

Figures 3 and 4 show the efficiency for combined muon reconstruction as a function of pseudo-

Figure 3: Combined muon reconstruction efficiency as a function of  $\eta$  and  $\phi$  for muons from  $W'$  boson decays.

Figure 4: Combined muon reconstruction efficiency as a function of  $p_T$  for muons from  $W'$  boson decays.

rapidity ( $\eta$ ), azimuthal angle ( $\phi$ ) and transverse momentum ( $p_T$ ) for muons from fully simulated  $W'$  boson decays. An overall efficiency of 93.6% and 92.4% is measured for  $m = 1$  TeV and 2 TeV  $W'$  boson samples, respectively. The regions with lower efficiency in muon reconstruction are observed, as expected, in the middle plane ( $\eta = 0$ ) and in the transition regions between the barrel and the end-cap sections of the MS (at  $|\eta| \sim 1.2$ ). The regions with low efficiency in  $\phi$  correspond to the feet of the detector ( $\phi \simeq -2, -1$ ) and to passages for services.

One important issue in this study concerns the background that can rise from badly reconstructed muons. Their momentum being wrongly estimated upwards, can cause both the presence of a high  $p_T$  muon and, correspondingly, large missing transverse energy. In the definition of the muon, extra quality criteria may be imposed in order to diminish this probability. In this study, the following mild requirements are adopted:

- A matching  $\chi^2$ , between MS and ID tracks, smaller than 100 (further discussed in [30]).
- An impact parameter in the  $z$ -axis (i.e. the beam axis) smaller than 200 mm.
- An impact parameter significance in the transverse (R- $\phi$ ) plane smaller than 10.

Figure 5: Electron energy resolution as a function of pseudo-rapidity (left) and energy (right) in  $W'$  boson decays. Filled circles represent electrons from  $m = 1$  TeV  $W'$  bosons, while open circles correspond to  $m = 2$  TeV  $W'$  bosons.

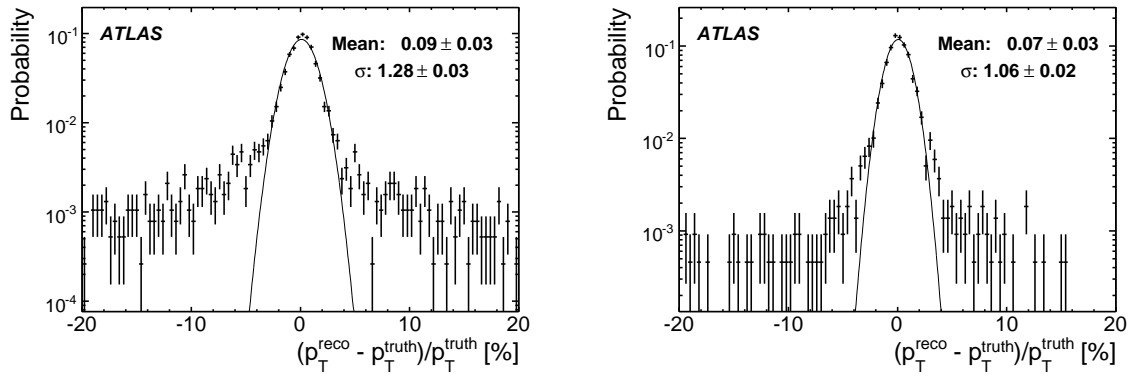

Figure 6: Electron  $p_T$  resolution in  $W'$  boson decays; left:  $p_T < 400$  GeV (muons from  $m = 1$  TeV  $W'$  bosons), right:  $p_T > 800$  GeV (muons from  $m = 2$  TeV  $W'$  bosons).

### 3.2 Electron Reconstruction

Electron candidates are built starting from clusters of calorimeter cell energy depositions, which are matched to a track from the inner detector. Electron identification and reconstruction are described in detail in [31] and [32], where three standard selections were developed to be used in physics searches. The present study uses the *medium* set of selection requirements, which consists in several requirements on the clusters used (size, containment, association with a track, shower shapes and quality of the track match).

Figure 5 shows the electron energy resolution (in percentage) as a function of pseudo-rapidity ( $|\eta|$ ) and true energy. The average energy resolution for electrons in this energy range is close to 1%, and is worse in the transition region between the two calorimeter systems. Figure 6 shows the relative difference between reconstructed and true transverse momenta of isolated electrons with true  $p_T$  lower than 400 GeV and higher than 800 GeV. The fractions of events in the upper tails (more than  $2\sigma$  over the fitted mean) are  $(11.8 \pm 0.6)\%$  and  $(5.3 \pm 0.5)\%$ , respectively. These non-Gaussian tails are due to the amount of material in the inner detector and are, therefore,  $\eta$ -dependent.

Figure 7:  $\cancel{E}_T$  resolution in muonic  $W'$  boson decays.  $m_{W'} = 1$  TeV (left) and 2 TeV (right).

Figure 8:  $\cancel{E}_T$  resolution in  $W'$  boson decays to electrons.  $m_{W'} = 1$  TeV (left) and 2 TeV (right).

### 3.3 Reconstruction of the Missing Transverse Energy

The final state under consideration includes a neutrino, whose momentum information can be inferred only partially from the energy imbalance in the detector (since the total transverse momentum of the event has to add up to zero). The reconstruction of the missing transverse energy ( $\cancel{E}_T$ ) in ATLAS is described in detail in [33].

The resolution of  $\cancel{E}_T$  reconstruction in  $W'$  boson events containing muons can be seen in Fig. 7. An average resolution of about 18 GeV is observed for  $m_{W'} = 1$  TeV (25 GeV for  $m_{W'} = 2$  TeV). In the case of  $m_{W'} = 2$  TeV the non-Gaussian tails in the resolution are more pronounced, and come from the degraded performance of muon reconstruction at high  $p_T$ .

Figure 8 shows the  $\cancel{E}_T$  resolution for events that contain one high- $p_T$  electron from a  $W'$  boson decay. The left plot corresponds to the  $m = 1$  TeV  $W'$  boson, and the right plot to 2 TeV; the resolutions are around 10 and 14 GeV, respectively. These values agree well with the expected  $\cancel{E}_T$  resolution from the mean of the scalar sum of transverse energy ( $\langle \sum E_T \rangle$ ) in each case; for the  $m = 1$  TeV sample,  $\langle \sum E_T \rangle$  for the selected events is 439 GeV, which yields an estimated  $\sigma(\cancel{E}_T) \sim 0.5\sqrt{\sum E_T} = 10.5$  GeV; for  $m = 2$  TeV, the expected value (based on  $\langle \sum E_T \rangle$ ) is 13.3 GeV.

Figure 9: Transverse mass distribution for  $m = 1$  TeV  $W'$  bosons, as obtained from the true particles' momenta (filled histograms), and from reconstructed information after basic selection (black outline). Left: electron mode; right: muon mode.

Figure 10: As Fig. 9, for  $m = 2$  TeV  $W'$  bosons, filled: from true information; outline: reconstructed transverse mass.

### 3.4 Transverse Mass Reconstruction

In the  $W'$  boson search, the transverse momentum  $p_T$  of the single lepton in the event and the missing transverse energy  $\cancel{E}_T$  are combined to obtain the *transverse mass* as follows:

$$m_T = \sqrt{2p_T \cancel{E}_T (1 - \cos \Delta\phi_{\ell, \cancel{E}_T})} \quad (1)$$

where  $\Delta\phi_{\ell, \cancel{E}_T}$  is the angle between the momentum of the lepton and the missing momentum, in the transverse plane. Figures 9 and 10 show the transverse mass distributions for  $m = 1$  and 2 TeV signals, respectively, as obtained from truth information (light gray filled histograms) and the degradation due to detector resolution and efficiency (black hollow histograms). As can be expected from Figs. 2 and 5, the shape of the transverse mass spectrum has a larger distortion in the muon channel than in the electron channel, with larger tails for higher  $W'$  boson masses. On the other hand, the reconstruction efficiency is higher in the muon channel (over 86% for each mass) than in the electron channel (about 72%).

Figures 11 and 12 show the distribution of the difference between the “true” transverse mass (i.e. as obtained from the true momenta of the lepton and the neutrino) and its reconstructed value, for electron and muon modes, and for  $m = 1$  and 2 TeV  $W'$  boson masses. In Fig. 11, single Gaussian fits are shown; a fitted width of about 12 GeV is obtained for the electron channel, while the muon channel, besides having much larger non-Gaussian tails, has a fitted width of about 23 GeV.

Figure 11: Distribution of the event-by-event difference between the reconstructed and “true” transverse mass for the electron and muon channel, for  $m = 1$  TeV  $W'$  bosons.

Figure 12: As Fig. 11, for  $m = 2$  TeV  $W'$  bosons.

Figure 12 shows the corresponding comparison for a 2 TeV signal; however, in this case, the muon channel (on the right) has a stronger non-Gaussian character, which is why no fit was performed. The quadratic mean of the distribution is about 84 GeV.

## 4 Trigger

The ATLAS trigger [34] has three levels: events passed by the L1 (level 1) hardware trigger are partially reconstructed in L2 (level 2) processors and, if accepted there, are fully processed in the EF (event filter) processor farm. Only events accepted by the EF (and thus also by L1 and L2) are recorded for later reconstruction and analysis.

Trigger rates are estimated in separate studies of the electron [35] and muon [36] trigger systems. However, these studies were performed with a more recent version of the software than the one used here<sup>1</sup>. Therefore, we have measured some of the rates directly in simulation using the dijet and top samples described earlier in this note. We additionally measured L1 rates and efficiencies for single-electron and single-muon triggers with thresholds higher than those defined in the simulated trigger menu. The errors we assign to our rate estimates are purely statistical.

<sup>1</sup>Especially for electrons, the trigger menu and algorithms in the simulated samples are quite different from those in the above notes which are much closer to those expected to be used during actual data acquisition.

#### 4.1 Electron trigger

For a single electron trigger with an  $E_T$  threshold of 100 GeV, we measure a L1 rate of  $14 \pm 1$  Hz at an instantaneous luminosity of  $10^{32} \text{ cm}^{-2}\text{s}^{-1}$ , similar to the electron trigger study estimate of 10 Hz. The efficiency to trigger on  $W' \rightarrow e\nu$  events for  $|\eta| < 2.5$  is 98% for a mass of either 1 or 2 TeV. If the threshold is raised to 250 GeV, we measure a rate of  $25 \pm 4$  Hz at  $10^{33} \text{ cm}^{-2}\text{s}^{-1}$  and an efficiency of 96% for the 2 TeV mass.

Loose requirements in L2 and EF can further reduce these rates with a moderate degradation of the efficiency. For definiteness in the calculations in the following sections, we assume that a trigger efficiency (applied after all requirements) of  $0.90 \pm 0.10$  is achieved with an acceptable rate for all  $W'$  boson masses.

#### 4.2 Muon trigger

The trigger menu and algorithms in the simulation samples are similar to those in the muon trigger study and those expected for data acquisition. In contrast to the electron case, lower thresholds can be applied thanks to the lower fake rates. A significant decrease in rate is then obtained thanks to an improved measurement of  $p_T$  at each level. Applying a threshold of 20 GeV at each trigger level, we obtain an EF rate of  $20 \pm 10$  Hz for an instantaneous luminosity of  $10^{32} \text{ cm}^{-2}\text{s}^{-1}$ , consistent with the muon study prediction of 13 Hz. We measure a  $W' \rightarrow \mu\nu$  trigger efficiency for  $|\eta| < 2.5$  of 74% for  $m = 1$  TeV and 73% at 2 TeV. At  $10^{33} \text{ cm}^{-2}\text{s}^{-1}$ , we apply a  $p_T$  threshold of 40 GeV, the maximum L1 value, and obtain a trigger rate of  $4.1 \pm 0.7$  Hz close to the 5.6 Hz obtained in the trigger study. The corresponding trigger efficiency for the  $m = 2$  TeV  $W'$  boson is 69%.

It should be noted that most of the efficiency loss comes from holes in the coverage of the muon system, where the reconstruction is also inefficient.

### 5 Event Selection

The decay  $W' \rightarrow \ell\nu$  provides a rather clean signature consisting of a high-energy isolated lepton and large missing transverse energy. The largest backgrounds are the high- $p_T$  tail of the  $W \rightarrow \ell\nu$  decays and  $t\bar{t}$  production. Both these final states are accompanied by significant jet activity, but contain also leptons that are as isolated as those expected from  $W' \rightarrow \ell\nu$  decays.

A potentially dangerous background is the one arising from fake leptons; since this issue is more likely to be significant for electrons than for muons, the backgrounds will be presented separately for  $W' \rightarrow e\nu$  and  $W' \rightarrow \mu\nu$  final states.

#### 5.1 Event Preselection

In addition to the electron and muon identification criteria described above, events are required to have:

- Only one reconstructed lepton with  $p_T > 50$  GeV within  $|\eta| < 2.5$ .
- Missing transverse energy  $\cancel{E}_T > 50$  GeV.

Figure 13 shows, on top, differential cross-section as a function of the lepton  $p_T$  for the  $m = 1$  TeV and 2 TeV signal samples, Standard Model  $W$  boson,  $t\bar{t}$  and dijet production. The dashed vertical line shows the requirement value (50 GeV). The bottom plots in Fig. 13 show the  $\cancel{E}_T$  distributions for the same processes after requiring only one lepton with  $p_T > 50$  GeV; again, the requirement value (at 50 GeV) is shown with the dashed vertical line. This selection provides a relatively clean signal in the high transverse mass region, as shown in Fig. 14, which shows the differential cross-section as a function

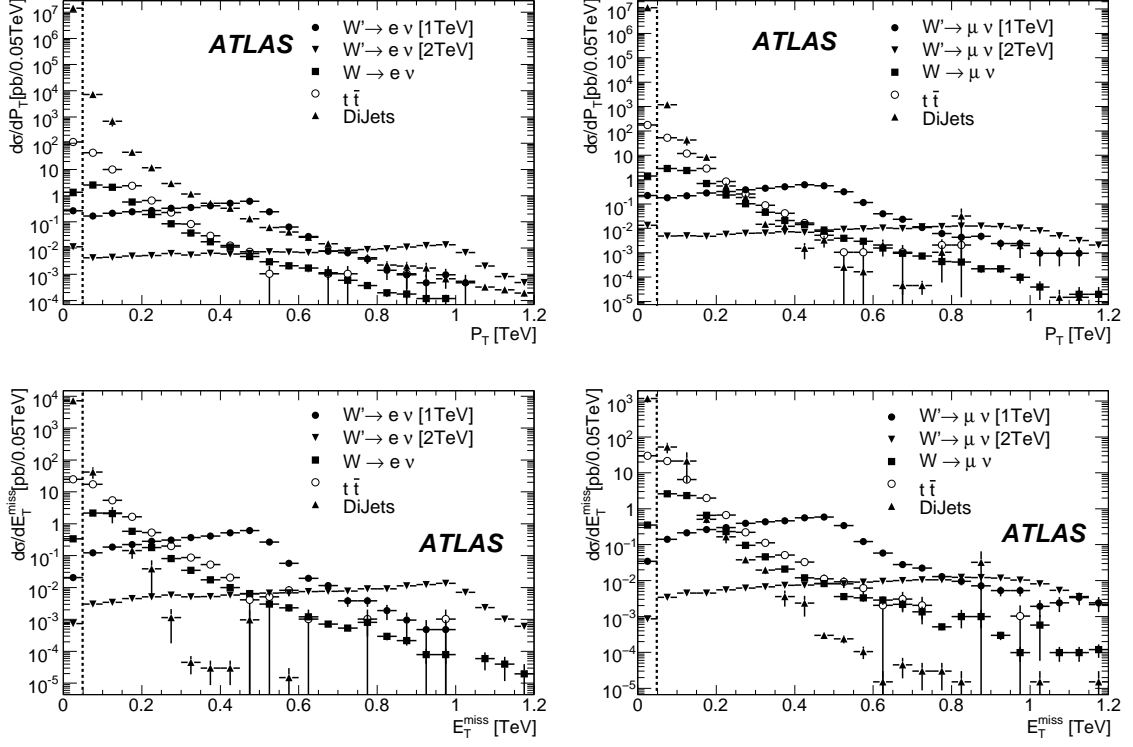

Figure 13: Top: leading lepton  $p_T$  distributions (left: electron events, right: muon events). Bottom:  $E_T^{\text{miss}}$  distribution of events with only one reconstructed lepton with  $p_T > 50$  GeV (left: electron events, right: muon events).

of the transverse mass after the requirements on  $p_T$  and  $E_T^{\text{miss}}$ . The background can be further rejected by exploiting additional observables, described in next sections: lepton isolation, lepton fraction and jet veto criteria.

## 5.2 Background Rejection

After the kinematic requirements are applied, the  $t\bar{t}$  and dijets backgrounds are still larger than the high-mass tail of the Standard Model  $W$  boson close to the threshold value on the lepton  $p_T$  and on  $E_T^{\text{miss}}$ . Since the uncertainties on the rate of these backgrounds are large, it is desirable to bring them below the irreducible background from  $W$  bosons. To achieve this, additional requirements are imposed on lepton isolation and on the lepton fraction, described below. A simpler selection strategy, based on a jet veto, is also explored, since it could prove useful during the first stages of data taking.

### 5.2.1 Lepton Isolation

As the lepton from a  $W'$  boson decay is expected to be isolated, only events without high energy tracks around the lepton trajectory are accepted. The tracking isolation is done by requiring that the sum of the  $p_T$  of tracks in a  $\Delta R$ -cone around the lepton be below a threshold;  $\Delta R$  is defined as

$$\Delta R \equiv \sqrt{(\Delta\phi)^2 + (\Delta\eta)^2},$$

where  $\Delta\phi$  and  $\Delta\eta$  are the distances in azimuthal angle and in pseudo-rapidity, respectively, from the lepton under consideration.

Figure 14: Transverse mass spectrum after the basic kinematic requirements for background and signal ( $m_{W'} = 1$  and 2 TeV). Left: electron mode; right: muon mode.

Figure 15:  $t\bar{t}$  background rejection and signal efficiency for different requirement values on the  $\sum p_T$  (open markers) and  $(\sum p_T)/p_{T\text{lepton}}$  (filled markers), for the muon channel. Each marker type corresponds to a different value for  $\Delta R$ , from 0.1 to 0.5.

Calorimeter isolation was also explored (the calorimetric energy deposited within the volume between two  $\Delta R$ -cones is required to be below a threshold).

Besides requiring a maximum value of  $\sum p_{T\text{tracks}}$  (of 10 GeV to 1 GeV), the use of a *normalized* isolation requirement was also explored, in which the requirement is applied to the  $\sum p_{T\text{tracks}}/p_{T\text{lepton}}$  ratio. This ratio is required to be smaller than 0.1 to 0.01. Five different  $\Delta R$  values were used in both cases; as shown in Fig. 15 for muons, the normalized isolation selection achieves a higher  $t\bar{t}$  rejection for the same efficiencies. The efficiencies and rejections achieved for electrons are similar.

The calorimeter energy difference in two cones is not only of use in the electron case, but also in the muon one. High  $p_T$  muons coming from  $W'$  boson decays can also radiate a lot inside the material preceding the MS. This radiation appears as energy depositions close to the muon in the calorimeters. As can be seen in Fig. 16 (right), the energy deposition in a cone of  $\Delta R < 0.1$  around the muon is much higher, around 30 GeV on average, than the deposition in a cone of  $\Delta R < 0.5$  when the inner cone is subtracted (in this case the average is about 7 GeV). Moreover, in Fig. 16 (left) it is shown that in the majority of the cases, a high reconstructed energy deposition indicates the existence of high final state radiation. Therefore, the energy deposition in an inner cone (e.g.  $\Delta R < 0.1$ ) must be subtracted also in the case of muons when isolation criteria based on calorimetry are applied. Also on track based isolation criteria an inner cone containing the muon track itself must be subtracted. In this case however, the inner cone can be much narrower, since it only needs to be able to exclude the track associated with the

Figure 16: Left: the true energy deposition as a function of the reconstructed one in a cone of  $\Delta R=0.1$  for muons coming from decays of  $m = 2$  TeV  $W'$  bosons. Right: the solid histogram shows the energy recorded in a cone of  $\Delta R=0.1$  around the muon. The dashed histogram shows the energy recorded in a cone of  $\Delta R=0.5$  after the subtraction of the inner cone deposition.

Figure 17: Left: distribution of an absolute track based isolation variable for muons. Right: distribution of a relative calorimetry based isolation variable for muons. In both cases the inner cone of  $\Delta R=0.1$  is subtracted.

lepton under consideration. Figure 17 shows the distributions of the isolation energy for different event categories. For these plots, muons with  $p_T > 20$  GeV are considered.

For the analysis, a loose requirement of 0.05 is used on the normalized track-based isolation for both channels (electron and muon), and no requirement on the calorimeter-based isolation is applied. Tracks are included in the sum if  $0.02 < \Delta R(\text{track}, \text{lepton}) < 0.3$ . This requirement keeps about 99% of the signal for both masses ( $m_{W'} = 1$  and 2 TeV), rejects about 10% of the  $t\bar{t}$  events left after the basic selection and rejects over 99% of the dijet background.

### 5.2.2 Lepton Fraction

Another variable that can be used to reduce the dijet and  $t\bar{t}$  backgrounds is the “lepton fraction” of the event, which can be expressed as  $\sum p_T^{\text{leptons}} / (\sum p_T^{\text{leptons}} + \sum E_T)$ , where the scalar sum on the lepton  $p_T$  sums over  $\cancel{E}_T$  as well. Essentially this variable measures the fraction of energy that can be attributed to leptons (including neutrinos, which are assumed to be the main contribution to  $\cancel{E}_T$ ) in an event. Here, out of the visible leptons, only the most energetic one is included in the sum (its  $p_T$  is added to the  $\cancel{E}_T$  to form  $\sum p_T^{\text{leptons}}$ ). The distribution of this variable is shown for different event categories in Fig. 18 (left). As expected, it shows a much lower value for  $t\bar{t}$  events (in pink) than for the rest of the samples used

Figure 18: Left: distribution of the lepton fraction variable (see text) for different event categories. Right: signal efficiency versus  $t\bar{t}$  efficiency for different requirement values on the lepton fraction variable.

( $W'$  boson signals and Standard Model  $W$  bosons). The efficiency for signal versus  $t\bar{t}$  events for different values of the variable, is shown in Fig. 18 (right). A requirement at 0.5 results in a signal efficiency of  $\sim 96\%$  in both channels and a rejection factor of  $\sim 45$  against the  $t\bar{t}$  background, and it suppresses all the remaining dijet events. This value will be used subsequently.

### 5.2.3 Jet Veto and Jet Multiplicity Requirements

A selection procedure based solely on veto-ing events with high jet activity could provide an alternative way to extract a signal in this search. Several requirements on jet activity were explored; in some, events are rejected if they include any jet over an energy threshold, in others, jet multiplicity information is used. The jet veto was applied just after the basic selection (i.e., lepton identification,  $p_T$  and  $\cancel{E}_T$  requirements).

Figure 19 shows the distribution of the  $p_T$  of the leading jet after the basic selection; the distribution on the left corresponds to the electron channel and the one on the right to the muon channel. Tables 2 and 3 show the expected rates for several jet veto criteria.

Figure 20 shows how after a 200 GeV jet veto requirement (and without isolation or lepton fraction requirements), most of the  $t\bar{t}$  and dijet background is rejected, and the signal to background ratio is good for high transverse mass values. Although the signal is reduced by between 5 and 10% with respect to selecting on isolation and lepton fraction, a jet veto requirement may be a good tool if the calibration of the  $\sum E_T$  (used to compute the lepton fraction) is not well understood in early data. However, in what follows, this requirement is not used.

## 5.3 Event Selection Results

Figure 21 shows the expected transverse momentum spectra for signal and background for both channels after all requirements (preselection, isolation, and lepton fraction). The selection requirement flow is shown in Tables 4 and 5. The transverse mass requirement has been chosen by minimizing the luminosity needed to get a  $5\sigma$  excess. The initial cross-sections for the  $W'$  boson signals and for the high mass  $W$  boson tail include the  $K$ -factor obtained in section 6.1.

## 6 Systematic Uncertainties

### 6.1 Generator-level Systematic Uncertainties

The input for the full simulation studies described in earlier sections was obtained by generating  $W'$  boson events using PYTHIA [27]. Events in the high-mass tail of the  $W$  boson were generated using PYTHIA as well. Both use the default PYTHIA parton distribution functions (PDFs), CTEQ6l, the CTEQ6 [37] LO (leading-order) fit with NLO (next-to-leading-order)  $\alpha_S$ . Here we report on generator-level studies which examine the effects of making use of the NLO matrix elements and varying the PDFs.

#### 6.1.1 Higher Orders

To evaluate contributions from higher order diagrams, we used MC@NLO [38] input to the HERWIG [39] event generator. Both  $W$  and  $W'$  boson events were generated using the  $W$  boson production process with the  $W$  boson mass set to the  $W'$  boson value for the latter. The  $W'$  boson widths were set to the values calculated by PYTHIA. The masses and widths used are listed in Table 6. Both MC@NLO and HERWIG were run using the default HERWIG PDFs, MRST2004nlo, the MRST 2004 fit using the standard  $\overline{\text{MS}}$  scheme at NLO [40].

One million events were generated for each generator at each of the masses. The cross-section is

Requirement	$\sigma$ [pb]				
	$W'$ (1 TeV)	$W'$ (2 TeV)	$W$ tail	$t\bar{t}$	Dijets[1-7]
(No requirement)	4.99	0.231	10.28	452	$1.91 \times 10^{10}$
Preselection	$3.67 \pm 0.04$	$0.160 \pm 0.002$	$6.80 \pm 0.06$	$150.57 \pm 0.40$	$(13.6 \pm 0.2) \times 10^6$
$p_T > 50$ GeV	$3.43 \pm 0.04$	$0.150 \pm 0.002$	$5.53 \pm 0.05$	$51.13 \pm 0.23$	$(7.23 \pm 0.6) \times 10^3$
$E_T > 50$ GeV	$3.40 \pm 0.04$	$0.149 \pm 0.002$	$5.19 \pm 0.05$	$25.78 \pm 0.16$	$45.33 \pm 16.65$

Table 5: Cross-section for signal and backgrounds after each requirement. Muon mode.

calculated for transverse mass above 70% of the  $W'$  boson mass, i.e. above the values listed in Table 6.

We define the  $K$ -factor to be the ratio of the MC@NLO cross-section to that from PYTHIA. These are shown as functions of  $\eta$  in Fig. 22.

Integrals of the  $W'$  boson and  $W$  boson tail differential cross-sections are given in Table 7. The NLO predictions are 30-40% higher than those from PYTHIA, with little change with the variations in scale. Although the NLO/LO cross-section and acceptance ratios are of order 40%, the uncertainties on the NLO values are expected to be significantly smaller. Also, the QED corrections are partially included through PHOTOS [41] for FSR, and should have a small impact on the measurements in case of the observation of a signal.

### 6.1.2 Parton Distribution Functions

The LHC will take data in a new energy regime and so we expect significant uncertainty in signal and background predictions due to our uncertainty in knowledge of the PDFs.

The CTEQ6.1 fits include 40 error PDFs corresponding to the two limits on each of 20 eigenvectors.

M (GeV)	$\Gamma$ (GeV)	Minimum $m_T$ (GeV)
1000	34.739	700
2000	70.540	1400
3000	106.390	2100

Table 6: Masses and widths used as input to MC@NLO/HERWIG generation of  $W'$  boson events. The third column gives the lower limit for the masses used to calculate cross-sections.

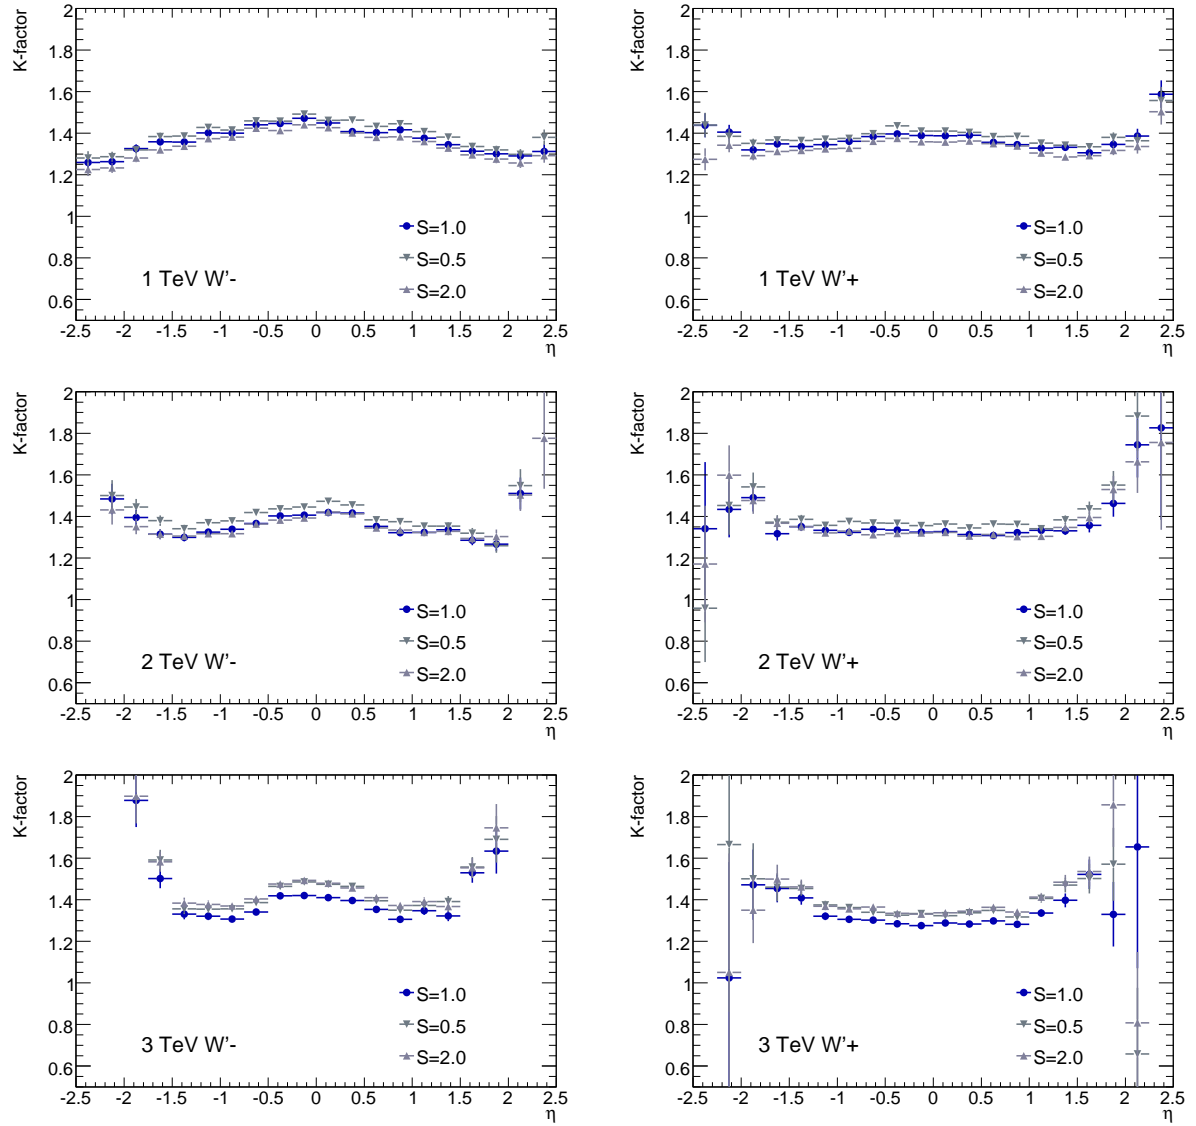

Figure 22:  $W'$  boson  $K$ -factors (ratios of MC@NLO and PYTHIA cross-sections) as functions of  $\eta$  for positive (left) and negative (right) charge for masses of 1 (top), 2 (middle) and 3 TeV (bottom).  $S$  is the common scale factor. The errors are statistical.

Process	Min. $m_T$	PYTHIA $\sigma$ (fb)	NLO $\sigma$ (fb)	$K$ -factor	S=0.5	S=2.0
$W'(m = 1 \text{ TeV})+$	700	534. (1)	742. (1)	1.389 (4)	1.8% (2)	-1.8% (2)
$W'(m = 1 \text{ TeV})-$	700	1204. (1)	1644. (2)	1.365 (3)	1.7% (2)	-1.8% (2)
$W'(m = 2 \text{ TeV})+$	1400	62.6 (1)	83.0 (1)	1.327 (3)	2.7% (2)	-1.6% (2)
$W'(m = 2 \text{ TeV})-$	1400	20.3 (6)	27.7 (4)	1.362 (4)	3.0% (2)	-1.4% (2)
$W'(m = 3 \text{ TeV})+$	2100	6.73 (1)	8.69 (1)	1.292 (3)	3.7% (2)	4.4% (2)
$W'(m = 3 \text{ TeV})-$	2100	1.791 (6)	2.540 (4)	1.370 (5)	3.7% (2)	4.4% (2)
$W+$	700	20.22 (7)	27.66 (8)	1.368 (6)	2.2% (4)	-0.6% (4)
$W-$	700	8.93 (5)	12.56 (4)	1.407 (9)	2.6% (5)	-0.8% (5)
$W+$	1400	1.042 (4)	1.424 (4)	1.366 (7)	2.2% (5)	-1.5% (5)
$W-$	1400	0.354 (2)	0.499 (2)	1.41 (1)	1.8% (6)	-1.6% (5)
$W+$	2100	0.1231 (3)	0.1657 (3)	1.346 (4)	3.0% (3)	2.4% (3)
$W-$	2100	0.0346 (1)	0.0492 (1)	1.421 (6)	3.1% (3)	2.5% (3)

Table 7: Integrated  $W'$  boson and  $W$  boson tail cross-sections for PYTHIA and MC@NLO with common scale factor  $S=1$ . Integral is over the full  $\eta$  range  $-2.5 < \eta < 2.5$ . The listed  $K$ -factors are the ratios of the integrated MC@NLO and PYTHIA cross-sections. The last two columns give the change in the MC@NLO cross-section when the common scale factor is changed by a factor of two. The statistical error in the last digit of each calculated quantity is shown in parentheses.

These can be used to estimate the uncertainty in predictions obtained with the fit. Figure 23 shows the PYTHIA prediction for the  $m = 1 \text{ TeV}$   $W'$  boson differential cross-section as a function of  $\eta$  for the CTEQ6.1 central value and each of the 40 error sets. Events are required to have transverse mass above the threshold in Table 6. The difference in shape between the positively and negatively charged bosons is a consequence of the parton distribution functions since  $W'^{++}$  are from  $u\bar{d}$  fusion and  $W'^{-}$  from  $d\bar{u}$  fusion.

Figure 23: Muon  $\eta$  distributions for positively- and negatively-charged  $m = 1 \text{ TeV}$   $W'$  bosons using the CTEQ 6.1 PDF central value (black) and 40 error sets.

We calculated cross sections for  $W'$  boson production with mass of 1 TeV using the CTEQ6.1 central value and error PDFs by integrating over the full  $\eta$  range ( $|\eta| < 2.5$ ) in Fig. 23. To estimate the overall uncertainty, the positive and negative deviations for each eigenvector were summed separately in quadrature for each charge sign. Where both deviations for an eigenvector had the same sign, only the

larger magnitude was included in the sums. Table 8 shows the results.

Process	Min. $m_T$	$W+$	$W-$
$W' (m = 1 \text{ TeV})$	700	-4.1% (5), +8.2% (5)	-11.1% (7), +3.5% (8)

Table 8: CTEQ6.1 combined error set deviations for  $W'$  boson cross-sections. The statistical error on the last digit is shown in parentheses.

Combining all the above, we assign a common  $K$ -factor of 1.37 for all masses and charges and assign an 8% uncertainty on this factor.

## 6.2 Instrumental Uncertainties

Detector related uncertainties for these studies can be divided in two categories: the ones related to the reconstruction of the leptons and the ones corresponding to the global event activity as the  $\cancel{E}_T$  and the jet characteristics. However, the lepton reconstruction uncertainties can be the dominant factor in the  $\cancel{E}_T$  resolution.

### 6.2.1 Lepton Reconstruction

Three main contributions can be identified in this category. The efficiency of lepton identification, as well as the fake rates associated with this, the  $p_T$  or  $E_T$  scale and its measurement resolution.

Systematic errors on the momentum scale of the muons can arise for instance due to the non-perfect knowledge of the magnetic field. To take into account such effects, a variation of  $\pm 1\%$  is applied to the  $p_T$  of the reconstructed muons. Positive and negative variations are considered separately. In a similar way but for energy, a variation of  $\pm 0.5\%$  was made for electrons.

An incomplete understanding of the material distributions inside the detector as well as possible misalignments in the MS can lead to an additional smearing of the momentum measurement resolution of muons. To evaluate the impact of such contributions on the analysis, a smearing, based on early calibrations of  $\sigma(1/p_T) = 0.011/p_T \oplus 0.00017$  is applied. The first term enhances the Coulomb scattering smearing, while the second enhances the alignment contribution, and is the crucial factor in this study.

For the energy measurement resolution for electrons, the total  $\sigma(E_T)$  is smeared by  $0.0073 \times E_T$ , which enhances the constant term only.

Lepton identification efficiency is obviously important for this analysis. The identification efficiency can be estimated from the data, using the tag-and-probe method described in [42] for muons in the region  $20 < p_T < 50 \text{ GeV}$  and extrapolated to higher  $p_T$  using simulated data. A value of  $\pm 5\%$  has been chosen for the evaluation of this uncertainty, corresponding to the early running period of integrated luminosities  $\mathcal{L} < 100 \text{ pb}^{-1}$ . In the case of electrons a  $\pm 1\%$  variation has been applied.

### 6.2.2 Jet Reconstruction

An uncertainty on the jet energy scale of  $\pm 7\%$  was imposed, together with an uncertainty on its resolution of  $\sigma(E_T) = 0.45 \times \sqrt{E_T} \oplus 5\%$ .

### 6.2.3 Missing Energy

If jets or leptons are systematically shifted, then missing transverse energy should be systematically shifted in a known direction. Based on the jet and leptons performance, the missing energy is shifted as follows:

- $\cancel{E}_{T(shifted)}(x) = \cancel{E}_T(x) + E^{lepton/jet}(x) - E_{shifted}^{lepton/jet}(x)$
- $\cancel{E}_{T(shifted)}(y) = \cancel{E}_T(y) + E^{lepton/jet}(y) - E_{shifted}^{lepton/jet}(y)$
- $\sum E_{T(shifted)} = \sum E_T + E_T^{lepton/jet} - E_{T(shifted)}^{lepton/jet}$

In the case of muons, momentum is used instead of energy.

#### 6.2.4 Summary of Experimental Systematic Uncertainties

The effects of the experimental uncertainties are summarized in Tables 9 and 10. In the high- $p_T$  range

Description of systematic	electrons		muons	
	$\delta_s$ [%]	$\delta_b$ [%]	$\delta_s$ [%]	$\delta_b$ [%]
Lepton energy scale +	+0.8	+1.8	+1.2	+4.6
Lepton energy scale -	-0.7	-2.1	-1.2	-4.4
Lepton energy resolution	+0.1	+0.2	-1.0	+3.7
Lepton identification efficiency +	+1.0	+1.0	+5.	+5.
Lepton identification efficiency -	-1.0	-1.0	-5.	-5.
Jet energy scale +	+0.1	-0.2	-0.1	+0.1
Jet energy scale -	+0.1	-0.2	+0.1	+0.7
Jet energy resolution	+0.0	+0.1	-0.1	+0.3
Luminosity	$\pm 3.$		$\pm 3.$	

Table 9: Effect of the detector systematics in percentage for  $m_{W'} = 1$  TeV.  $\delta_s$  is the uncertainty on the signal,  $\delta_b$  is the uncertainty on the background.

Description of systematic	electrons		muons	
	$\delta_s$ [%]	$\delta_b$ [%]	$\delta_s$ [%]	$\delta_b$ [%]
Lepton energy scale +	+0.7	+1.2	+1.5	+3.4
Lepton energy scale -	-0.4	-3.7	-1.7	-2.5
Lepton energy resolution	-0.03	0.0	-4.2	+6.8
Lepton identification efficiency +	+1.0	+1.0	+5.	+5.
Lepton identification efficiency -	-1.0	-1.0	-5.	-5.
Jet energy scale +	+0.1	1.2	+0.1	+0.8
Jet energy scale -	-0.1	0	-0.3	-0.1
Jet energy resolution	-0.1	0	+0.1	-0.1
Luminosity	$\pm 3.$		$\pm 3.$	

Table 10: Effect of the detector systematics in percentage for  $m_{W'} = 2$  TeV.  $\delta_s$  is the uncertainty on the signal,  $\delta_b$  is the uncertainty on the background.

under consideration, the systematic uncertainties on the quality of single lepton reconstruction have a stronger effect on the muon channel, for which there are comparable contributions from energy scale, resolution and identification efficiency (with the resolution uncertainty becoming more important for a higher  $W'$  mass); out of these three, the energy scale uncertainty dominates in the electron channel for  $m_{W'} = 1$  TeV, but becomes less important for  $m_{W'} = 2$  TeV. Jet uncertainties do not play a strong role on either channel.

## 7 Discovery Potential

In order to assess the ATLAS discovery potential in the search for a  $W' \rightarrow \ell + \cancel{E}_T$  signal, the luminosity needed for a  $5\sigma$  excess is obtained as a function of the mass of the  $W'$  boson.

The significance is obtained from the expected number of signal and background events in the region  $m_T > 0.7m_{W'}$ , where  $m_{W'}$  is the mass of the hypothesized  $W'$  boson. Calling these expected numbers  $s$  and  $b$ , respectively, the significance  $S$  is obtained as

$$S = \sqrt{2((s+b)\ln(1+s/b) - s)}$$

which gives a good approximation to the likelihood-ratio based significance in the low statistics regime. Figure 24 shows the expected integrated luminosity needed for a 5-sigma excess as a function of the mass of the  $W'$  boson.

Higher order corrections for  $W'/W \rightarrow \ell\nu$  processes are taken into account as stated in section 6.1. Systematic uncertainties listed in Tables 9 and 10 are taken into account by increasing the expected background by the sum in quadrature of its positive expected variations, and by reducing the signal by the sum in quadrature of its expected negative variations; this assumes no correlations of the expected signal and background expectations and, as a result, produces a conservative estimate.

For comparison, the integrated luminosity values for a  $5\sigma$  significance were also obtained taking into account the shape of the signal and background  $m_T$  distributions. This was done using a technique in which, instead of an ensemble of Monte Carlo pseudo-experiments [43], a Fast Fourier Transform (FFT) is used to calculate the experimental estimator distributions [44]. This method allows a fast determination of the probability that background fluctuations produce a signal-like result, but it depends on the assumption that both the location of the signal and its shape are well known. Treating each bin of the transverse mass distribution as an independent search channel, and combining them accordingly, the resulting sensitivity is in general higher than the estimation given in the number counting approach. With this method, the luminosity required for a  $5\sigma$  effect was reduced between 20 and 35% with respect to the values shown in Fig. 24.

Even for very low integrated luminosities (of the order of picobarns), a  $W'$  boson with a mass above the current experimental limits could be found with a significance in excess of  $5\sigma$ , while, with  $1 \text{ fb}^{-1}$ , masses of the order of 3 TeV can be reached. As an illustration, Figs 25 and 26 show Monte Carlo outcomes of pseudo-experiments corresponding to  $10 \text{ pb}^{-1}$  and  $100 \text{ pb}^{-1}$ , respectively, for both channels. The solid line histograms depict the expected background, those in dotted lines the  $m = 1 \text{ TeV}$   $W'$  boson signal and the dashed-dotted line histograms show possible  $m = 2 \text{ TeV}$   $W'$  boson signals.

## 8 Summary and Conclusion

The potential for the ATLAS experiment to reconstruct and identify the decay of a heavy, charged gauge boson into a lepton and a neutrino has been studied. Various systematic and theoretical uncertainties have been considered, as well as plausible estimations of our uncertainties about the performance of the detector in the early stages of data taking. These studies show that, even with integrated luminosities as low as  $10 \text{ pb}^{-1}$  of data, it would be possible to discover this type of bosons, should they exist not far beyond the current experimental limits and have Standard Model like couplings. With an integrated luminosity of a few  $\text{fb}^{-1}$ , ATLAS has the potential to discover these particles for masses up to 4 TeV.

Figure 24: Integrated luminosity needed to have a  $5\sigma$  discovery as a function of the mass of the  $W'$  bosons; triangles correspond to the  $e\nu$  search, squares to  $\mu\nu$ , circles to the combined search. Filled markers include the effect of systematic uncertainties.

# Search for Leptoquark Pairs and Majorana Neutrinos from Right-Handed $W$ Boson Decays in Dilepton-Jets Final States

## Abstract

Final states with high- $p_T$  leptons and jets are predicted by many Beyond the Standard Model scenarios. Two prominent models are used here as guides to understanding the event topologies: the scalar leptoquarks and the Left-Right Symmetry. In contrast to many SUSY signatures, their topologies rarely contain missing energy. Their discovery potential with early ATLAS data, corresponding to an integrated luminosity of a few hundred inverse picobarns, is discussed.

## 1 Introduction

Grand Unification has inspired many extensions of the Standard Model. Such models introduce new, usually very heavy particles, and previous searches for Grand Unification Theory (GUT) signatures have placed limits on masses and interaction strengths of the new particles. The LHC will probe new regions of parameter space, allowing for a direct search for these particles. Decays characterized by final states with two highly energetic leptons, two jets and no missing transverse energy are studied in this note. The models for new physics considered for this note are described below. The simulation of signal and background processes is described in section 2. In section 4 the baseline selection that is used for all analyses is explained. After the trigger requirements are given (section 3), section 5 details the specifics of each of the analyses. The systematics are described in section 6 and the final sensitivity estimates are given in section 7.

### 1.1 Leptoquarks

The experimentally observed symmetry between leptons and quarks has motivated the search for leptoquarks (LQ), hypothetical bosons carrying both quark and lepton quantum numbers, as well as fractional electric charge [1–5]. Leptoquarks could, in principle, decay into any combination of a lepton and a quark. Experimental limits on lepton number violation, flavor-changing neutral currents, and proton decay favour three generations of leptoquarks. In such a scenario, each leptoquark couples to a lepton and a quark from the same Standard Model generation [6]. Leptoquarks can either be produced in pairs by the strong interaction or in association with a lepton via the leptoquark-quark-lepton coupling. Figure 1 shows the Feynman diagrams for leptoquark production processes accessible at the LHC.

This note describes the search for leptoquarks decaying to either an electron and a quark or a muon and a quark. The branching ratio of a leptoquark to a charged lepton and a quark is denoted as  $\beta$ . Decays to neutrinos are not considered, and events are not explicitly selected based on the flavor of the quark. The experiments at the Tevatron have searched for first (decaying to  $eq$ ), second (decaying to  $\mu q$ ), and third (decaying to  $\tau q$ ) generation scalar leptoquarks. For  $\beta = \mathcal{B}(LQ \rightarrow \ell^\pm q) = 1$ , the DØ [7] and CDF [8] collaborations have set 95%CL limits for first generation scalar leptoquarks of  $m_{LQ_1} > 256$  GeV and  $m_{LQ_1} > 236$  GeV, respectively. These limits are based on integrated  $p\bar{p}$  luminosities of approximately  $250 \text{ pb}^{-1}$  and  $200 \text{ pb}^{-1}$ . The results for second generation leptoquarks,  $m_{LQ_2} > 251$  GeV and  $m_{LQ_2} > 226$  GeV, were obtained with  $300 \text{ pb}^{-1}$  and  $200 \text{ pb}^{-1}$  by the DØ [9] and CDF [10] experiments, respectively.

The Tevatron exclusion limits are expected to reach 300-350 GeV in the near future.

Figure 1: Feynman diagrams for leptoquark production.

## 1.2 Left-Right Symmetry

Left-Right Symmetric Models (LRSMs) of the weak interaction address two important topics: the nonzero masses of the three known left-handed neutrinos [11] and baryogenesis. LRSMs conserve parity at high energies by introducing three new heavy right-handed Majorana neutrinos  $N_e$ ,  $N_\mu$  and  $N_\tau$ . The smallest gauge group that implements an LRSM is  $SU(2)_L \times SU(2)_R \times U(1)_{B-L}$ . At low energies, the left-right symmetry is broken and parity is violated. The Majorana nature of the new heavy neutrinos explains the masses of the three left-handed neutrinos through the see-saw mechanism [12]. The lepton number  $L$  could be violated in processes that involve the Majorana neutrinos. This opens a window to the very attractive theoretical scenario for baryogenesis via leptogenesis, where baryon and lepton numbers  $B$  and  $L$  are violated but  $B - L$  is conserved.

In addition to the Majorana neutrinos, most general LRSMs also introduce the new intermediate vector bosons  $W_R$  and  $Z'$ , Higgs bosons, and a left-right mixing parameter. The most restrictive lower limit on the mass of the  $W_R$  boson comes from the  $K_L - K_S$  mass difference which requires  $m_{W_R} > 1.6$  TeV. This lower limit is subject to large corrections from higher-order QCD effects. Heavy right-handed Majorana neutrinos with masses of about a few hundred GeV would be consistent with the data from supernova SN1987A. Such heavy neutrinos would allow for a  $W_R$  boson at the TeV mass scale. This scenario would also be consistent with LEP data on the invisible width of the  $Z$  boson. Present experimental data on neutral currents imply a lower limit on the mass of a  $Z'$  boson of approximately 400 GeV. Recent direct searches [13] for the  $W_R$  boson at DØ give a lower mass limit of 739 GeV and 768 GeV, assuming the  $W_R$  boson could decay to both lepton pairs and quark pairs, or only to quark pairs, respectively. However, heavy Majorana neutrinos decaying to a lepton and a pair of quarks (detected as jets) were not searched for in those analyses.

The new intermediate vector bosons  $W_R$  and  $Z'$  would be produced at the LHC via the Drell-Yan (DY) process like Standard Model  $W$  and  $Z$  bosons. Their decays would be a source of new Majorana neutrinos. The Feynman diagram for  $W_R$  boson production and its subsequent decay to a Majorana neutrino is shown in Fig. 2. This note describes an analysis of  $W_R$  boson production and its decays  $W_R \rightarrow eN_e$  and  $W_R \rightarrow \mu N_\mu$ , followed by the decays  $N_e \rightarrow eq'\bar{q}$  and  $N_\mu \rightarrow \mu q'\bar{q}$ , which can be detected in final states with (at least) two leptons and two jets.

 Figure 2: Feynman diagram for  $W_R$  boson production and its decay to a Majorana neutrino  $N_\ell$ .

$m_{LQ}$ in GeV	$\sigma(pp \rightarrow LQ\bar{L}\bar{Q})$ (NLO) in pb
300	$10.1 \pm 1.5$
400	$2.24 \pm 0.38$
600	$0.225 \pm 0.048$
800	$0.0378 \pm 0.0105$

Table 1: NLO cross-sections for scalar leptoquark pair production at the LHC [16].

## 2 Simulation of Physics Processes

### 2.1 Leptoquarks

The signals have been studied using samples of first generation (1st gen.) and second generation (2nd gen.) scalar leptoquarks simulated with the Monte Carlo (MC) generator PYTHIA [14] and using the CTEQ6L1 parameterization [15] of the parton density functions (PDFs). A leptoquark-lepton-quark coupling  $\lambda = 0.8$  was used in the event generation leading to a natural width of the leptoquarks of 0.63 GeV and 1.3 GeV for leptoquark masses of 400 GeV and 800 GeV respectively. The next to leading order (NLO) cross-sections for leptoquark pair production at 14 TeV  $pp$  centre-of-mass energy were taken from Ref. [16] and are shown in Table 1 for the four simulated leptoquark masses.

### 2.2 Left-Right Symmetry

Studies of the discovery potential for  $W_R$  bosons and the Majorana neutrinos,  $N_e$  and  $N_\mu$  produced in their decays, were performed using datasets simulated with the MC generator PYTHIA according to a particular implementation [17] of an LRSM described in [18]. The Standard Model axial and vector couplings, the CKM matrix for the quark sector, no mixing between the new and Standard Model intermediate vector bosons, and phase space isotropic decays of Majorana neutrinos are assumed for the right-handed sector in this model. The products of leading-order production cross-sections  $\sigma(pp \rightarrow W_R X)$  and branching fractions to studied final states  $W_R \rightarrow \ell N_\ell \rightarrow \ell \ell jj$  are 24.8 pb for  $m_{W_R} = 1800$  GeV,  $m_{N_e} = m_{N_\mu} = 300$  GeV and 47.0 pb for  $m_{W_R} = 1500$  GeV,  $m_{N_e} = m_{N_\mu} = 500$  GeV. In the rest of this note, these samples are referred to as LRSM\_18\_3 and LRSM\_15\_5, respectively. The Majorana nature of the new heavy neutrinos allows for same-sign and opposite-sign dileptons.

### 2.3 Background Processes

The main sources of background for the analyses presented here are  $t\bar{t}$  and inclusive  $Z/\gamma^*$  production processes. Multijet production, where two jets are misidentified as leptons, represents another background. In addition, minor contributions arise from diboson production. Other potential background sources, such as single-top production, were also studied. Their contribution was found to be insignificant.

- $Z/\gamma^*$  background was studied using a combination of two MC samples with generator-level dilepton invariant mass preselections of  $m_{\ell\ell} > 60$  GeV and  $m_{\ell\ell} > 150$  GeV, the latter sample corresponding to a much larger integrated luminosity than the former. The samples were normalized to the given luminosity using their partial cross-sections and the NLO estimate  $\sigma(pp \rightarrow Z) \times \mathcal{B}(Z \rightarrow \ell^+\ell^-) = 2032$  pb, obtained with the MC generator FEWZ [19, 20]. A lepton filter was applied at the event generation, requiring at least one electron or muon with transverse momentum greater than 10 GeV and absolute pseudo-rapidity smaller than 2.7, resulting in an effective cross-section of 1808 pb.

For logistical reasons, the sample with the lower mass preselection was generated using the MC generator PYTHIA [14], and the sample with higher mass preselection was generated using HERWIG [21]. In both cases, the CTEQ6L1 [15] parton distribution functions were used. The consistency between the two samples was verified at high dilepton masses.

- $t\bar{t}$  background was simulated using the MC generator MC@NLO [22] using the CTEQ6M [15] parton distribution functions. It was normalized to the given integrated luminosity using a production cross-section of 833 pb estimated to the next-to-leading order (NLO+NLL) [23]. In addition, a lepton filter was applied, requiring at least one electron or muon with transverse momentum greater than 1 GeV, which resulted in an effective cross-section of 450 pb.
- The diboson samples were generated using HERWIG with a generator-level preselection on the invariant mass of  $Z/\gamma^* > 20$  GeV. With this requirement, the NLO partial cross-sections for  $WW$ ,  $WZ$  and  $ZZ$  boson pair production processes were numerically estimated (using MC@NLO) to be 117.6 pb, 56.4 pb, 17.8 pb, respectively. The CTEQ6L1 parton distribution functions were used for event generation. Again, a lepton filter was applied, with a transverse momentum threshold of 10 GeV and a maximum absolute pseudo-rapidity of 2.8. This resulted in a total effective cross-section of 60.9 pb.
- The multijet background was simulated using PYTHIA with the CTEQ6L1 structure functions. The normalization was based on PYTHIA cross-section estimates. The statistics of these samples are very limited, such that no reliable estimate of this background could be made at this time.

## 3 Trigger Requirements

The trigger system [24] of the ATLAS experiment has three levels, L1, L2 and the Event Filter (EF). To ensure high overall trigger efficiencies, our analyses rely on single lepton trigger streams with relatively low thresholds. The dielectron analyses rely on the single electron-based trigger called e55 which has a threshold of around 60 GeV [24]. When selected events fail this trigger, the analyses rely on the lower-threshold (about 25 GeV) single electron trigger called e22i [24] in which the electron is required to be isolated. A single muon trigger with threshold about 20 GeV (mu20 [24]) is used in the dimuon analyses.

Final states studied in this note always contain two high- $p_T$  leptons. While the baseline selection described in section 4 requires two leptons with  $p_T > 20$  GeV, most signal events contain at least one lepton with significantly higher  $p_T$ . As a result, the overall trigger efficiency for events that satisfy all

analysis selection criteria (section 5) exceeds 95%. The trigger efficiencies for signal MC events that satisfy all selection criteria are shown in Table 2.

Process	L1	L2	EF	L1*L2*EF
1st gen. leptoquarks $m_{LQ} = 400$ GeV	100.0%	99.4%	97.6%	97.0%
2nd gen. leptoquarks $m_{LQ} = 400$ GeV	97.7%	99.1%	99.7%	96.5%
LRSM (ee) $m_{W_R} = 1800$ GeV, $m_{N_e} = 300$ GeV	100.0%	99.2%	97.2%	96.4%
LRSM ( $\mu\mu$ ) $m_{W_R} = 1800$ GeV, $m_{N_\mu} = 300$ GeV	96.8%	98.7%	98.9%	94.5%

Table 2: Overall trigger efficiencies for signal events that satisfy all selection criteria.

## 4 Baseline Event Selection

The baseline event selection, common for all analyses presented in this note, requires two leptons and two jets. All analyses use the same selection criteria for signal electron, muon, and jet candidates. The baseline selection criteria for these reconstructed objects are summarized below. Performance studies are described elsewhere [25–28].

Electron candidates are identified as energy clusters reconstructed in the liquid argon electromagnetic calorimeter that match tracks reconstructed in the inner tracking detector and satisfy the *medium* electron identification requirements [25].

Muon candidates are identified as tracks reconstructed in the muon spectrometer [26] that, when extrapolated to the beam axis, match a track reconstructed in the inner detector, and satisfy relative isolation energy requirements  $E_T^{iso}/p_T^\mu \leq 0.3$ .  $p_T^\mu$  is the muon candidate’s transverse momentum and  $E_T^{iso}$  is the energy detected in the calorimeters in a cone of  $\Delta R = \sqrt{\Delta\eta^2 + \Delta\phi^2} = 0.2$  around the muon candidate’s reconstructed trajectory, corrected for the expected energy deposition by a muon.

Jets are identified as energy clusters reconstructed in the calorimeters using a  $\Delta R = 0.4$  cone algorithm [27].  $\Delta R$  between a jet and any electron candidate (as defined above) must be larger than 0.1. This veto is imposed to avoid electrons being misidentified as jets. It is applied in all analyses, regardless of whether electrons are explicitly considered in the final states or not. The jet energy scale calibration is performed using full MC simulation and requires that the average reconstructed jet energy agrees with the average energy of the jets reconstructed with the Monte Carlo truth particles. The same jet reconstruction algorithm, with cone size  $\Delta R = 0.4$ , is used for both reconstruction and calibration.

All objects are required to have  $p_T \geq 20$  GeV, the leptons must have an absolute pseudo-rapidity  $|\eta|$  smaller than 2.5 and jets must have  $|\eta| \leq 4.5$ .

To suppress contributions from Drell-Yan backgrounds, the dilepton invariant mass is required to be at least 70 GeV. Tighter analysis-specific requirements are later applied to this and other variables in order to achieve the best sensitivities in individual studies, as described in the following section.

## 5 Individual Analyses

### 5.1 Search for Leptoquark Pair Production

Following the baseline object identification criteria described above, the leptoquark pair analyses require events to have at least two oppositely charged leptons of the same flavour and at least two jets. Signal sensitivity and discovery potential are estimated using a sliding mass window algorithm: only events in the mass region around the assumed mass of the leptoquark are analyzed.

For large leptoquark masses, signal leptons and jets have, on average, larger transverse momenta than background particles. The following kinematic quantities are used to separate the signal from backgrounds: the transverse momentum of the leptons ( $p_T$ ), the scalar sum of the transverse momenta of the two most energetic jets and leptons ( $S_T = \sum |\vec{p}_T|_{jet} + \sum |\vec{p}_T|_{lep}$ ), the dilepton invariant mass ( $m_{\ell\ell}$ ), and lepton-jet invariant mass. The lepton-jet invariant mass represents the mass of the leptoquark if the correct lepton-jet combination is chosen. Since there are two leptons and two jets there are two possible combinations, and we choose the combination which gives the smallest difference between the masses of the first and second leptoquark candidates.

Physics sample	Before selection	Baseline selection	$S_T \geq 490$ GeV	$m_{ee} \geq 120$ GeV	$m_{lj}^1 - m_{lj}^2$ window (GeV) [320-480] - [700-900] - [320-480] [700-900]

Multijet	$10^8$	0.0	0.0	0.0	0.0	0.0	0.0

Table 4: 2nd generation leptoquark analysis. Partial cross-sections (pb) that survive selection criteria.

In both channels, the values of these selection criteria are optimized<sup>1</sup> to achieve discovery with  $5\sigma$  significance at the lowest luminosity possible. Tables 3 and 4 show the values of the selection criteria and resulting signal and background cross-sections for 1st and 2nd generation channels, respectively. One important difference between the two channels is the background due to jets being misidentified as electrons. This background can be significantly reduced by requiring both reconstructed jet-electron masses, ( $m_{lj}^1, m_{lj}^2$ ), to be close to the tested leptoquark mass. However, such a selection in the 2nd generation analysis would significantly reduce the signal efficiency, especially for larger leptoquark masses. Therefore, a less stringent selection is applied, and only the average of the two muon-jet masses ( $m_{lj}^{av}$ ) is required to be near the tested leptoquark mass.

Figure 3 shows the  $S_T$  variable distribution with  $m_{LQ} = 400 \text{ GeV}$ , along with the main backgrounds, Drell-Yan and  $t\bar{t}$  production, after baseline selection plus, for the 2nd generation case, the requirements

<sup>1</sup>At this stage, only statistical uncertainties are taken into account.

Figure 3:  $S_T$  in leptoquark MC events ( $m_{LQ} = 400$  GeV) after baseline selection. Left: 1st generation, right: 2nd generation with the additional requirements  $p_T^\mu > 60$  GeV and  $p_T^{jet} > 25$  GeV.

$p_T^\mu > 60$  GeV and  $p_T^{jet} > 25$  GeV.

Figure 4:  $m_{\ell\ell}$  of the selected lepton pair after  $S_T$  selection in leptoquark 1st generation (left) and 2nd generation (right) events ( $m_{LQ} = 400$  GeV).

The dilepton mass distribution after the  $S_T$  selection is shown in Figure 4.

Figures 5 and 6 show the reconstructed invariant mass of leptoquark candidates ( $m_{LQ}=400$  GeV) in signal events and the main backgrounds, Drell-Yan and  $t\bar{t}$  production, after the subsequent selections on dimuon mass and  $S_T$ . Due to gluon radiation, quarks produced in the decays of heavy particles are not equivalent to standard jets. This shifts the peak of the jet energy resolution function towards smaller energies and results in a low-mass shoulder in the distribution of reconstructed masses of heavy particles. Figure 5 shows two entries per event corresponding to the two reconstructed electron-jet objects obtained by adding x and y mass projections of  $(m_{lj}^1, m_{lj}^2)$  on a common axis,  $m_{lj}$ .

All figures show predicted distributions for an integrated luminosity of  $100 \text{ pb}^{-1}$ .

The trigger efficiency is not included in the plots and tables shown in this section. However events satisfying all selection criteria would trigger with an efficiency exceeding 95%, as discussed in Section 3.

Figure 5: Reconstructed electron-jet invariant mass in the 1st generation leptoquark ( $m_{LQ}=400$  GeV) analysis for signal and background MC events after baseline selection (left) and after all selection criteria (right). All distributions are given for  $100 \text{ pb}^{-1}$  of integrated luminosity.

Figure 6: Reconstructed muon-jet invariant mass for 2nd generation leptoquarks ( $m_{LQ} = 400$  GeV) in signal and background MC events after baseline selection (left) and after all selection criteria (right). All distributions are given for  $100 \text{ pb}^{-1}$  of integrated luminosity.

## 5.2 Search for New Particles from Left-Right Symmetric Models

Signal event candidates are required to contain (at least) two electron or muon candidates and two or more jets that pass the baseline selection criteria. As previously described, the minimum separation between a jet and an electron candidate  $\Delta R \geq 0.1$  is required. The two leading  $p_T$  lepton candidates and the two leading  $p_T$  jets are assumed to be the decay products of the  $W_R$  boson. The signal jet candidates are combined with each signal lepton, and the combination that gives the smallest invariant mass is considered as the heavy neutrino ( $N_\ell$  in Fig. 2). This assignment is correct in more than 99% of signal MC events. The other lepton is assumed to come directly from the decay of the  $W_R$  boson.

When the  $W_R$  boson is at least twice as heavy as the Majorana neutrino, the daughter lepton from the neutrino's decay often begins to partially merge with one of the daughter jets. In the dielectron analysis, when the separation between this lepton and a signal jet candidate is in the range  $0.1 \leq \Delta R \leq 0.4$ , using all three reconstructed objects to estimate the invariant mass of the neutrino would often result in double-counting. To solve this problem, signal event candidates in the dielectron analysis are divided into two groups. When the separation is outside the discussed range, *i.e.*  $\Delta R > 0.4$ , all three objects are used. However, when the separation is in the critical range, *i.e.*  $0.1 \leq \Delta R \leq 0.4$ , only jets are used to estimate

the mass of the  $N_e$  neutrino. It must be noted that this procedure has little effect on the  $N_e$  neutrino mass resolution, because it is dominated by the resolution on the jets energy. The fraction of events falling in the critical range depends on the ratio of  $W_R$  boson and Majorana neutrino masses, and increases with this ratio, being 8% for the 1500 GeV to 500 GeV ratio and 26% for the 1800 GeV to 300 GeV ratio considered here. No such problem exists in the dimuon analysis because muon reconstruction is possible even when the reconstructed trajectory's projection into the calorimeters randomly coincides with jet activity. The mass of the Majorana neutrino can be reconstructed with a relative resolution of about 6%, and the mass of the  $W_R$  boson can be reconstructed with a relative resolution of 5% to 8%; better resolution on the latter is achieved in the dielectron analyses because the muon spectrometer resolution is degraded at high transverse momenta.

Figure 7: LRSB analysis.  $S_T$  distributions for signals and backgrounds normalized to  $100 \text{ pb}^{-1}$  of integrated luminosity after baseline selection in dielectron (left) and dimuon (right) analyses. Vertical lines indicate the region used in the analysis.

While the main background sources in LRSB analyses are  $t\bar{t}$ ,  $Z/\gamma^*$ , and vector boson pair production processes, multijets were also identified as a source of potentially dangerous background in the dielectron analysis. The distributions of the scalar sum of signal object candidates' transverse momenta  $S_T$ , and the reconstructed dilepton invariant mass  $m_{\ell\ell}$  for signal and background events, normalized to an integrated luminosity of  $100 \text{ pb}^{-1}$ , are shown in Figs. 7 and 8.

The choice of the selection criteria  $S_T \geq 700 \text{ GeV}$  and  $m_{\ell\ell} \geq 300 \text{ GeV}$  is made in order to maintain good efficiency not only for mass values used in this study, but also for signals with  $m_{W_R} \geq 1000 \text{ GeV}$ .

Partial cross-sections for signal and background processes passing the selection criteria are shown in Tables 5 and 6. Some remarks are in order concerning the selection criteria's efficiencies. First, the dimuon channel is more efficient than the dielectron channel. This is due to the jet-electron merging discussed previously. This issue becomes especially important for a larger ratio of masses  $m_{W_R}/m_{N_e}$ . However, for a very heavy  $W_R$  boson, the dielectron channel could become more significant because the  $W_R$  boson mass resolution does not become as wide in the dielectron channel as it does in the dimuon channel. Also, because of its heavy mass, the potential to discover the  $W_R$  boson and the heavy neutrino together is much better than in the inclusive search for the new heavy neutrino (assuming the same production mechanism) because of backgrounds.

Figure 8: LRSB analysis. The distributions of  $m_{\ell\ell}$  for signals and backgrounds normalized to  $100 \text{ pb}^{-1}$  of integrated luminosity after baseline selection in dielectron (left) and dimuon (right) analyses. Vertical lines indicate the region used in the analysis.

Physics sample	Before selection	Baseline selection	$m_{ejj} \geq 100 \text{ GeV}$	$m_{eejj} \geq 1000 \text{ GeV}$	$m_{ee} \geq 300 \text{ GeV}$	$S_T \geq 700 \text{ GeV}$

Table 5: LRSB dielectron analysis. Partial cross-sections (pb) that survive the selection criteria.

Figures 9 and 10 show the distributions of the reconstructed invariant masses of the heavy neutrino and  $W_R$  boson candidates for signal and background MC samples before and after the selection criteria are applied. All distributions are normalized to  $100 \text{ pb}^{-1}$  of integrated luminosity. It should be remarked that the trigger efficiency is not included in the plots and tables shown in this section. However, events satisfying all selection criteria would trigger with an efficiency exceeding 95%, as discussed in Section 3.

Background contributions to signal invariant mass spectra could also arise from jets that are misidentified as signal electrons. In principle, such misidentified jets are efficiently suppressed because at least two signal electron candidates are required, but at present this background remains poorly understood because larger statistics of multijet MC, or better, real data, would be necessary to evaluate its contribution reliably. If needed, a better suppression of events with multijets that are misidentified as electrons is possible by applying a more sophisticated isolation energy requirement. The multijet background does not pose a problem in the dimuon analysis, where estimates of the misidentification rate predict a vanishing contribution from multijet to dimuon events.

Physics sample	Before selection	Baseline selection	$m_{\mu jj}$ $\geq 100$ GeV	$m_{\mu\mu jj}$ $\geq 1000$ GeV	$m_{\mu\mu}$ $\geq 300$ GeV	$S_T$ $\geq 700$ GeV

Table 6: LRSB dimuon analysis. Partial cross-sections (pb) that survive selection criteria.

Finally, the analyses described in this note do not discriminate between same-sign and opposite-sign dileptons. Same-sign dileptons, however, are a very important signature of Majorana neutrinos, which, being their own anti-particles, could decay to a lepton of either charge. The background contribution to same-sign dileptons is much smaller than to opposite-sign dileptons. Of course, both channels would have to be studied if the discovery is made. The studies of charge misidentification performed in the framework of the presented analyses, predict a rate as high as 5% for high- $p_T$  leptons which is strongly  $\eta$ -dependent.

## 6 Systematic Uncertainties

The following sources of systematic uncertainties have been considered in the described analyses:

- 20% uncertainty was assumed on the integrated luminosity.
- In the dielectron analyses, 1% was used for the uncertainty in overall trigger efficiency.
- For electron identification and reconstruction efficiency, an uncertainty of 1% was assumed.
- For muon identification, including trigger and reconstruction efficiencies, an uncertainty of 5% was assumed.
- The uncertainty on the electron energy scale was assumed to be  $\pm 1\%$ .
- The uncertainty on the muon momentum scale was assumed to be  $\pm 1\%$ .
- The uncertainty on the jet energy scale was estimated by changing the energies of all jets simultaneously by  $\pm 10\%$  and  $\pm 20\%$ , for  $|\eta_{jet}| \leq 3.2$  and  $|\eta_{jet}| > 3.2$ , respectively.
- The 20% uncertainty in electron  $p_T$  resolution was estimated using a Gaussian smearing of  $p_T$  with a relative width of  $0.66 * (0.10/\sqrt{p_T} \oplus 0.007)$ , where  $p_T$  is in GeV.
- The uncertainty due to muon  $1/p_T$  resolution was estimated using a Gaussian smearing of  $1/p_T$  with a width of  $0.011/p_T \oplus 0.00017$ , where  $p_T$  is in GeV.
- The uncertainty due to jet energy resolution was estimated using a Gaussian smearing of jet energies in such a way that the relative jet energy resolution widens from  $0.60/\sqrt{E} \oplus 0.05$  to  $0.75/\sqrt{E} \oplus 0.07$  for  $|\eta_{jet}| \leq 3.2$ , and from  $0.90/\sqrt{E} \oplus 0.07$  to  $1.10/\sqrt{E} \oplus 0.10$  for  $|\eta_{jet}| > 3.2$ , where  $E$  is in GeV.

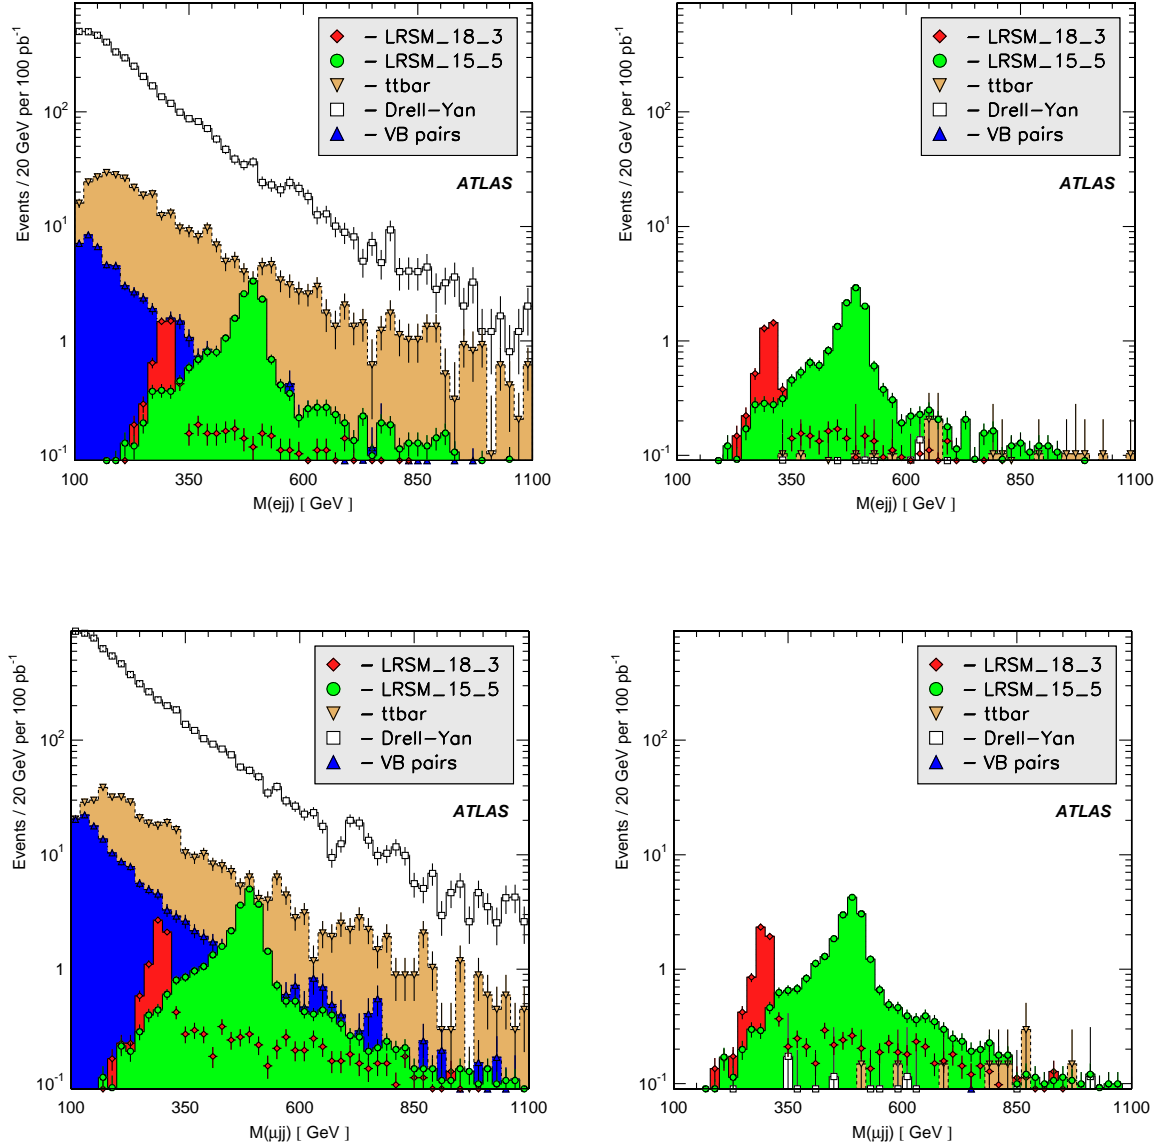

Figure 9: LRSB analysis. The distributions of the reconstructed invariant masses for  $N_e$  (top) and  $N_\mu$  (bottom) candidates in background and signal (LRSB\_18.3 and LRSB\_15.5) events before (left) and after (right) background suppression is performed in dielectron and dimuon analyses. All distributions are normalized to 100 pb<sup>-1</sup> of integrated luminosity. LRSB\_15.5 and LRSB\_18.3 refer to two sets of LRSB mass hypotheses. See the text for more information.

- Statistical uncertainties on the number of background MC events were considered as systematic uncertainties on the number of background events.
- The systematic uncertainty on the leptoquark cross-section (NLO) [16] was calculated by taking the 40 PDF CTEQ6M tables (two per eigenvector of PDF variations, provided by the CTEQ group for calculating uncertainties [15]), recalculating the leptoquark cross-section with each of these tables, and taking the largest difference of the two variations for each of the 20 eigenvectors to

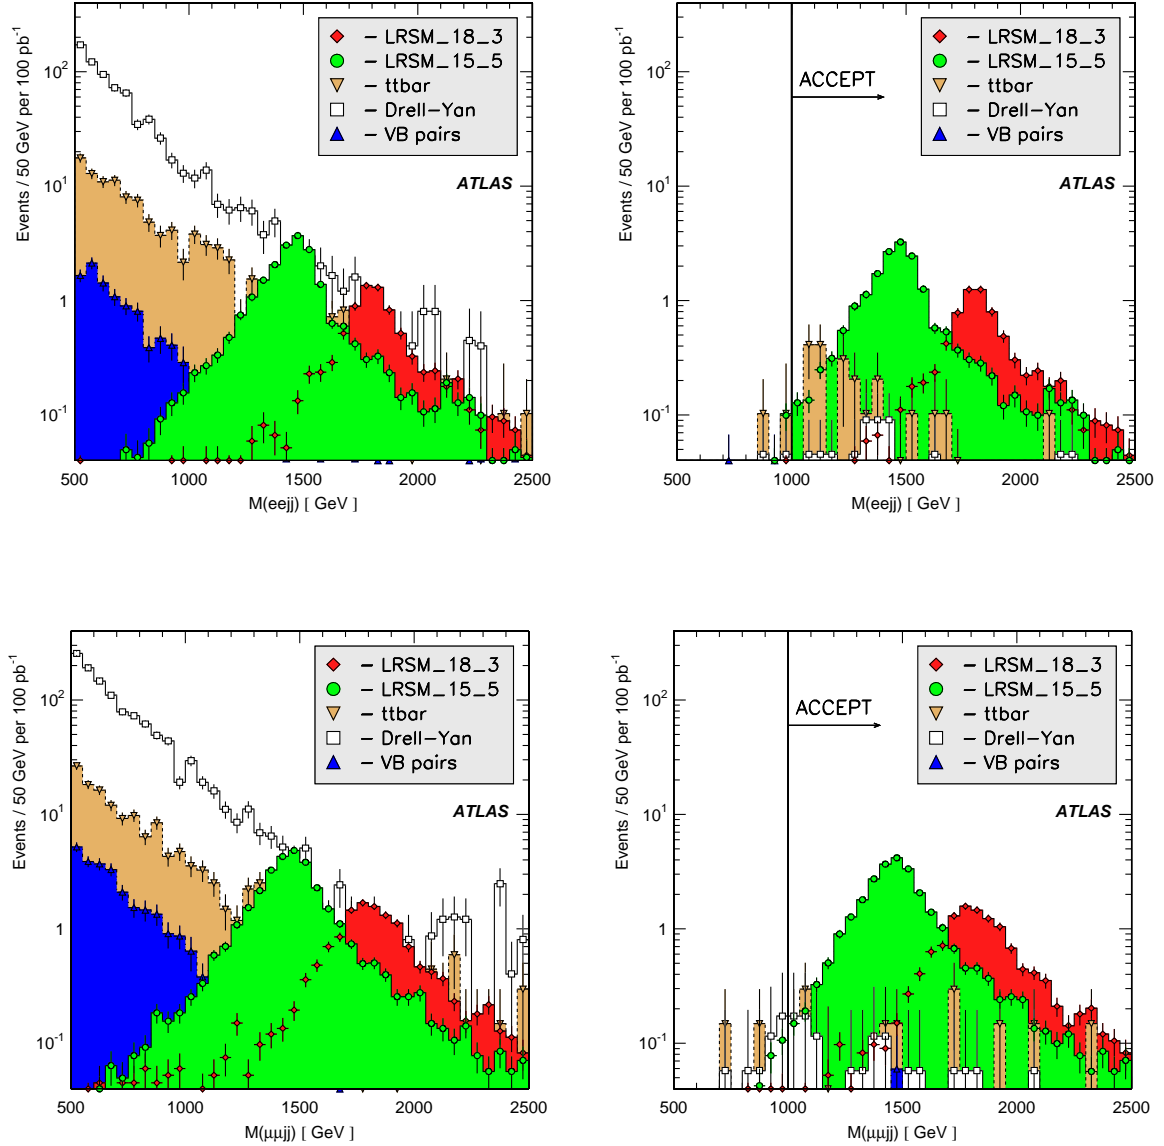

Figure 10: LRSM analysis. The distributions of the reconstructed invariant masses for  $W_R \rightarrow eN_e$  (top) and  $W_R \rightarrow \mu N_\mu$  (bottom) candidates in background and signal (LRSM\_18\_3 and LRSM\_15\_5) events before (left) and after (right) background suppression is performed in dielectron and dimuon analyses. All distributions are normalized to 100 pb<sup>-1</sup> of integrated luminosity. Notice that the invariant mass of the  $W_R$  boson is shown *before* the requirement  $m_{\ell\ell jj} \geq 1000$  GeV is imposed. This variable is strongly correlated with the background-suppressing variables  $S_T$  and  $m_{\ell\ell}$ . LRSM\_15\_5 and LRSM\_18\_3 refer to two sets of LRSM mass hypotheses. See the text for more information.

the cross-section calculated with the standard CTEQ6M table. The estimate shown is the sum in quadrature of these 20 differences and the relative difference in cross-section obtained by varying renormalization and factorization scales by a factor of 2. The systematic uncertainty is between 15% and 28% for the tested leptoquark masses.

- The uncertainty of the jet modeling in  $Z/\gamma^*$  events was estimated by comparing the background

predictions obtained using MC samples produced with PYTHIA to MC samples produced with ALPGEN. For the leptoquark pair analysis, this results in an uncertainty of about 30% on the background from  $Z/\gamma^*$  events.

- Background cross-sections for  $t\bar{t}$  and  $Z/\gamma^*$  processes were assumed to have uncertainties of 12% and 10%, respectively.

Systematic uncertainties affect both signal and background efficiencies, however the significance computation (next section) is mainly affected by the uncertainty on the background. The dominant systematic effects on the background are due to the uncertainties in integrated luminosity (20%), the jet energy scale (16%-35%), jet energy resolution (6%-28%), and the limited statistics of background MC samples (15%-30%). Possible other sources of systematic uncertainties such as initial and final state radiation modeling, or pile-up, were not evaluated. The total systematic uncertainties for signals and backgrounds are summarized in Table 7.

analysis	effect on signal events		effect on background events	
	1st gen.	2nd gen.	1st gen.	2nd gen.
leptoquark	$\pm 27\%$	$\pm 29\%$	$\pm 53\%$	$\pm 51\%$
LRSB	$\pm 23\%$	$\pm 25\%$	$\pm 45\%$	$\pm 40\%$

Table 7: Summary of total systematic uncertainties (%) for 100 pb<sup>-1</sup> luminosity.

## 7 Results

The program  $S_{cp}$  [29] is used to calculate the significances of possible observations of the signals studied in this note. The significance is defined in units of Gaussian standard deviations, corresponding to the (one-sided) probability of observing a certain number of events exceeding the MC-predicted background  $N_b$  at a given integrated luminosity. This probability is usually referred to as  $CL_b(N)$ , where  $N$  is the number of observed events. We report the  $5\sigma$  discovery potential evaluated in terms of  $CL_b(N_s + N_b)$ , where  $N_s$  is the expected number of signal events. Systematic uncertainties in the number of background events were also included in the significance calculations. For second generation leptoquarks, the signal selection was optimized at each mass point to minimize the cross-section times branching ratio needed to reach a  $5\sigma$  discovery, while for all other analyses the selection cuts presented in earlier sections were used.

The overall reconstruction and trigger efficiencies discussed earlier are used to estimate ATLAS' sensitivity and discovery potential for the studied final states below. These estimates include the trigger efficiency for signal and background events, as discussed in Section 5, Table 2.

### 7.1 Leptoquarks

The integrated luminosities needed for a  $5\sigma$  discovery of the 1st and 2nd generation scalar leptoquark signals are shown in Table 8 as function of leptoquark mass, assuming  $\beta = 1$ . Also, Fig. 11 predicts the integrated luminosities needed for a 400 GeV leptoquark mass discovery, with various values of  $\beta^2$ , at a  $5\sigma$  level.

Finally, Fig. 12 shows the minimum  $\beta^2$  that can be probed with ATLAS with 100 pb<sup>-1</sup> of integrated luminosity as a function of leptoquark mass. Lighter leptoquark masses can be probed with a smaller  $\beta$  because of their larger cross-section. It is evident from this figure that ATLAS is sensitive to leptoquark

Leptoquark mass	Expected luminosity needed for a $5\sigma$ discovery	
	1st gen.	2nd gen.
300 GeV	$2.8 \text{ pb}^{-1}$	$1.6 \text{ pb}^{-1}$
400 GeV	$11.8 \text{ pb}^{-1}$	$7.7 \text{ pb}^{-1}$
600 GeV	$123 \text{ pb}^{-1}$	$103 \text{ pb}^{-1}$
800 GeV	$1094 \text{ pb}^{-1}$	$664 \text{ pb}^{-1}$

Table 8: The integrated luminosities needed for a  $5\sigma$  discovery of 1st and 2nd gen. scalar leptoquarks for different mass hypotheses.

Figure 11:  $5\sigma$  discovery potential for 1st and 2nd gen.  $m = 400 \text{ GeV}$  scalar leptoquarks versus  $\beta^2$  with and without background systematic uncertainty included.

Figure 12: Minimum  $\beta^2$  of scalar leptoquarks versus leptoquark mass for  $100 \text{ pb}^{-1}$  of integrated luminosity at  $5\sigma$  (background systematic uncertainty included.)

masses of about 565 GeV and 575 GeV for 1st gen. and 2nd gen., respectively, at the given integrated luminosity, provided leptoquarks always decay into charged leptons and quarks.

## 7.2 Left-Right Symmetry

The significances of studied signals versus integrated luminosity are shown in Fig. 13. Figure 14 shows the product of signal cross-section and dilepton branching fraction versus the integrated luminosity necessary for a  $5\sigma$  discovery.

The overall relative systematic uncertainties on Drell-Yan and  $t\bar{t}$  backgrounds are approximately 45% and 40% in the dielectron and dimuon analyses, respectively. These estimates are dominated by contributions from jet reconstruction, uncertainty in integrated luminosity and insufficient MC statistics. Currently, multijet background is poorly understood and is not included in the presented sensitivity estimates for the dielectron channel.

## 8 Summary and Conclusions

Studies of final states with two leptons and multiple jets have been discussed, considering both electrons and muons. The early-data discovery potential for Beyond the Standard Model physics predicted by two prominent GUT-inspired models has been investigated.

Both 1st and 2nd generation scalar leptoquark pair production could be discovered with less than  $100 \text{ pb}^{-1}$  of integrated luminosity, provided that the mass of the leptoquarks is smaller than 500 GeV and the branching ratio into a charged lepton and a quark is 100%.

Figure 13: LRSM analysis. Expected signal significances versus integrated luminosity for  $N_e$ ,  $N_\mu$  neutrino and  $W_R$  boson mass hypotheses, according to signal MC samples LRSM\_18\_3 and LRSM\_15\_5. Open symbols show sensitivities without systematic uncertainties. Sensitivities shown with closed symbols include an overall relative uncertainty of 45% (40%) estimated for background contributions in the dielectron (dimuon) analysis. LRSM\_15\_5 and LRSM\_18\_3 refer to two sets of LRSM mass hypotheses. See the text for more information.

Two LRSM mass points ( $m_{W_R} = 1.8 \text{ TeV}, m_{N_\ell} = 300 \text{ GeV}$  and  $m_{W_R} = 1.5 \text{ TeV}, m_{N_\ell} = 500 \text{ GeV}$ ) for the right-handed  $W_R$  boson and Majorana neutrinos  $N_\ell$  have been studied in the dielectron and dimuon channels. It was found that discovery of these new particles at these mass points would require integrated luminosities of  $150 \text{ pb}^{-1}$  and  $40 \text{ pb}^{-1}$ , respectively.

Figure 14: LRSB analysis. The product of signal cross-section and branching fraction to dielectron and dimuon final states versus integrated luminosity necessary for a  $5\sigma$  discovery.  $N_e, N_\mu$  neutrino and  $W_R$  boson mass hypotheses are for signal MC samples LRSB\_18\_3 and LRSB\_15\_5. Horizontal lines indicate nominal cross-sections for two signal MC samples, according to the LRSB implementation in the MC simulation. Open symbols show discovery potentials without systematic uncertainties. Discovery potentials shown with closed symbols include an overall relative uncertainty of 45% (40%) assumed for the background contribution in the dielectron (dimuon) analysis. LRSB\_15\_5 and LRSB\_18\_3 refer to two sets of LRSB mass hypotheses. See the text for more information.

# Vector Boson Scattering at High Mass

## Abstract

In the absence of a light Higgs boson, the mechanism of electroweak symmetry breaking will be best studied in processes of vector boson scattering at high mass. Various models predict resonances in this channel. Here, we investigate  $WW$  scalar and vector resonances,  $WZ$  vector resonances and a  $ZZ$  scalar resonance over a range of diboson centre-of-mass energies. Particular attention is paid to the application of forward jet tagging and to the reconstruction of dijet pairs with low opening angle resulting from the decay of highly boosted vector bosons. The performances of different jet algorithms are compared. We find that resonances in vector boson scattering can be discovered with a few tens of inverse femtobarns of integrated luminosity.

## 1 Introduction

In the absence of a light Higgs boson, an alternative scenario to the Standard Model, Supersymmetry, or Little Higgs models must be invoked. In particular, Electroweak Symmetry Breaking (EWSB) could result from a strong coupling interaction. Here, we will make no assumptions about the underlying dynamics of EWSB; we treat the Standard Model as a low energy effective theory, and evaluate the potential for measuring vector boson scattering. In the Standard Model, perturbative unitarity is violated [1] in vector boson scattering at high energy for a Higgs mass  $m_H > 870$  GeV or, if there is no Higgs ( $m_H \rightarrow \infty$ ), for a centre-of-mass energy above a critical value of around 1.7 TeV. The only way to avoid a light Higgs boson is therefore to presume new physics at high energy [2], possibly in the form of vector boson pair resonances. Such resonances are predicted in many models such as QCD-like technicolour models with the required Goldstone bosons resulting from chiral symmetry breaking [3]; Higgsless extra dimension models [4], where Kaluza-Klein states of gauge bosons are exchanged in the  $s$ -channel [5]; as well as in models with extra vector bosons, from GUT or from strong interaction (BESS models [6]) mixing with the Standard Model vector bosons. The present search for resonances in vector boson scattering can be considered generic and may be interpreted in terms of any of these models.

### 1.1 The Chiral Lagrangian Model

The Chiral Lagrangian (ChL) model is an effective theory valid up to  $4\pi v \sim 3$  TeV, where  $v = 246$  GeV is the vacuum expectation value of the Standard Model Higgs field. It can provide a description of longitudinal gauge boson scattering at the TeV scale when no light scalar Higgs boson is present. Electroweak symmetry breaking is realised non-linearly. A set of dimension-4 effective operators describe the low energy interactions (see for example [7]). Since, at the LHC, vector boson scattering can occur at the TeV energy scale where the interaction becomes strong, it is necessary to unitarise the scattering amplitudes. One popular unitarisation prescription is the so-called Padé prescription, or Inverse Amplitude Method [8]. This is based on meson scattering in QCD, where it gives an excellent description [9], reproducing observed resonances. Among the terms of the Lagrangian which describe vector boson scattering, under some basic assumptions (custodial symmetry and CP conservation), only 2 parameters (namely  $\alpha_4$  and  $\alpha_5$ ) are important for this process. Depending on the values of these two parameters, one can obtain Higgs-like scalar resonances and/or technicolour-like vector resonances [10]. The resulting properly-unitarised amplitudes for vector boson scattering may therefore give information in a higher energy range. They yield poles for certain values of  $\alpha_4$  and  $\alpha_5$  that can be interpreted as resonances, as shown in Fig. 1. The hashed region in the figure is forbidden by causality arguments [11].

Figure 1: Left: regions in the  $(\alpha_5, \alpha_4)$  parameter space indicating which values exhibit vector and/or scalar resonances in the Padé unitarisation scheme. Right: number of events per  $\text{fb}^{-1}$  as a function of the di-boson invariant mass for different resonance masses studied here.

Other unitarisation procedures are possible, such as the K-matrix method [12] or the  $N/D$  method [13]. In general, resonances are not necessarily produced. In non-resonant cases, it remains vital to measure the vector boson scattering cross section, but high luminosity and a very good understanding of backgrounds will be required in order to measure the regularisation of the cross section.

## 1.2 Characteristic Signatures of Vector Boson Scattering

Discovery of the physics signals studied here will, in general, require high integrated luminosity. It will require also extremely large samples of simulated backgrounds, fine tuning of all reconstruction algorithms, and a good understanding of the detector performance, which will only gradually develop after the first few years of LHC running. The main purpose of this note is not, therefore, to evaluate with precision the discovery potential of ChL resonances, but to establish a strategy for the search of this important signal. The main emphasis will be put on those aspects most particular to the high mass vector boson scattering process; that is, the reconstruction of hadronically decaying vector bosons at high  $p_T$  and the reconstruction of the high rapidity tag jets.

The decay of a high mass ChL resonance will produce two highly boosted vector bosons in the central rapidity region of the detector. For transverse momenta greater than about 250 GeV, a hadronically decaying vector boson will be seen as one single wide and heavy jet. Methods of distinguishing such jets from single-parton jets will be investigated with different jet algorithms.

A characteristic signature of vector boson scattering is the presence of two high rapidity and high energy “tag” jets [14], arising from the quarks which radiate the incoming vector bosons. The process can thus be efficiently distinguished from contributions to the production of (mostly transversely polarised) final state vector bosons due to bremsstrahlung of these vector bosons from the quarks. In that case, the accompanying jets are softer and more central. A further component of the signature is the suppression of QCD radiation in the rapidity interval between the tag jets due to the fact that no colour is exchanged between the protons in these processes [15]. This characteristic feature allows for efficient use of central jet veto to suppress backgrounds.

The high QCD background at the LHC naturally leads us to focus on “semi-leptonic” vector boson events; that is, those events when one  $W$  or  $Z$  boson decays leptonically, and the other decays hadronically. These channels represent the best compromise in that there is only at most one neutrino, so the diboson mass may be reconstructed with reasonable resolution, and the backgrounds can be reduced to a manageable level by the requirement of leptons and/or missing transverse energy ( $\cancel{E}_T$ ). Fully-leptonic

events are also useful in cases where clear resonances are present, where a kinematic edge may be visible and the backgrounds may be reduced even further. The case of resonant  $ZZ \rightarrow \ell^+ \ell^- \nu \bar{\nu}$  can also lead to a clean signature. Fully hadronic events may be useable at very high diboson energies, but this possibility is not considered further here. Thus, the study of vector boson scattering events will also require a good understanding of detector performance for electrons, muons and  $\cancel{E}_T$ . Although many ATLAS analyses will depend on the reconstruction of these objects, the quality of such reconstruction is evaluated here for the case of high energy leptons.

The note is organised as follows. In the next section (2) we describe the Monte Carlo simulations and the samples used. Next, the trigger is discussed (Section 3), then the detector performance with particular focus on the challenges of this analysis (Section 4). After this, the event selections, efficiencies and purities for the various final states are given (Section 5). An attempt to evaluate the expected sensitivity is made (Section 6), and the systematic uncertainties are discussed (Section 7), before a final summary and conclusion.

## 2 Signals and Background Simulation

### 2.1 Definition of Signal

In order to have a gauge invariant set of diagrams for the background, in spite of a Higgsless scenario, a low mass Higgs will be assumed. A resonance *signal* will be defined here as an excess of events in the resonance mass region over the number expected from the Standard Model continuum when the Higgs boson mass is set at 100 GeV. This ensures that longitudinal vector boson scattering will contribute negligibly to the process. This definition follows the prescription of [16]. We note that measurement of even a continuum cross section for this process at such high energies would be of great importance, but will not be considered here as it should require high luminosity and a very good understanding of backgrounds.

### 2.2 Overview of Generators

The Monte Carlo (MC) generators used in the main analysis are as follows.

- PYTHIA [17] version 6.4.0.3 was used for the signal, with the CTEQ6L parton distribution function and the renormalisation and factorisation scale  $Q^2 = m_W^2$ . The hard process was modified to include new vector boson scattering amplitudes (see below).
- MADGRAPH [18], version 3.95, with PYTHIA for parton shower, hadronisation and underlying event, was used for  $W$ +jets and  $Z$ +jets backgrounds. The default values of fixed renormalisation and factorisation scales of  $Q^2 = m_Z^2$  were set and CTEQ6L1 parton distribution functions were used.
- MC@NLO [19], with HERWIG [20], for parton shower and hadronisation and JIMMY [21,22] for underlying event, was used for  $t\bar{t}$  background.

The underlying event samples were tuned to data from previous experiments [22]. All samples use PHOTOS [23] to simulate final state radiation. WHIZARD [24] and ALPGEN [25,26] are also used for some generator level comparisons. WHIZARD uses PYTHIA for parton showering, hadronisation, and underlying event. ALPGEN uses HERWIG/JIMMY.

The different choice of scales for MADGRAPH and PYTHIA is not ideal, but retained for historical reasons since large samples were generated with these choices. However, studies showed that the

Sample name	Generator	$\sigma \times Br$ , fb
$qqWZ \rightarrow qqjj\ell\ell$ , $m = 500$ GeV	PYTHIA-73	25.2
$qqWZ \rightarrow qq\ell vjj$ , $m = 500$ GeV	PYTHIA-73	83.9
$qqWZ \rightarrow qq\ell v\ell\ell$ , $m = 500$ GeV	PYTHIA-73	8.0
$qqWZ \rightarrow qqjj\ell\ell$ , $m = 800$ GeV	PYTHIA-ChL	10.5
$qqWZ \rightarrow qq\ell vjj$ , $m = 800$ GeV	PYTHIA-ChL	35.2
$qqWZ \rightarrow qq\ell v\ell\ell$ , $m = 800$ GeV	PYTHIA-ChL	3.4
$qqWZ \rightarrow qqjj\ell\ell$ , $m = 1.1$ TeV	PYTHIA-ChL	3.7
$qqWZ \rightarrow qq\ell vjj$ , $m = 1.1$ TeV	PYTHIA-ChL	12.3
$qqWZ \rightarrow qq\ell v\ell\ell$ , $m = 1.1$ TeV	PYTHIA-ChL	1.18
$qqWW \rightarrow qq\ell vjj$ , $m = 499$ GeV (s)	PYTHIA-ChL	66.5
$qqWW \rightarrow qq\ell vjj$ , $m = 821$ GeV (s)	PYTHIA-ChL	27.5
$qqWW \rightarrow qq\ell vjj$ , $m = 1134$ GeV (s)	PYTHIA-ChL	17.0
$qqWW \rightarrow qq\ell vjj$ , $m = 808$ GeV (v)	PYTHIA-ChL	29.8
$qqWW \rightarrow qq\ell vjj$ , $m = 1115$ GeV (v)	PYTHIA-ChL	17.9
$qqWW \rightarrow qq\ell vjj$ , non-resonant	PYTHIA-ChL	10.0
$qqZZ \rightarrow qqv\ell\ell$ , $m = 500$ GeV	PYTHIA-ChL	4.0
$jjWZ \rightarrow jj\ell v\ell\ell$ , background	MADGRAPH	96
$jjZZ \rightarrow jjv\ell\ell$ , background	MADGRAPH	45.5
		$\sigma$ (no Br), pb
$W^+ + 4$ jets	MADGRAPH	$165 \pm 0.1$
$Z + 4$ jets	MADGRAPH	$87 \pm 0.7$
$W^+ + 3$ jets	MADGRAPH	$6.2 \pm 0.02$
$Z + 3$ jets	MADGRAPH	$3.8 \pm 0.02$
$t\bar{t}$	MC@NLO	$833 \pm 100$

Table 1: Data samples and generators used in the present study

major effect is on the cross section rather than on event shapes, and the cross section normalisation is determined independently as described below.

Further details specific to the samples are given below.

### 2.3 List of samples

Table 1 lists the Monte Carlo samples, produced with full detector simulation, used in the present analysis.

The first set of samples represents different reference cases of vector boson scattering signals:

- PYTHIA-73: For the samples labelled “PYTHIA-73”, the process 73 (longitudinal  $WZ$  scattering) was selected, with MSTP(46)=5 (QCD-like model of [27] with Padé unitarisation). All other switches were left as default. This is meant to represent a generic narrow  $WZ$  resonance.
- PYTHIA-ChL: datasets with generator labelled “PYTHIA-ChL” in the table use a modified version of PYTHIA routine PYSGHG. The modification involves replacing the scattering amplitudes calculated for processes 73–77 by those given by Dobado et al [10] with parameters  $a_4$  and  $a_5$ . These parameters were chosen so as to produce a vector or scalar (indicated by a (v) or an (s) in the table) resonance at the desired mass, or signal with no resonances at all. Note that only vector  $WZ$  and

scalar  $ZZ$  resonances are possible, but both scalar and vector  $WW$  resonances can be produced. A continuum sample was also generated using this model.

Background samples include events with two vector bosons and two jets in the final state, arising from gluon or electroweak vector boson exchange between incoming quarks. The vector bosons are here mostly transverse and emitted more centrally than in the case of longitudinal vector boson pair scattering.

- $jjWZ$  final state, where  $j$  is a quark or gluon: The decays of the vector bosons are performed in PYTHIA. Note that the semi-leptonic cases are already included in samples  $W$ +jets and  $Z$ + jets (see below). Only the purely leptonic cases make use of this background.
- The background process:  $\ell\ell\nu\nu$  with a pair of jets (quark or gluons). The cross section shown in Table 1 is for non-hadronic decay of the  $ZZ$ 's, with a filter requiring two leptons with  $p_T > 5$  GeV and  $|\eta| < 2.8$ .
- $W/Z + 3$  jets and  $W/Z + 4$  jets: they constitute backgrounds for the cases of high mass and lower mass resonances respectively since, in the former case, we expect that most of the vector bosons which decay hadronically will be reconstructed as a single jet. A correction factor of 1.38 is applied to the  $W^+$ +jets cross sections to account for the  $W^-$ +j process. These datasets include all tree level diagrams leading to  $W+4j$ ,  $Z+4j$ ,  $W+3j$  and  $Z+3j$ , with the vector bosons decaying leptonically, including all QCD and electroweak contributions. To keep the cross section manageable, preselection cuts were applied at MADGRAPH level. For the  $W, Z + 4$  jets case, we tag the highest rapidity jet (fjet), backward jet (bjet) and 2 central jets by requiring that  $|\eta_{fjet}| > 1.5$ ,  $|\eta_{bjet}| > 1.5$ , that the forward and backward jet candidates be on different hemispheres:  $\eta_{fjet}\eta_{bjet} < 0$ , that at least one forward jet have energy  $E > 300$  GeV, and that the invariant mass of the combined forward jets be  $m_{jj} > 250$  GeV. We further require  $p_T$  of at least one of the central jets to be  $p_T^j > 50$  GeV, the  $p_T$  of the vectorial addition of the central jets to be  $p_T^{jj} > 60$  GeV and the invariant mass of the combined central jets  $m_{jj} > 60$  GeV. We note that the forward jet preselection suppresses this background by a factor of 3.5.

For the case  $W, Z + 3$  jets, we add the requirements:  $p_T$  of the  $W$  or  $Z$  boson  $p_T > 200$  GeV,  $|\eta_{W/Z}| < 2$ , and  $p_T$  of one jet (central)  $p_T^j > 200$  GeV,  $|\eta_j| < 2$ .

Additional samples were produced with fast detector simulation to improve background statistics.

## 2.4 Comparative studies of generators

### 2.4.1 Parton shower matching to matrix elements

Here, MADGRAPH was used to generate the  $W$ +jets background. A better evaluation of this background would be obtained using a generator for which  $W$ + $n$  partons,  $n=0, 1, 2, 3$  or  $4$  inclusive, are combined in a manner which avoids double counting of jets produced by the parton shower in PYTHIA. ALPGEN is one such generator (and in fact such matching is now implemented in more recent versions of MADGRAPH). However, due to time constraints, and in order to have a manageable size of background samples, it was not practical to use this technique. In order to validate the use of MADGRAPH, a comparison was made of the  $W + 4$ jets sample with an appropriate ALPGEN sample, with same analysis cuts applied. The ALPGEN samples are not used in the final analysis since they lack sufficient statistics.

Distributions of the vector bosons and jets were compared. As an example, the distributions for the forward jets are shown in Fig. 2. The overall conclusion is that the shapes of the distributions are in reasonable agreement. Therefore, neglecting the effect of parton shower double counting does not significantly affect the event topology. To the extent that such an error is made, the tag jets in the

Figure 2: Distributions of the forward jets in the  $W + 4\text{jet}$  background for MADGRAPH (red) and ALPGEN (black) samples (area normalised). The error bars show the statistical error in each sample.

ALPGEN sample have a lower energy (leading to a depletion with respect to the MADGRAPH samples at high energies of a few %) and so the backgrounds in this analysis can be considered to be conservatively overestimated. The sensitivity of such backgrounds to the scales has been discussed, for example, in [28, 29]. The difference in  $Q^2$  scale of the two samples (ALPGEN uses  $Q^2 = m_W^2 + p_T(W)^2$ ) leads to about a factor two discrepancy in cross section. This was confirmed by running MADGRAPH on a small sample with the same scale as ALPGEN, yielding cross sections smaller by factors 2.05 and 1.77 for the QCD and QED processes respectively. These factors will be applied in the present analysis.

#### 2.4.2 Effective $W$ Approximation

WHIZARD [24] is a relatively new event generator originally developed for the ILC. It is able to calculate the full  $2 \rightarrow 6$  matrix element needed for the vector boson scattering processes and it implements the Chiral Lagrangian model with the K-Matrix unitarisation scheme [27] which does not lead to vector boson resonances. Further unitarisation schemes in the form of arbitrary resonances are planned.

The generator does not assume an effective  $W$  approximation, whereby the bosons emitted from the quarks are treated as partons, allowing vector boson scattering diagrams to form a gauge-invariant subset. This approximation is made in the PYTHIA signal samples, and might be expected to particularly affect the tag jet kinematics. Comparisons between the tag jet distributions from WHIZARD and PYTHIA are shown in Fig. 3. The two samples are not strictly comparable since here, WHIZARD simulates the  $2 \rightarrow 4$  processes including non-scattering electroweak diagrams and applies K-matrix unitarisation. Although there are differences (e.g. the tag jets from WHIZARD are somewhat harder than those from PYTHIA) they do not strongly depend upon the vector boson centre-of-mass, and thus the effective  $W$  approximation is unlikely to be the culprit. The harder tag jets in WHIZARD mean that if the signal looks more like WHIZARD than PYTHIA, it would be more likely to pass the selection cuts, thus improving the sensitivity. The potential size of the effect was investigated and estimated to be at the few per cent level.

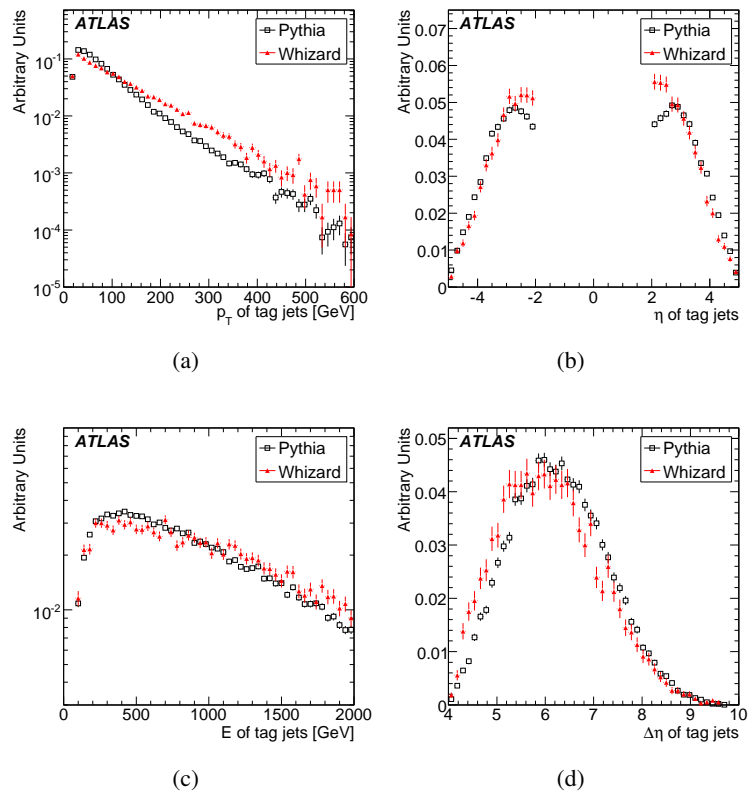

Figure 3: Differences between WHIZARD (red) and PYTHIA (black) for vanishing anomalous couplings for tag jet distributions of: transverse momentum (a), pseudo rapidity (b), energy (c) and pseudo rapidity difference (d).

### 3 Trigger

As a first step in the analysis, it is important to evaluate the efficiency of the basic trigger menus for a luminosity of  $10^{33} \text{ cm}^{-2}\text{s}^{-1}$ . The triggers chosen were based on an early menu [30] as an example, and the real physics menu is likely to be very different. However, since the signal is at relatively high  $p_T$ , and triggering on vector bosons is a high priority, this is not likely to have a large impact. To evaluate this efficiency, we apply the following cuts: for electrons and muons we require single leptons to have  $p_T$  greater than the value corresponding to the threshold dictated by the trigger signature and  $|\eta| < 2.5$ ; similarly for jets, but with a pseudorapidity cut of  $|\eta| < 3.2$ . This is necessary because trigger signatures for forward jets exist separately, but unfortunately that trigger information was not available in the simulation version used for this study. The trigger efficiency is defined as the number of times the trigger passed (with the corresponding cuts applied) divided by the number of truth events in the samples (with the same cuts applied). In Table 2 we present a detailed list of efficiencies for the signals  $qqWZ \rightarrow qqjj\ell\ell$  ( $m = 1.1 \text{ TeV}$ ) in the left column and  $qqWW \rightarrow qqjj\ell\nu$  (non-resonant) in the right<sup>1</sup>.

The poor efficiency of the e25i (see Fig. 4, left) and 2e12i triggers is understood to be due to the isolation criterion, which was not optimised for high energy electrons.

Figure 4: Trigger efficiencies computed with the  $WW$  continuum signal. Left: efficiency of the e25i trigger as a function of the  $p_T$  of electrons from the true leptonically-decaying  $W$  boson. Right: efficiency of the j160 trigger (black triangles) as a function of the  $p_T$  of the true hadronically-decaying  $W$  boson. Also shown with blue circles is the efficiency when the j160 and 2j120 triggers are logically OR'ed.

It is worth mentioning that the efficiency for the 2j120 trigger (Fig. 4, right), which requires two jets with  $p_T > 120 \text{ GeV}$  suffers partly from the fact that the two jets from the vector boson decay are merged due to the boost as described in Section 4.1. It is also significantly higher for events with true electrons than for those with true muons, probably because the electrons themselves are also reconstructed as jets in the calorimeter.

Finally, various combinations of the trigger signatures might be explored in the future to improve the efficiency. For instance, the e60 trigger might be used in conjunction with the e25i to compensate the low efficiency of the latter for high-momentum electrons (Fig. 4). Likewise, the 2j120 trigger might be used together with j160, since the efficiency of the latter drops significantly when the hadronically-decaying vector boson has  $p_T < 300 \text{ GeV}$  and decays into two distinctly resolvable jets.

<sup>1</sup>Triggers 2j120 and j160 have been removed from the menu as they are expected to give too high a rate. However, forward jet triggering will be available, and more recent developments in the electron trigger has resulted in improved efficiency.

	WZ signal		WW signal	
Trigger Signature	Cut Loss	Efficiency	Cut Loss	Efficiency
<i>Electrons</i>				
2e12i	13%	36%	> 99%	—
e25i	1%	78%	11%	65%
e60	5%	82%	29%	73%
<i>Muons</i>				
mu6	5%	95%	6%	80%
mu20	5%	92%	9%	73%
<i>Jets</i>				
2j120	67%	73%	50%	80%
j160	34%	96%	30%	86%

Table 2: Table of high level trigger efficiencies for  $qqWZ \rightarrow qqjj\ell\ell$  ( $m = 1.1$  TeV) and  $qqWW \rightarrow qqjj\ell\nu$  (non-resonant). The “Cut Loss” columns indicate the fraction of true events that would be lost by applying the  $p_T$  requirements of each trigger signature on the true electrons, muons and jets. Since such events are unlikely to satisfy the trigger conditions, they are not taken into account when the trigger efficiencies are evaluated.

## 4 Reconstruction Challenges

In this section, we focus on those parts of the reconstruction which are most particular to vector boson fusion at high masses. We discuss the following:

- Reconstruction of hadronically-decaying vector bosons. In our regime these typically have high  $p_T$  and the decay products are very collimated. We discuss two alternative methods, using  $k_\perp$  jets and subjets, and using cone jets with different radii.
- Leptonically decaying vector bosons. These require good lepton and  $\cancel{E}_T$  measurement, but the challenges here are not unique to these channels.
- Forward ‘tag’ jets. Measuring jets close to the edge of the detector rapidity acceptance is a challenge in common with low mass Higgs searches in vector boson fusion.
- Central jet veto. Since the vector boson scattering process involves no colour exchange between the protons, a suppression of QCD radiation is expected. This can be used to distinguish between signal and background, but is sensitive to underlying event and pile-up.
- Top veto.  $t\bar{t}$  production is a major background for the channels which do not contain leptonic  $Z$  boson decays. A large fraction of this is removed by explicitly rejecting events containing top candidates.

### 4.1 Hadronic Vector Boson Identification

At lower masses and  $p_T$ , the hadronically-decaying vector bosons are identified as dijet pairs. However, for events where a hadronically-decaying vector boson is highly boosted, the decay products are often collimated into a single jet. Cuts such as a dijet invariant mass window are no longer applicable in this scenario, but a single jet mass cut can be used.

The single jet mass is defined as the invariant mass evaluated from the 4-vectors of the constituents of the jet. In the ATLAS detector, these constituents are at present calorimeter objects, either topologically defined clusters with some local hadronic calibration, called here *topoclusters*, or calorimeter towers. For jets containing the decay products of a boosted vector boson, this single jet mass is near the mass of the parent boson. For light quark and gluon jets this mass is generally much lower. Since the background to hadronic vector boson identification is so severe, further cuts may be applied on the subjet structure of the candidate jet.

In addition, the transition between the dijet and single jet case as  $p_T$  increases needs to be dealt with. Two methods are used, as follows;

1. Dynamically select the appropriate method. To do this, we first look at the highest  $p_T$  jet. If this passes the mass window cut, then the single jet selection is applied, as described below. If it does not, then combinations of jet pairs in the event are considered. The vector boson is still expected to be the highest  $p_T$  hadronic system, and so the  $p_T$  of all jet pairs is evaluated, and the highest  $p_T$  pair is taken to be the vector boson candidate. A mass window cut (dependent upon the jet algorithm) is then applied to this pair. Thus a single analysis can be used to scan the data for signs of resonances without bias.
2. When the single jet and jet pair cases yield very different signal to background ratios, it is preferable to choose a priori which mass region is being investigated, and to use the single jet reconstruction for high masses and the dijet reconstruction for low masses. This approach is used in the cone algorithm analysis. For the  $m = 800$  GeV resonance, both the dijet and single jet approaches are tried independently.

#### 4.1.1 $K_{\perp}$ Algorithm

The  $k_{\perp}$  algorithm is run with an  $R$ -parameter (which determines the “jet size”) of 0.6 on calibrated topoclusters. The algorithm [31] merges pairs of constituents.

The  $k_{\perp}$  analysis uses the dynamic selection technique described above to decide whether to use a dijet or a single jet for the vector boson candidate. The fraction of vector bosons reconstructed as a single jet, as a function of  $p_T$  of the vector boson candidate, is given in Fig. 5. The transition between dijet and single jet takes place between  $p_T = 200$  and 300 GeV for this algorithm.

Figure 5: Fraction of  $W$  boson candidates reconstructed from a single jet, as a function of the transverse momentum of the reconstructed vector boson, for the  $WW$   $m = 1.1$  TeV signal sample.

Figure 6: Single jet mass residuals (left) and Y scale residuals (right) from different detector simulations, using the  $k_{\perp}$  algorithm. The truth is defined by running the jet algorithm on the hadronic final state of the MC generator.

### Single jet mode

The resolution of the single jet mass for the  $k_{\perp}$  algorithm has been evaluated for both detector simulations (full and fast) for several samples. For the sample with a  $WW$  resonance at  $m = 1.1$  TeV (Fig. 6 left) for example, the  $W$  boson singlet jet mass resolution was found to be  $7.4 \pm 0.2\%$  GeV from full and fast detector simulation.

A mass cut around the window from  $m = 68.4$  GeV to  $97.2$  GeV is applied to  $W$  boson candidates, and from  $m = 68.7$  GeV to  $106.3$  GeV for hadronic  $Z$  boson candidates reconstructed in the single jet mode. These mass windows are determined by considering the resolution, the tails, and the background contamination.

The  $k_{\perp}$  merging is intrinsically ordered in scale, making the final merging the hardest. The algorithm provides a  $y$  value for this final merging, which is a measure of the highest scale at which a jet can be resolved into two subjets. The  $y$  value can be converted into a “Y scale” in GeV using the relation  $Y \text{ scale} = E_T \times \sqrt{y}$ , where  $E_T$  is the jet transverse energy. This Y scale is expected to be  $\mathcal{O}(m_V/2)$  (where  $m_V$  is the mass of the vector boson) for boosted vector boson jets, and much lower than  $E_T$  for light jets [32]. At the truth and fast simulation levels this variable has been shown to have discriminating power even after a single jet mass cut [32–35]. The resolution of the ATLAS detector for this variable is presented in Fig. 6 (right). The resolutions, for the same sample as above, are  $12.3 \pm 0.3\%$  and  $8.8 \pm 0.2\%$  with full and fast detector simulation, respectively.

Based on the resolution, the tails, and the background contamination, a Y scale cut around the window from 30 GeV to 100 GeV is applied to  $W$  and  $Z$  boson candidates reconstructed in the single jet mode. To evaluate the benefit of cutting on Y scale, a sample of single jet vector boson candidates is selected in signal and background by applying a  $p_T > 300$  GeV cut, motivated by Fig. 5, and a mass window cut. Starting from this sample, the efficiency of the Y scale cut is given in Table 3 for full and fast simulation. The numbers suggest that for the  $W$ +jets background, an additional rejection factor of approximately 2 is provided by the Y scale cut even after a single jet mass cut has been applied. This is achieved with a signal efficiency of approximately 80%.

Figure 7: Dijet mass residuals (left) and  $y$  residuals (right) from different detector simulations, using the  $k_{\perp}$  algorithm. The truth is defined by running the jet algorithm on the hadronic final state of the MC generator.

	1.1 TeV Vector Resonance	$W+4$ jets	$t\bar{t}$
Jet Mass	68% (67%)	14% (14%)	28% (28%)
Y Scale	77% (84%)	29% (40%)	63% (70%)

Table 3: Efficiency of the jet mass cut and of the Y scale cut in the one-jet case for full (fast) simulation. The Y scale cut is applied after the mass cut.

	800 GeV Scalar Resonance	$W+4$ jets	$t\bar{t}$
Jet Mass	17% (20%)	6% (7%)	14% (14%)
Y Scale	79% (83%)	48% (49%)	84% (82%)

Table 4: Efficiency of the jet mass cut and of the Y scale cut in the two-jet case for full (fast) simulation. The Y scale cut is applied after the mass cut.

### Dijet mode

A mass cut around the window from  $m = 62$  GeV to 94 GeV is applied to  $W$  boson candidates, and from  $m = 66.6$  GeV to 106.2 GeV for hadronic  $Z$  boson candidates reconstructed in the dijet mode.

A variable analogous to the  $y$  may be calculated, using the  $p_T$  of the softer jet relative to the harder one. This variable is required to be in the range  $0.1 < \sqrt{y} < 0.45$ . The efficiency is shown in Table 4.

The mass and  $y$  windows are again determined by considering the resolution, the tails, and the background contamination.

The resolutions of the dijet mass and the  $y$  variable for dijet vector boson candidates are shown in Fig. 7. They are found to be approximately 5% for the mass and for the  $y$  variable, and are comparable in fast and full simulation.

#### 4.1.2 Cone Algorithm

The problem of the two jets from a boosted hadronically decaying vector boson merging into a single jet has also been studied for jets reconstructed using the Cone Algorithm. With this algorithm, jet reconstruction starts from *seeds* i.e. constituents (clusters) with  $p_T > 1$  GeV. The algorithm collects all constituents around a seed within  $\Delta R = \sqrt{(\Delta\eta)^2 + \Delta\phi^2} < R_0$  (where  $R_0$  can be, for instance 0.4) and adds their momenta vectorially. Then it repeats the procedure over the collection around the direction of the sum, and computes a new sum. It continues repeating this operation until the resulting sum direction is stable.

Single jet hadronic  $W$  boson candidates are identified with the highest  $p_T$  object in the central region, after having removed overlaps with all electrons in the event within a  $\Delta R$  of 0.1. A mass cut in a window around the reconstructed  $W$  boson mass is applied.

Figure 8 shows an example of  $W$  boson reconstruction using the cone algorithm for the jet-pair case ( $m = 500$  GeV resonance) and single jet case ( $m = 800$  GeV resonance). A cone size of 0.8 is used for selecting a single jet  $W$  boson and 0.4 for the case of a jet pair. The low mass tail is due to events where the two jets from the  $W$  are well separated. There is a small difference in the  $W$  boson mass peak reconstruction for the two cases. The jets chosen for this selection have a minimum  $p_T$  cut of 20 GeV, and those overlapping with electrons have been removed.

Figure 8: Reconstructed  $W$  boson for cases where it forms two separated jets (500 GeV) and a single jet (800 GeV). The samples used are the  $m = 500$  GeV resonance (in green) and  $m = 800$  GeV resonance (in red).

The exploration of the substructure of a wide jet (typically of size 0.8) is done by searching for 2 narrow jets (size  $\sim 0.2$ ) fitting inside the big jet. Various variables can then be studied, among which

	1.1 TeV Vector Resonance	$W+4\text{jets}$ (QCD)	$t\bar{t}$	$Z+3\text{jets}$ (QED)
small jets cut	76.3%	15.2%	38.6%	13.8%

Table 5: Comparison of efficiencies for the jet sub-structure selection for a typical signal and backgrounds. Efficiencies are relative to the selection of a single jet as described in the Y scale method (Table 3). For the subjet selection, we require 2 small jets with  $p_T > 15$  GeV and invariant mass  $> 60$  GeV (see text).

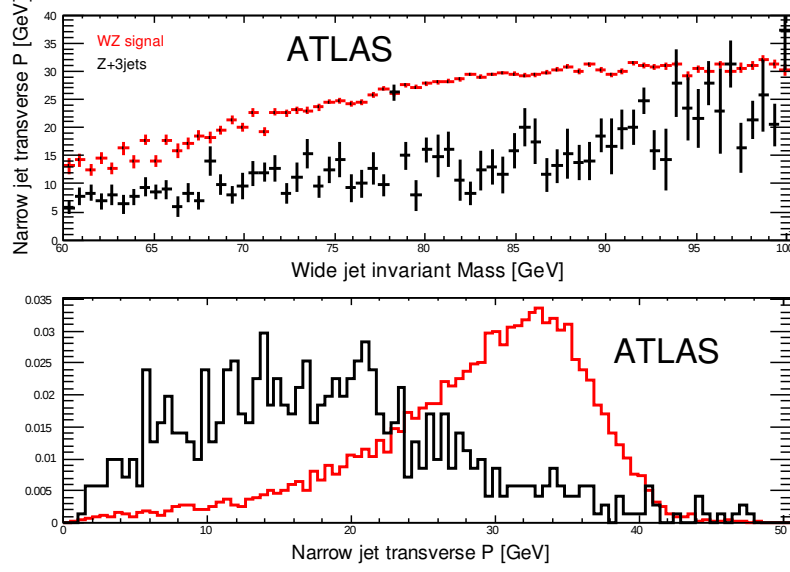

Figure 9: Profile histogram of the momentum of the narrow jet orthogonal to the wide jet direction vs the invariant mass of the wide jet, for  $W$  boson hadronic decay of the resonance signal  $qqW_{jj}Z_{\ell\ell}$  of  $m = 1.1$  TeV (red) and for  $Z+3$  jets sample (black). Lower graph : normalized distributions of narrow jet orthogonal momentum.

are the energy ratio of the narrow jets, their invariant mass, the distance  $\Delta R$  between the leading narrow jet and the wide jet, or the momentum component of this narrow jet transverse to the wide jet direction. The discriminating power is illustrated for the  $WZ \rightarrow \ell\ell jj$  channel (1.1 TeV resonance) and its principal background in Fig. 9 which shows the latter variable (called here ‘p transverse’) versus the invariant mass reconstructed from two narrow jets. Cutting in the  $(p_T, \text{invariant mass})$  plane gives results comparable to those obtained with the Y scale method above, as illustrated in Table 5. Similarly, Fig. 10 shows the  $p_T$  versus  $\Delta R$  between the leading narrow jet and the wide jet.

## 4.2 Leptonic Vector Boson Identification

### 4.2.1 Lepton Reconstruction Efficiencies

All the signals studied in this note involve at least one leptonic vector boson decay. Electrons and muons are selected using standard ATLAS criteria [36, 37] for the case of a resonance  $m(WZ)$  of 800 MeV. Figure 11 shows the efficiency for  $W$  boson daughter leptons, where the trigger condition has not been applied. The results for different electron selection criteria are given. The loss of efficiency occurs in the forward regions, near the limits of the tracking detectors and at  $p_T$  values close to the applied cut. The efficiencies for the leptonic  $Z$  boson channels have been found to be similar.

Figure 10: Profile histogram of the distance (narrow jets, wide jet) versus the invariant mass of the wide jet, for W boson hadronic decay of the resonance signal  $qqW_{jj}Z_{\ell\ell}$  of  $m = 1.1$  TeV (red) and for Z+3 jets sample (black). Lower graph : normalized distributions of distance (narrow jets, wide jet).

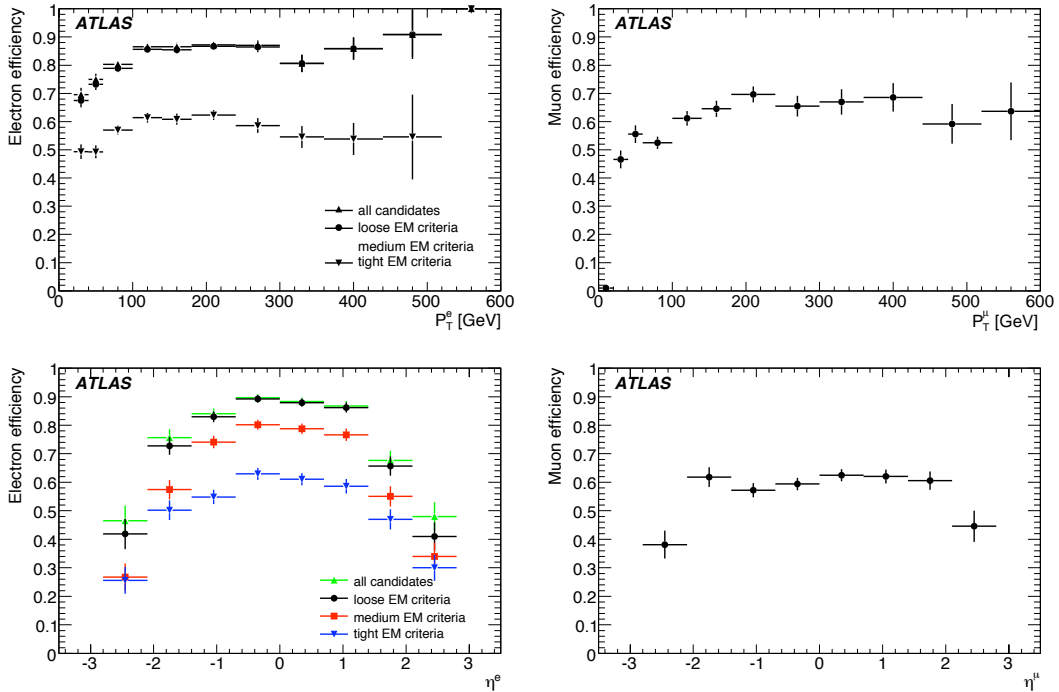

Figure 11: Efficiency of reconstructing and identifying W-daughter electrons (left) and muons (right) as functions of true lepton momentum (top) and pseudo-rapidity (bottom). The electron plots show the efficiency for 4 different electron selection criteria: All candidate objects (green), *loose* (black circles), *medium* (red squares), and *tight* (blue triangles).

Figure 12: Reconstructed Z boson from electron pairs (left) and muon pairs (right).

#### 4.2.2 Leptonic Z Boson Reconstruction

The Z boson candidates are reconstructed from pairs of  $e^+e^-$  or  $\mu^+\mu^-$ . In the electron case, the mass resolution is about 2.7 GeV as is shown in Fig. 12 left, suggesting a mass window selection between  $m = 85$  GeV and 97 GeV for  $m_{ee}$ . In the case of muons, the resolution for the Z mass reconstruction is 3.6 GeV (see Fig. 12 right), so the mass requirement is loosened to be between  $m = 83$  GeV and 99 GeV. Furthermore, to reduce the backgrounds (particularly the background from  $t\bar{t}$  events), the  $p_T$  of one of the leptons is required to be  $p_T > 50$  GeV, and that of the other  $p_T > 35$  GeV. In the unlikely case that more than one combination of leptons satisfy all these requirements, we choose the composite  $Z_{\ell^+\ell^-}$  with the mass closest to the actual Z boson mass.

#### 4.2.3 Leptonic W Boson Reconstruction

For the signal, after reconstruction of the hadronic vector boson candidate, the highest  $p_T$  lepton corresponds to the lepton from the W boson decay in 96% of cases. Attributing the missing momentum to the neutrino, and taking the nominal W boson mass ( $m_W = 80.42$  GeV) as a constraint, a quadratic equation is obtained for the z-component of the neutrino's momentum. The z component is required in order to reconstruct the diboson mass in the final analysis. Only events for which at least one real solution exists for this quadratic equation are retained. When there are two possible solutions, one is chosen at random to avoid kinematic bias on the resonance mass. Options such as selecting the reconstructed W boson which is more central have also been considered, and little difference was found in the purity of the reconstruction. In the fully leptonic case, the leptonic Z boson is reconstructed and its daughter leptons removed before applying the above procedure.

### 4.3 Tagged Forward Jets

One of the well known characteristic features of vector boson scattering is the presence of high energy forward jets [14], resulting from the primary quarks from which the vector bosons have radiated (see Fig. 13). Such forward jets are expected to be much less prominent in processes involving gluon or electroweak boson exchange with bremsstrahlung of vector bosons. In the latter case, these vector bosons are mostly transverse and have a harder  $p_T$  spectrum than in  $W_L W_L$  scattering. Correspondingly, the outgoing primary quarks have a harder  $p_T$  and are therefore less forward.

Figure 13: Pseudo-rapidity of the forward and backward quarks in signal events after they radiate the vector bosons, obtained from PYTHIA before any showering, fragmentation, etc.

Many different strategies are possible for implementing a tag-jet selection. A number of these were compared, and the best rejection factors for a given efficiency were obtained as follows:

1. Require two jets with
  - $|\eta(jet)| > \eta_{\text{cut}}$  and  $p_T(jet) > p_{T\text{cut}}$
  - opposite signed rapidity
  - at least one of them has an energy greater than a critical value  $E_{\text{cut}}$
2. If more than one jet with the same sign rapidity satisfies the above cuts, choose the most energetic, labelled FJ1. The next one is labelled FJ2.
  - Require the tag-jet with the opposite sign of rapidity to satisfy  $\Delta\eta(FJ1, FJ2) > \Delta\eta_{\text{cut}}$  and  $E(FJ2) > E_{2\text{cut}}$

In addition a dijet mass cut is currently applied in the cone algorithm analyses. The specific values of the cuts in each case are to be optimised depending upon the kinematic region under study.

#### 4.4 Central Jet Veto

A useful analysis strategy to suppress backgrounds such as  $t\bar{t}$  is to apply a central jet veto [15, 38, 39]. For vector boson scattering, one expects little QCD radiation in the central region since only colourless electroweak vector bosons are produced and the forward jets are not colour connected. Given the forward jet cut definition, we unambiguously define the central region of the event as the  $\eta$  region between them. The central jet veto then simply requires that no other high  $p_T$  jet (here taken as  $p_T > 30$  GeV) other than those resulting from the hadronically decaying vector boson lie in the central region.

Specifically, in the analyses where it is applied, the central jet veto rejects events if there are any additional jets with a chosen maximum value for  $|\eta|$  and minimum value for  $p_T$ .

## 4.5 Top Quark Rejection

While the final states from a leptonically decaying  $Z$  boson are mostly free of background from top processes,  $t\bar{t}$  and  $tW$  events form an important source of background for the  $WW$  signals. To suppress them, events can be vetoed if a reconstructed  $W$  boson candidate, combined with another jet in the event (excluding those overlapping with an identified electron or within  $\Delta R < 0.8$  of a  $W$  candidate), leads to an invariant mass close to that of the top quark [32]. A typical mass window is  $130 < m_t < 240$  GeV.

In a future analysis it is likely that this cut can be improved using  $b$ -tag information and better jet mass reconstruction, but this has not been investigated here.

## 5 Event Selection

Using the tools outlined in the previous section, we now characterise the samples and outline the specific cuts applied for each final state considered.

### 5.1 $W^+W^- \rightarrow \ell^\pm \nu jj$ and $W^\pm Z \rightarrow \ell^\pm \nu jj$

The hadronic vector boson candidates and the tag jets are obtained using the  $k_\perp$  algorithm as discussed in Section 4.1. The leptonic  $W$  is identified as described in Section 4.2.3. Both vector boson candidates are required to have  $p_T > 200$  GeV,  $|\eta| < 2$ . Tag jet cuts are made as described in Section 4.3, with  $p_{T\text{cut}} = 10$  GeV,  $E_{\text{cut}} = E_{2\text{cut}} = 300$  GeV and  $\Delta\eta_{\text{cut}} = 5$ . The top veto (Section 4.5) and the central jet veto (Section 4.4) are applied.

The kinematic distributions for the  $WW$  channel are shown in Fig. 14. Note that these are significantly biased by the generator-level cuts. The selection efficiencies of the cuts on  $WW$  events from four example scenarios are summarised in Table 6, along with the efficiency of the combined trigger selection described in Section 3. No significant differences are observed between the scalar and vector resonances, nor between the  $WZ$  and  $WW$  channels, except for the  $m = 500$  GeV-resonant samples, where the  $p_T$  requirements are found to be less efficient for the  $WZ$  sample. The QCD-like model of [27] tends to predict softer vector bosons.

Due to the small background statistics available with full simulation, the full-simulation signal samples are used together with fast-simulation background samples in obtaining the final results. The modelling of the kinematics is good, as shown in Fig. 14<sup>2</sup>. However, in general the efficiency for selecting both signal and background is higher in fast simulation by about 25% compared to full simulation. To account for this, a constant scaling factor is applied to the fast-simulation samples in estimating the significance of the signal over the background (Section 6).

Figure 15 shows a comparison of the final  $WW$  mass for the signal samples using fast and full simulation.

The final  $WW$  mass spectra obtained using this analysis are shown in Fig. 16. The backgrounds shown have been obtained from the fast-simulation samples and the above mentioned scaling factor has been applied.

### 5.2 $W^\pm Z \rightarrow jj \ell^+ \ell^-$

This channel benefits from a very good resolution on the  $Z$  boson leptonic reconstruction, which allows good suppression of the  $t\bar{t}$  background.

<sup>2</sup>To achieve this agreement it was necessary to correct the lepton-finding efficiency in the fast simulation by fitting a function to the efficiency from fast and full simulation as a function of lepton  $p_T$  and correcting the fast simulation by the ratio of the functions.

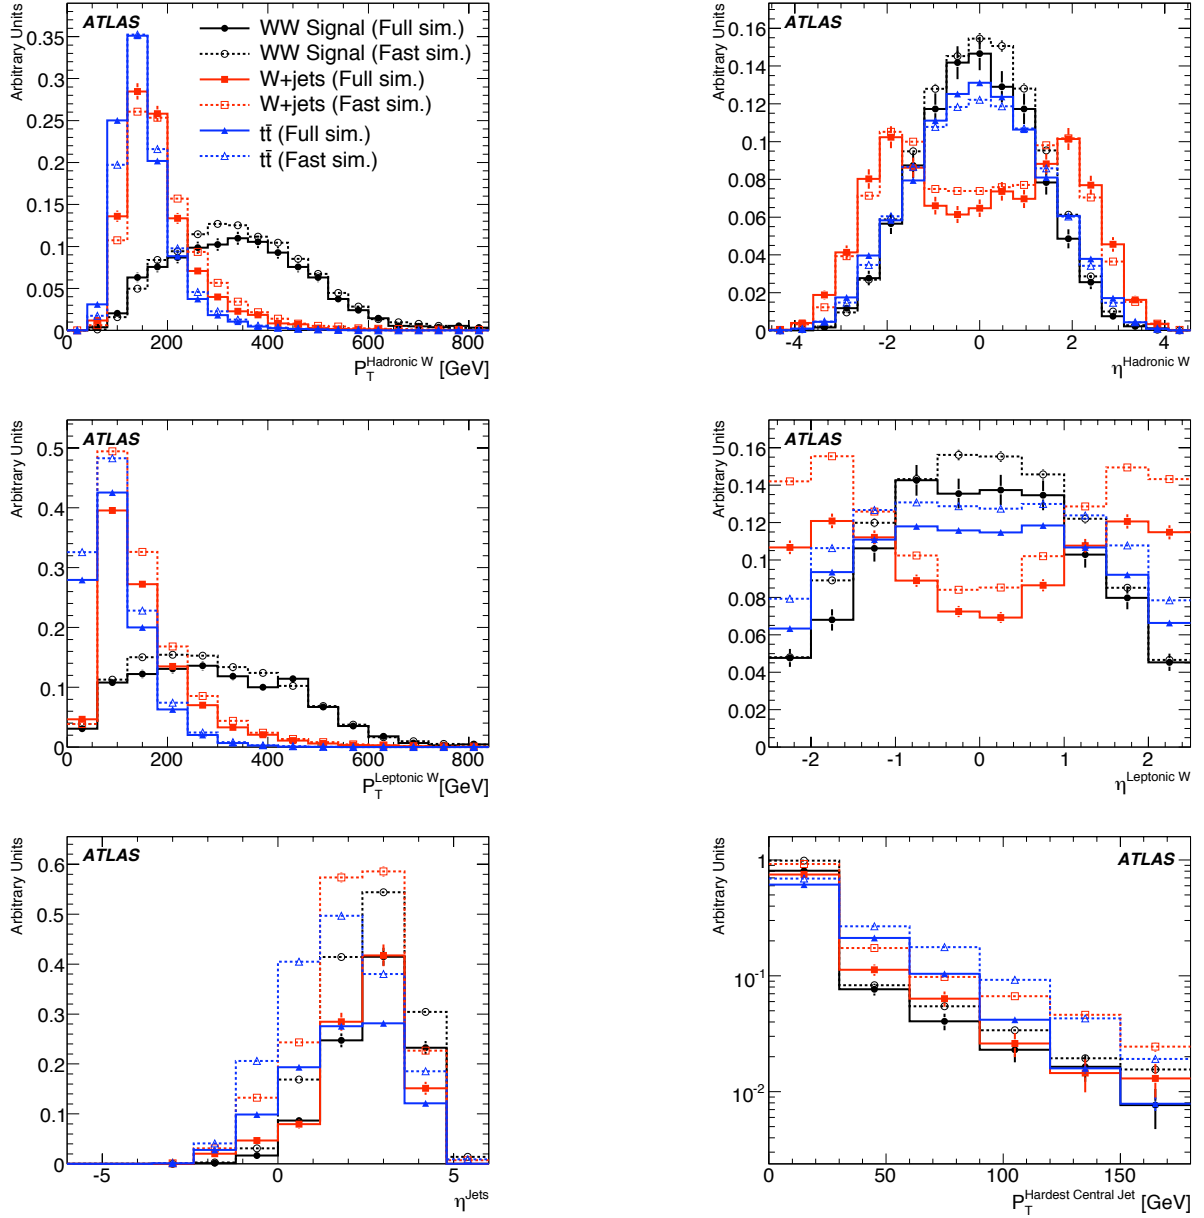

Figure 14: Kinematic distributions for the generated signal and backgrounds ( $t\bar{t}$  and  $W+4$  jets QCD) in the 1.1 TeV  $W^+W^- \rightarrow \ell^\pm \nu j(j)$  channel. The top two plots show the  $p_T$  and  $\eta$  for the hadronic  $W$  boson candidate. The middle two show the same variables for the leptonic  $W$  boson candidate. The bottom two plots show the  $\eta$  distribution of all jets which are at higher rapidity than the  $W$  boson candidates, and the  $p_T$  distribution of the highest- $p_T$  central jet. In each plot, the full-simulation histograms (solid lines) have been normalised to unit area and the fast-simulation histograms (dashed lines) have been normalised to the same cross section as their full-simulation counterparts.

Table 6: Efficiencies of the cuts for four different  $qqWW \rightarrow qq\ell\nu qq$  signal samples and the backgrounds. The trigger efficiency row shows the efficiency of the logical OR of mu201i, e251i and jet160 signatures on the samples after all the cuts have been consecutively applied. The numbers in brackets are from the fast simulation.

Figure 15: WW (left) and WZ (right) invariant mass spectra in the  $\ell\nu j(j)$  semileptonic channel for the three resonant signal samples. The WW plot shows a comparison of the fast- and full-simulation results.

For the  $m = 1.1$  TeV WZ resonance, only the case of a single heavy jet from the  $W$  boson decay will be considered as it constitutes the majority of the events. For the  $m = 800$  GeV resonance, not all  $W$  bosons are boosted sufficiently to produce a single jet. We therefore consider separately the cases of a  $W$  boson from a single heavy jet and from a jet pair. Finally, for the  $m = 500$  GeV resonance, we only consider the jet pair case. In this section, the cone algorithm will be used and compared with an analysis using the  $k_{\perp}$  jet algorithm.

### 5.2.1 $W$ boson from a single jet

The main backgrounds will here be  $Z + 3$  jets and  $t\bar{t}$ .

Table 7 shows the cut flow for the electron-based and the muon-based analyses for the ChL WZ resonances of mass  $m = 1.1$  TeV and  $m = 800$  GeV. The  $m = 500$  GeV case is not considered here since the  $W$  and  $Z$  bosons will not be sufficiently boosted, in general, to produce a single jet. The  $Z \rightarrow e^+e^-$  and  $Z \rightarrow \mu^+\mu^-$  selections are shown, which correspond each to about 50% of the sample events. After applying electron quality cuts (*medium* electrons) we select the two highest  $p_T$  leptons which should satisfy respectively:  $p_T(e, \mu) > 50$  GeV and  $p_T(e, \mu) > 35$  GeV. The low efficiency of the lepton pair cut is approximately consistent with the expected selection efficiency per lepton, as shown in Fig. 11, as well as the detector acceptance. As can be seen in Fig. 17, the  $p_T$  cut suppresses mostly the  $t\bar{t}$  background. A leptonic  $Z_{e^+e^-}$  or  $Z_{\mu^+\mu^-}$  is afterwards reconstructed as described in Section 4.2.2, almost eliminating completely this background. The efficiency of this cut is somewhat poorer for the signal than for the background because most of the background events have  $Z$  bosons of relatively low  $p_T$ , with different lepton pair energies and opening angle.

Using the cone algorithm, size 0.8, the hadronic  $W$  boson candidate is identified as a heavy single jet having a mass between 70 and 100 GeV, and separated in azimuthal angle from the  $Z$  boson candidate by  $\Delta\phi(W, Z) > 2$ , as described in Section 4.1 (see Fig. 18). At this stage, considering that the fraction of single jet  $W$  bosons becomes important for  $p_T > 250$  GeV (see Fig. 5), and in order to be consistent with the preselection cuts on the  $Z + 3$  jets background, we apply the following cuts to the reconstructed

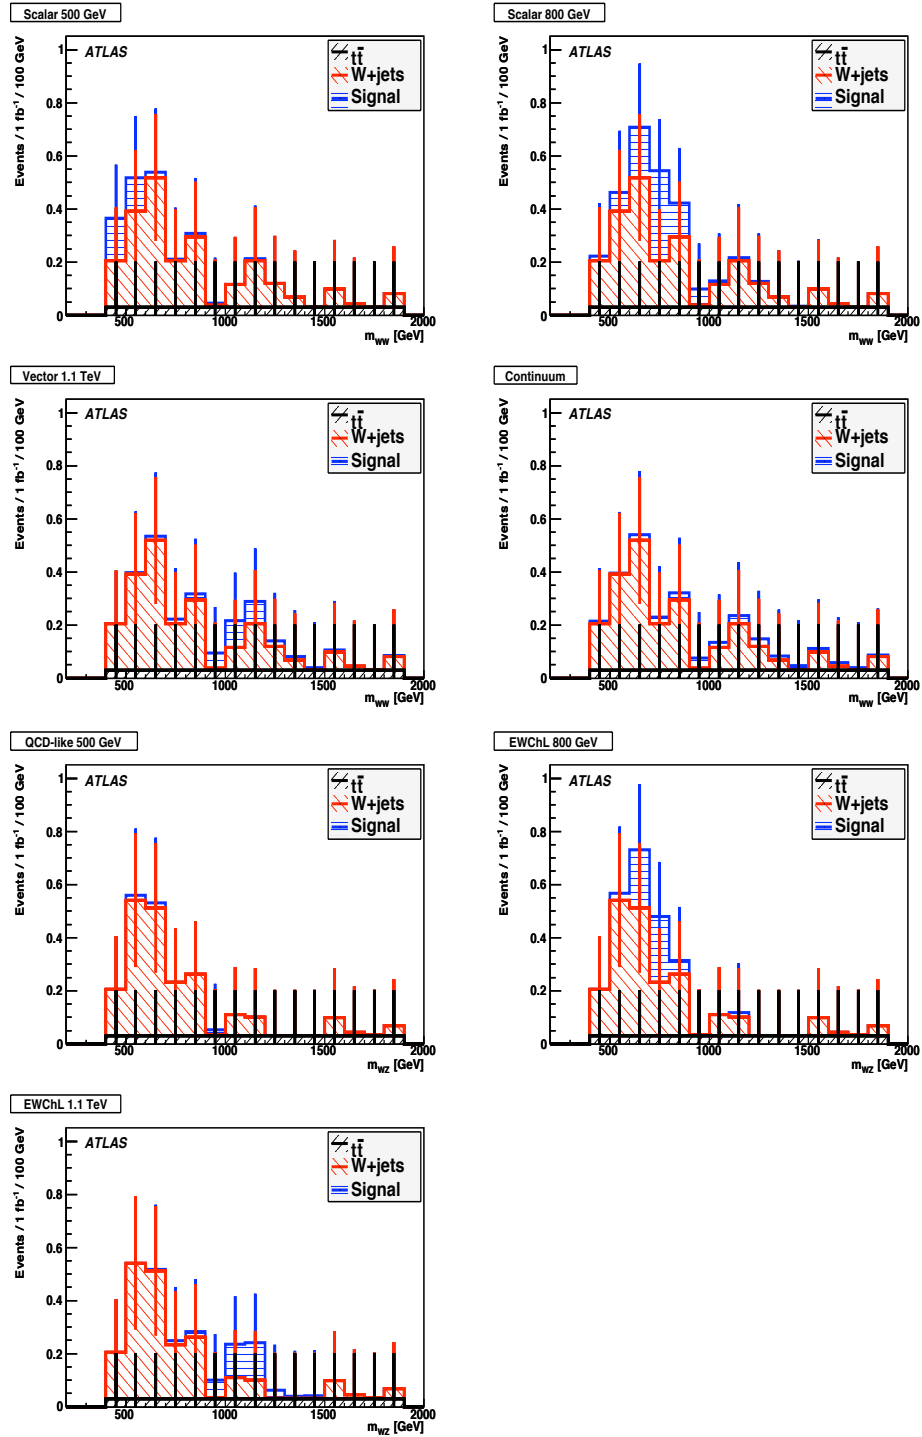

Figure 16: WW (top 4) and WZ (bottom 3) invariant mass spectra in the  $\ell\nu j(j)$  semileptonic channel, showing the total W+jets and  $t\bar{t}$  backgrounds and the signal for the three resonant signal samples and the continuum sample. The error bars reflect the uncertainty from the Monte Carlo statistics.

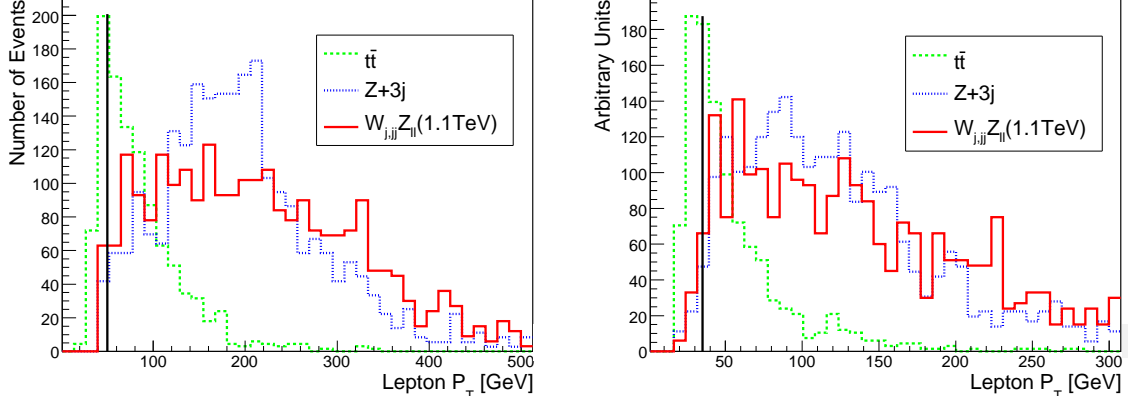

Figure 17:  $p_T$  of the highest  $p_T$  and second highest  $p_T$  electrons from reconstructed  $Z$  bosons in the  $m = 1.1$  TeV resonance sample. Distributions are arbitrarily normalised. The line indicates the cut value.

Figure 18: Mass of the heavy jet for the  $m = 1.1$  TeV ChL resonance and corresponding backgrounds. No  $t\bar{t}$  event is left.

Figure 19: Reconstructed  $W$  boson mass from a jet pair for the  $m = 800$  GeV resonance.

$W$  and  $Z$  bosons:  $p_T^{W,Z} > 250$  GeV and  $|\eta^{W,Z}| < 2.0$ .

After a forward jet selection, (see Section 4.3,  $p_{T\text{cut}} = 20$  GeV,  $E_{\text{cut}} = E_{2\text{cut}} = 300$  GeV,  $\eta_{\text{cut}} = 1.5$ ,  $|\eta_{f\text{jet}}| > \eta_{\text{central jet}}$ ,  $\Delta\eta_{\text{cut}} = 4.5$ ), the invariant mass of these two jets is required to be greater than 700 GeV. Note that the efficiency of the forward jet cuts appearing in Table 7 appears artificially good for the background because a preselection was already applied.

A central jet veto was found to be unnecessary, as no  $t\bar{t}$  event survived the selection. Because of the lack of statistics for the  $t\bar{t}$  sample, it is not possible to exclude completely a contribution from this background. The normalisation factor is 4.9, meaning that  $t\bar{t}$  is excluded, over the whole mass range, at the level of 11.3 fb at 90% C.L. To have an estimate of the efficiency of the last two cuts at rejecting this background, the mass window for the cut on the  $Z$  boson mass was loosened:  $60 < m_Z < 120$  GeV, allowing 44 events (215 fb) to pass for the  $Z \rightarrow ee$  channel and 38 events (185 fb) for the  $Z \rightarrow \mu\mu$  channel. The  $W$  boson mass cut alone is found to have an efficiency of 12% and the forward jet cut alone lets no event survive. Assuming that the cuts are independent, the overall efficiency of the heavy jet mass cut and forward jet tagging combined is higher than 0.15%. The exclusion limit at 95% C.L. ( $1.64 \sigma$ ) for the  $t\bar{t}$  background is shown in Table 7 and it will be assumed that this is negligible in the mass window of

Figure 20: Reconstruction of ChL resonance at  $m = 1.1$  TeV (left) and  $m = 800$  GeV (right) in the channel  $qqW_jZ_{\ell\ell}$  (with  $\ell = e, \mu$ ), where a single jet cone 0.8 has been used to reconstruct the  $W$ .

the resonance. The Z+4 jets background was not included here because it may be double-counting with Z+3 jets with parton shower. In order to evaluate the level of this background, an average over the high mass region was taken because of the relatively poor Monte Carlo statistics, yielding about 0.03 fb/100 GeV.

For the  $m = 1.1$  TeV case, it was found that the trigger efficiency, based on the OR of  $e60$ ,  $\mu20$  and  $j160$ , was 100% at the end of the selection.

Figure 20 shows the resonance mass resulting when the Z boson has been reconstructed from electrons or muons and the W boson from a single jet of size 0.8.

### 5.2.2 W boson from a jet pair

As above, after applying electron quality cuts, the lepton transverse momenta are required to satisfy  $p_T(e_1, \mu_1) > 50$  GeV and  $p_T(e_2, \mu_2) > 35$  GeV, and a  $Z_{e^+e^-}$  ( $Z_{\mu^+\mu^-}$ ) boson having a mass between 85 and 97 GeV (83 and 99 GeV) is then reconstructed. Considering all pairs of jets with  $p_T > 30$  GeV in the central region ( $|\eta| < 3.0$ ) not overlapping with the electron jets from the Z decay, the one yielding an invariant mass closest to the mass of a W boson will be the W boson candidate (see Fig. 19). The low efficiency of this cut can be explained in part by the fact that a good fraction of events are constituted of a single jet W boson. Forward and backward jet selection proceeds as in 5.2.1. A central jet veto is also applied: we exclude events with an extra jet, having a  $p_T > 30$  GeV, not corresponding to the jets from the W boson or the forward and backward jets and we require the W and Z directions to be in the central region  $|\eta| < 2$ . Figure 21 show the resulting reconstructed resonance masses. Table 7 summarizes the cut flow for this analysis. Here, by using the technique of widening the Z boson mass window as in Sect. 5.2.1, it is estimated that the  $t\bar{t}$  background could be approximately 0.13 fb and it will be assumed that this is negligible in the mass window of the resonance.

### 5.2.3 Comparison to $k_\perp$ analysis

This channel was also studied with the analysis techniques described in Section 5.1, with the  $k_\perp$  algorithm but using the leptonic Z boson identification (Section 4.2.2) instead of the leptonic W boson identification (Section 4.2.3). The hadronically-decaying W boson is reconstructed dynamically from one or two jets (Section 4.1).

The signal mass distributions for fast and full simulation are shown in Fig. 22. The final mass distributions are shown in Fig. 23, and are comparable to the results from the cone algorithm method for

	$m = 1.1 \text{ TeV}$		$m = 800 \text{ GeV}$		$m = 500 \text{ GeV}$		$Z + 3j$		$Z + 4j$		$t\bar{t}$

the 1.1 TeV case which is not sensitive to the cut on the  $p_T$  of the VB's of 200 GeV.

### 5.3 $W^\pm Z \rightarrow \ell^\pm \nu \ell^+ \ell^-$

This purely leptonic channel consists of four different signatures:  $W_{\ell^\pm \nu} Z_{\ell^+ \ell^-}$  with  $\ell = e, \mu$ . The main background will be  $WZjj$  production from the Standard Model. The analysis starts by identifying leptonic  $Z_{e^+e^-}$  ( $Z_{\mu^+\mu^-}$ ) bosons as described in Section 4.2.2, after requiring two leptons with  $p_T$  greater than 50 and 35 GeV.

As a second step, we proceed to reconstruct the  $W$  boson from the highest  $p_T$  lepton among those remaining in the event, if there is one, and the measured missing transverse energy, as described in Section 4.2.3. The solution which yields the highest  $p_T$   $W$  boson is kept.

The forward and backward jet selection follows the prescription of the Section 4.3 ( $p_{T\text{cut}} = 20$  GeV,  $E_{\text{cut}} = E_{2\text{cut}} = 300$  GeV,  $\eta_{\text{cut}} = 1.5$ ,  $|\eta_{fjet}| > \eta_{\text{central jet}}$ ,  $\Delta\eta_{\text{cut}} = 4.5$ ).

In Table 8 we present the cut flow of the reconstruction of the resonances for 1.1 TeV and 500 GeV. Also in Fig. 24 and Fig. 25 we present the reconstructed resonance and the background  $WZjj$  for the same resonance mass.

### 5.4 $ZZ \rightarrow \nu\nu \ell^+ \ell^-$

This scalar resonance can be interpreted as a Standard Model Higgs boson produced by vector boson fusion. At leading order, the cross section times branching ratio would be 6 fb, compared to 4 fb obtained for the ChL model. This signal is characterised by a leptonic  $Z$  boson accompanied by large  $\cancel{E}_T$ , yielding a large transverse mass. The backgrounds considered are:  $ZZjj \rightarrow \ell\ell\nu\nu jj$  and  $WZjj \rightarrow \ell\nu\ell\ell jj$ . Other

Figure 22: WZ invariant mass spectrum in the  $\ell^+\ell^-j(j)$  channel for the three resonant signal samples obtained using  $k_\perp$  algorithm approach. Dotted lines indicate the fast simulation results.

	$Z_{VV}Z_{\ell\ell}qq$ ( $m = 500\text{GeV}$ )		$W_{\ell V}Z_{\ell\ell}jj$ (SM)		$Z_{VV}Z_{\ell\ell}jj$ (SM)	
	$\sigma$ (fb)	eff.	$\sigma$ (fb)	eff.	$\sigma$ (fb)	eff.
$Z_{ee}$	0.72	17.6%	20.78	22%	9.1	20%
$Z_{\mu\mu}$	0.58	15%	16.7	17%	6.6	15%
Forward jet tagging	0.58	45%	3.2	8.6%	0.47	3%
$\cancel{E}_T > 150$ GeV	0.44	75%	0.46	14%	0.12	26%

Table 9: Cut flow for the  $Z_{VV}Z_{\ell\ell}qq$  ( $m = 500$  GeV) signal. All the cuts are described in detail in this section.

background can result from Z+jets production, where the tail of the missing transverse energy distribution can fake a signal.

After selecting the leptonically decaying  $Z_{e^+e^-}$  ( $Z_{\mu^+\mu^-}$ ) boson as usual, with mass between 85 and 97 GeV (83 and 99 GeV), a minimum  $\cancel{E}_T$  of 150 GeV is required. For this high value of  $\cancel{E}_T$ , Z+jets background is expected to be negligible for a Standard Model Higgs boson signal [39]. The forward jet selection is applied (see Section 4.3,  $p_{T\text{cut}} = 20$  GeV,  $E_{\text{cut}} = E_{2\text{cut}} = 300$  GeV,  $\eta_{\text{cut}} = 1.5$ ,  $\Delta\eta_{\text{cut}} = 4.5$ ).

The transverse mass, defined as:

$$m_T^2 = (\sqrt{p_T(Z)^2 + m_Z^2} + \cancel{E}_T)^2 - (\vec{p}_T(Z) + \vec{\cancel{p}}_T)^2 \quad (1)$$

is shown in Fig. 26 and the cut flow can be found in Table 9.

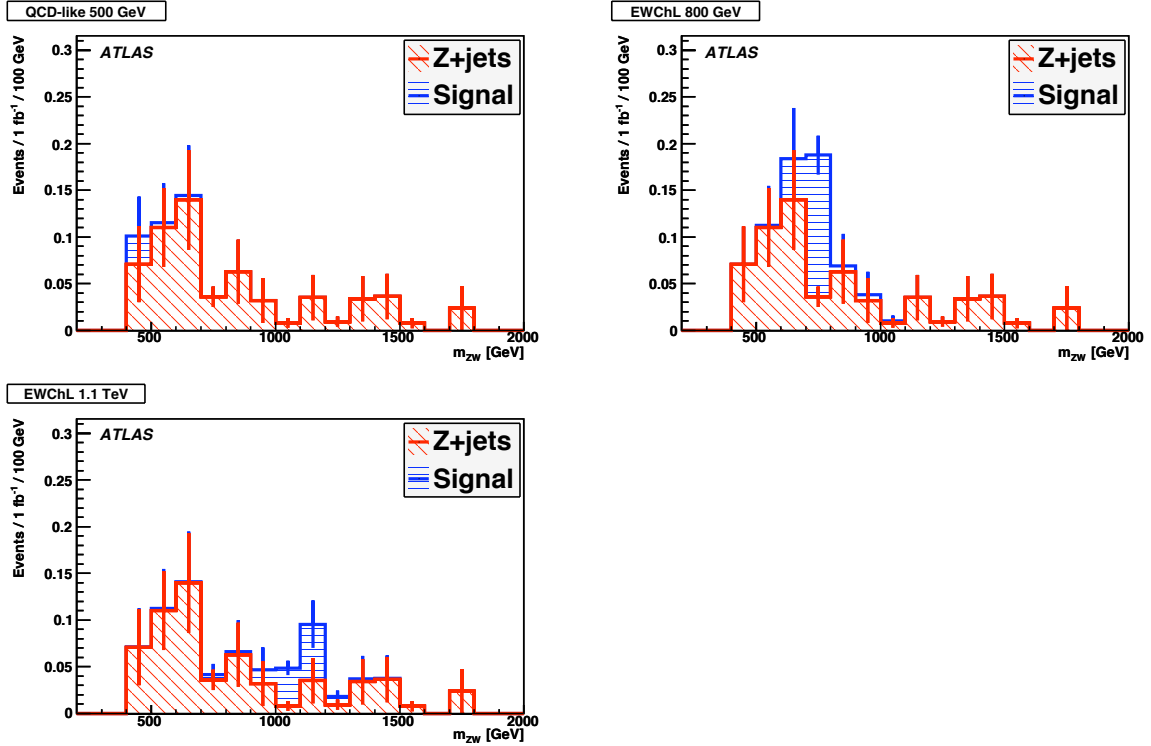

Figure 23: WZ invariant mass spectrum in the  $\ell^+\ell^-j(j)$  channel for the three resonant signal samples obtained using  $k_\perp$  algorithm approach. Z+jet histogram (in red) represents a direct sum of all Z+3 or 4 jets backgrounds with no matching, and hence is a conservative estimate. The background from  $t\bar{t}$  events has been found to be negligible.

Figure 24: Full reconstruction of ChL resonance  $m \sim 1.1$  TeV ( $W_{\ell^\pm\nu}Z_{\ell^\pm\ell^\mp}$ ).

Figure 25: Full reconstruction of QCD-like resonance  $m \sim 500$  GeV ( $W_{\ell^\pm\nu}Z_{\ell^\pm\ell^\mp}$ ).

 Figure 26: Transverse mass of the  $m = 500$  GeV resonance  $Z_{vv}Z_{\ell\ell}$ .

## 6 Results

The significance of the signals and the luminosity required for a possible discovery is estimated here. From the reconstructed resonance mass distributions in Section 5 one can evaluate the size of the signal and background in the resonance mass window. Table 10 summarises the approximate cross sections expected after the analyses described above. The table also gives the luminosity required to observe a significant excess over the background, showing the uncertainty from MC statistics only, and the significance of a signal for an integrated luminosity of  $100 \text{ fb}^{-1}$ . Because of the large statistical and systematic uncertainties (see Section 7), the numbers given here must be taken as an only an approximate indication of the reach of the LHC for such resonances.

The significance is calculated as

$$\text{significance} = \sqrt{2((S+B)\ln(1+S/B) - S)} \quad , \quad (2)$$

where  $S$  ( $B$ ) is the number of expected signal (background) events in the signal *peak* region, which is defined as the three consecutive bins (of size given in the figures, chosen to represent the resolution), with the highest total number of signal events. The background is averaged over this region.

In the  $WW$  case, only the semileptonic channel is accessible. Thus, as shown in Table 10, around  $25 \text{ fb}^{-1}$  is needed to start seeing indications of a resonance even in the most optimistic case studied here, and around  $70 \text{ fb}^{-1}$  is needed for a discovery.

In the continuum case, the “signal” is spread over an extended mass region with a total of about 0.3 events expected for each  $\text{fb}^{-1}$  in the mass range  $m = 400\text{--}1900$  GeV, compared to about 2.5 background events. Measuring this cross-section with any accuracy using the techniques developed here would require an integrated luminosity of several hundred  $\text{fb}^{-1}$ .

Since the mass windows for hadronic  $W$  and  $Z$  boson decays overlap, in practice these scenarios can probably not be distinguished in this channel, and a combined analysis would in reality have to be performed, which would then be compared to those channels containing a leptonic  $Z$  boson decay.

For each of the  $WZ$  resonances, results of the different channels,  $W_{\ell v}Z_{\ell\ell}$ ,  $W_{jj}Z_{\ell\ell}$  and  $W_{\ell v}Z_{jj}$  can, in principle, be combined. From Table 10, one can conclude that for two of three mass regions,  $m =$

Process	Cross section (fb)		Luminosity (fb <sup>-1</sup> )		Significance for 100 fb <sup>-1</sup>
	signal	background	for 3 $\sigma$	for 5 $\sigma$	
$WW/WZ \rightarrow \ell\nu jj$ , $m = 500$ GeV	$0.31 \pm 0.05$	$0.79 \pm 0.26$	85	235	$3.3 \pm 0.7$
$WW/WZ \rightarrow \ell\nu jj$ , $m = 800$ GeV	$0.65 \pm 0.04$	$0.87 \pm 0.28$	20	60	$6.3 \pm 0.9$
$WW/WZ \rightarrow \ell\nu jj$ , $m = 1.1$ TeV	$0.24 \pm 0.03$	$0.46 \pm 0.25$	85	230	$3.3 \pm 0.8$
$W_{jj}Z_{\ell\ell}$ , $m = 500$ GeV	$0.28 \pm 0.04$	$0.20 \pm 0.18$	30	90	$5.3 \pm 1.9$
$W_{\ell\nu}Z_{\ell\ell}$ , $m = 500$ GeV	$0.40 \pm 0.03$	$0.25 \pm 0.03$	20	55	$6.6 \pm 0.5$
$W_{jj}Z_{\ell\ell}$ , $m = 800$ GeV	$0.24 \pm 0.02$	$0.30 \pm 0.22$	60	160	$3.9 \pm 1.2$
$W_{jZ_{\ell\ell}}$ , $m = 800$ GeV	$0.27 \pm 0.02 \pm 0.05$	$0.23 \pm 0.07 \pm 0.05$	38	105	$4.9 \pm 1.1$
$W_{jZ_{\ell\ell}}$ , $m = 1.1$ TeV	$0.19 \pm 0.01 \pm 0.04$	$0.22 \pm 0.07 \pm 0.05$	68	191	$3.6 \pm 1.0$
$W_{\ell\nu}Z_{\ell\ell}$ , $m = 1.1$ TeV	$0.070 \pm 0.004$	$0.020 \pm 0.009$	70	200	$3.6 \pm 0.5$
$Z_{\nu\nu}Z_{\ell\ell}$ , $m = 500$ GeV	$0.32 \pm 0.02$	$0.15 \pm 0.03$	20	60	$6.6 \pm 0.6$

Table 10: Approximate signal and background cross sections expected after the analyses. An approximate value of the luminosity required for 3 $\sigma$  and 5 $\sigma$  significance, and the expected significance for 100 fb<sup>-1</sup> are shown. The uncertainties, when given, are due to Monte Carlo statistics only.

500 GeV and 800 GeV, a chiral Lagrangian vector resonance can be discovered with less than 100 fb<sup>-1</sup>. The expectations with the alternative  $k_{\perp}$  analysis described in Section 5.2.3 are not far from the values in Table 10. As an example, the integrated luminosity needed for 3 $\sigma$  observation of the  $m = 800$  GeV signal is 63 fb<sup>-1</sup>, and of the  $m = 1.1$  TeV signal is 81 fb<sup>-1</sup>.

A scalar resonance at  $m = 500$  GeV will require about 60 fb<sup>-1</sup> to be seen in the  $ZZ \rightarrow \nu\nu\ell\ell$  channel.

## 7 Systematic Uncertainties

A number of large systematic uncertainties affect the signals studied here. Because of the small cross sections and the important backgrounds, it is difficult to estimate them with precision from Monte Carlo simulations. Data driven tests will be required to understand better the systematic effects. Some discussion of the most significant effects is given here.

### 7.1 Background Cross sections

As was discussed in Section 2, the renormalisation and factorisation scales,  $Q^2$ , can affect the cross section by as much as a factor of two. This is especially true at high centre of mass energies, where the degree of virtuality of partons and choice of scale for  $\alpha_s$  are quite critical [28, 29]. At present this represents a theoretical uncertainty on the current sensitivity estimate. While the predictions may improve in future, in an eventual analysis, the backgrounds would have to be measured from data and the eventual size of the associated systematic uncertainty has not been studied here.

Another consideration is that for the analyses which dynamically move between the dijet and single jet reconstruction technique for the hadronically decaying vector boson (see Section 4.1), to evaluate the background with the samples available both  $W+3$  jet and  $W+4$  jet samples must be used. This implies some double-counting due to the lack of parton-shower matching in these samples, and so the background will be overestimated. This is in addition to the fact that as shown in Section 2.4.1, the MADGRAPH samples used overestimate slightly the energy of the tag jets. The effect is expected to be at the few per cent level.

## 7.2 Signal Cross sections

The PYTHIA signal generation produces softer tag jets than the more exact WHIZARD MC, and thus the signal efficiencies are likely to be underestimated.

## 7.3 Monte Carlo Statistics

We are limited by the very large size of the background samples required. Fast MC simulation was shown to be in good agreement with full simulation and was used to evaluate  $t\bar{t}$  background for the  $WW$  signals. In some cases, only upper limits on the backgrounds can be given, although it is expected that these limits are very conservative. Again, this represents a systematic uncertainty on the current sensitivity estimates, but will not be present in a final data analysis, assuming sufficient simulated data will eventually be available.

## 7.4 Pile-up and Underlying Event

Pile-up and underlying event are separate effects which have potentially similar and crucial impact on the efficiency of the forward jet cuts, the central jet veto and the top veto, as well as on the jet mass resolution.

Of particular concern is the fact that the top veto in the  $WW$  analysis uses jets down to  $p_T = 10$  GeV, expected to be strongly affected by these effects [40]. Simply raising the cut to 20 GeV admits significantly larger background. Some of this can be removed for the higher mass resonances by raising the  $p_T$  cut on the vector boson. However, a more promising approach is likely to be to exploit  $b$ -tagging and improved jet mass reconstruction to improve the veto.

### 7.4.1 Pile-up

Fully simulated samples with pile-up at low luminosity ( $10^{33} \text{ cm}^{-2} \text{ s}^{-1}$ ) were available, but with much lower statistics: we restricted the analysis to one signal sample and one background sample. However pile-up effects should be approximately independent of the underlying physics sample, and we assume we can safely generalise the results obtained here.

We compared the same events of the  $W_{jj}Z_{\ell\ell}$  at  $m = 1.1$  TeV sample reconstructed with and without pile-up simulation. This allows computation of the fraction of events with pile-up having tagged forward jets with respect to corresponding non-pile-up events which fail the tagged jet criterion, thus defining a ‘fake’ rate. The reciprocal fraction defines a ‘miss’ rate. The effect of pile-up increases with increasing jet radius and decreasing energy threshold, as would be expected. We found that both ‘fake’ and ‘miss’ effects are essentially due to the degradation of energy resolution in presence of pile-up and that their combination contributes to an uncertainty on the efficiency of the order of 5%.

### 7.4.2 Underlying Event

Current simulations use underlying event models tuned to Tevatron and other data [22], but there is a large extrapolation needed to 14 TeV. The underlying event would have to be measured in LHC data, and its level is not currently known.

## 7.5 Other Systematic Effects

Systematic effects, such as uncertainties in the luminosity, in efficiencies and resolutions, jet energy scale, etc. are of the order of a few percent and will therefore be completely dominated by the above effects and by statistical uncertainties.

## 8 Summary and Conclusion

The Chiral Lagrangian model with Padé unitarisation provides a framework for studying vector boson scattering at high mass, in case a light Higgs boson is not found at the LHC in the first years of running. With full detector simulation, the search for vector and scalar resonances of masses  $m = 500, 800$  and  $1100$  GeV is studied. To suppress the very high backgrounds from  $W$ +jets and  $Z$ +jets to acceptable levels requires special techniques investigated here. In particular, at these high masses, hadronic vector boson decay results in a single jet. The reconstruction of the jet mass is found to be generally quite efficient at rejecting QCD jets. The  $k_{\perp}$  and the cone algorithms can be applied to this heavy jet to resolve it into two light jets, suppressing further the background. Other conventional techniques for the study of vector boson fusion are also found essential for the present analysis: forward jet tagging, central jet veto and top-jet veto.

The cut-based analysis presented here is performed with realistic simulation and reconstruction of leptons and jets. Improvements can be expected by more sophisticated analysis and, with real data and a good understanding of the detector, further gains can be achieved by improvements in the reconstruction efficiencies.

The discovery of resonances in vector boson scattering at high mass will take a few tens of  $\text{fb}^{-1}$ , but the different decay channels of the vector boson pairs allow a cross-check of the presence of a resonance. These results can be considered generic of vector boson scattering and can therefore be interpreted in terms of other theoretical models with possibly different cross-sections.

# Discovery Reach for Black Hole Production

## Abstract

Models with extra space dimensions, in which our Universe exists on a 4-dimensional brane embedded in a higher dimensional bulk space-time, offer a new way to address outstanding problems in and beyond the Standard Model. In such models the Planck scale in the bulk can be of the order of the electroweak symmetry breaking scale. This allows the coupling strength of gravity to increase to a size similar to the other interactions, opening the way to the unification of gravity and the gauge interactions. The increased strength of gravity in the bulk space-time means that quantum gravity effects would be observable in the TeV energy range reachable by the LHC. The most spectacular phenomenon would be the production of black holes, which would decay semi-classically by Hawking radiation emitting high energy particles. In this note, we discuss the potential for the ATLAS experiment to discover such black holes in the early data ( $1\text{--}1000\text{ pb}^{-1}$ )

## 1 Introduction

In this study we simulate the search for black holes in the first  $100\text{ pb}^{-1}$  of LHC data with the ATLAS detector and software framework.

The document's structure is as follows: Section 2 gives an overview of the extra dimension models, present limits on the size of the extra dimensions and a discussion of black hole production and decay. In Section 3 the Monte Carlo simulation samples are described. Section 4 presents basic event properties, and is followed by Sections 5 and 6 dealing with the triggering and analysis selection, respectively. The expected systematic uncertainties are given in Section 7. Finally, the extraction of model parameters, especially of black hole properties, is covered in Section 8. A summary is given in Section 9.

## 2 Theory

### 2.1 Theoretical Motivation

The electroweak energy scale and the Planck scale, at which gravitational interactions become strong, differ by about sixteen orders of magnitude. This large difference between the scales of the two fundamental interactions is known as the hierarchy problem. Explaining the hierarchy problem is one of the outstanding challenges in particle physics.

Arkani-Hamed, Dimopoulos and Dvali (ADD) [1–3], and Randall and Sundrum (RS) [4, 5] have pioneered approaches to solving the hierarchy problem by using extra-dimensional space. The hierarchy is generated by the geometry of the additional spatial dimensions. ADD models postulate additional flat extra dimensions, while RS models invoke a single warped extra dimension. The observed weakness of gravity is thus due to the gravitational field being allowed to expand into the higher-dimensional space (bulk), while the Standard Model particles are confined to our familiar three-dimensional space (3-brane). Extra-dimensional models can also be motivated by string theory.

In extra-dimensional models, the  $D$ -dimensional Planck scale  $M_D$  is the fundamental scale from which the Planck scale  $M_{\text{Pl}} = 1.22 \times 10^{19}\text{ GeV}$  in four dimensions is derived<sup>1</sup>. The relationship between

---

<sup>1</sup>Several conventions exist for the  $D$ -dimensional Planck scale in the ADD model. We denote by  $M_D$  the parameter defined by Giudice, Rattazzi and Wells [6] and used by the PDG [7]:  $M_D^{D-2} = (2\pi)^{D-4}/(8\pi G_D)$ , where  $G_D$  is the  $D$ -dimensional Newton gravity constant. In an alternative convention given by Dimopoulos and Landsberg [8] the  $D$ -dimensional Planck scale

the two scales is determined by the volume of the extra dimensions in ADD models or by the warp factor in RS models. For large extra dimensions or a strongly warped extra dimension, the fundamental scale of gravity can be as low as the electroweak scale. If the Planck scale is low enough, black holes could be produced at the Large Hadron Collider (LHC) [9, 10]. Detecting them will not only test general relativity and probe extra dimensions, but would also teach us about quantum gravity.

## 2.2 Experimental Limits

Assuming that low-scale gravity is due to the existence of extra dimensions<sup>2</sup>, most experimental searches for unusual low-scale gravity effects have focused on detecting evidence for extra dimensions. Current experimental limits allow the fundamental scale of gravity to be as low as about 1 TeV. In testing the ADD models and deriving limits in these models, the compactification radius of all extra dimensions is assumed to be the same. ADD models have been tested at length scales comparable to the radius of the compactified (i.e. curled-up) dimensions  $R$ . Were the effective number of large extra dimensions to be  $n = D - 4$ , the inverse-square law would smoothly change from the  $1/r^2$  form for  $r \gg R$  to a  $1/r^{2+n}$  form for  $r \ll R$ . Searches have been performed and constraints on the Planck scale have been set by tabletop and particle accelerator experiments, astrophysical observations, cosmic-ray measurements and cosmological considerations. Direct searches for black holes at collider experiments have not yet been performed. The only direct limits on black hole production in high energy interactions were obtained using cosmic-ray data. Table top experiments lead to an upper bound of  $R \leq 44 \mu\text{m}$ , at the 95% confidence level [12]. The LEP bounds obtained with direct searches vary from 1.5 TeV for  $n = 2$  extra dimensions to 0.75 TeV for 5 extra dimensions [13]. The latest direct search result from the CDF collaboration has set lower bounds with  $1.1 \text{ fb}^{-1}$  of Run II data on  $M_D$  of 1.33 TeV for  $n = 2$  to 0.88 TeV for  $n = 6$  [14]. All four LEP experiments combined set a lower limit on  $M_D$  of 1.2 TeV for positive interference, or 1.1 TeV for negative interference between Standard Model diagrams and graviton exchange [15, 16]. Indirect searches by the DØ [17] collaboration set lower limits around  $1.28 \text{ TeV}^3$ . Astrophysics places the most stringent lower limits on  $M_D$  in ADD models which however fall sharply with increasing number of extra dimension [18–24]. Considerations of neutron star dynamics imposes the strongest constraints:  $M_D > 1760, 77, 9$  and  $2 \text{ TeV}$  for  $n = 2, 3, 4$  and  $5$  extra dimensions, respectively [18]. One should note that all astrophysical and cosmological constraints are based on a number of assumptions, whose uncertainties are not included in the limit derivations, so the results are reliable only as order of magnitude estimates. Ultra high-energy cosmic-ray particles, through their interaction with the Earth’s atmosphere, offer a complementary probe of extra dimensions. Cosmic-rays interact with the atmosphere and earth’s crust with centre-of-mass energies of the order of 100 TeV. The particles can produce black holes deep in the atmosphere, leading to quasi-horizontal giant air showers. So far a lower bound on  $M_D$  in the ADD model, ranging from 1.0 to 1.4 TeV for scenarios with 4 to 7 extra dimensions has been set at 95% confidence level [25]. It is expected that the Pierre Auger Observatory will be able to set more stringent limits during the first five years of operation; the estimates place  $M_D \gtrsim 3 \text{ TeV}$  for  $n \geq 4$  [26].

## 2.3 Working Model

Our working model for black holes uses the black disk cross-section, which depends only on the horizon radius. The  $(4 + n)$ -dimensional Myers-Perry solution [27], similar to the 4-dimensional Schwarzschild radius, is chosen for the horizon radius  $r_h$ . It depends only on the number of dimensions and the Planck

---

$M_{\text{DL}}$  is defined via  $M_{\text{DL}}^{D-2} = 1/G_D$ .

<sup>2</sup>See Ref. [11] for a model of TeV gravity in four dimensions.

<sup>3</sup>This lower limit uses the Hewett approach for the calculation of  $M_D$  and implies a positive interference term  $\lambda$  with the Standard Model diagrams.

scale. The classical black hole cross-section at the parton level is

$$\hat{\sigma}_{ab \rightarrow \text{BH}} = \pi r_{\text{h}}^2, \quad (1)$$

where  $a$  and  $b$  are the parton types. In most cases, we work with initial black hole masses at least five times higher than the Planck scale at which the expression for the cross section should be valid.

The total cross-section is obtained by convoluting the parton-level cross-section with the parton distribution functions (PDFs), integrating over the phase space, and summing over the parton types.

Throughout this study we use the CTEQ6L1 (leading order with leading order  $\alpha_s$ ) parton distribution functions [28] within the LHAPDF framework [29]. The momentum scale for the PDFs is set equal to the black hole mass for convenience.

The transition from the parton-level to the hadron-level cross-section is based on a factorisation ansatz. The validity of this formula for the energy region above the Planck scale is unclear. Even if factorisation is valid, the extrapolation of the parton distribution functions into this transplanckian region based on Standard Model evolution from present energies is questionable, since the evolution equations neglect gravity and possible KK states in the proton.

The details of horizon formation, and the balding and spin-down phases have been ignored<sup>4</sup>. The important effects of angular momentum in the production and decay of the black hole in extra dimensions are not accounted for in the Monte Carlo event generator. The black holes are considered as  $D$ -dimensional Schwarzschild solutions. Only the Hawking evaporation phase is generated by the simulation.

We can view the Hawking evaporation phase as consisting of two parts: determination of the particle species and assigning energy to the decay products. A particle species is selected randomly with a probability determined by its number of degrees of freedom and the ratio of emissivities<sup>5</sup>. The degrees of freedom take into account polarisation, charge and colour. The emitted charge is chosen such that the magnitude of the black hole charge decreases. All Standard Model particles are considered, including a Higgs boson<sup>6</sup>. The particles are treated as massless, including the gauge bosons and heavy quarks.

Gravitons have not been included in the simulation, which is another drawback of the current model. Because the graviton lives in the bulk, the number of degrees of freedom of the graviton becomes significant for high numbers of dimensions. In addition, the graviton emissivity is highly enhanced as the space-time dimensionality increases. Therefore the black hole may lose a significant fraction of its mass into the bulk, resulting in missing transverse energy.

The energy assignment to the decay particles in the Hawking evaporation phase has been implemented as follows. The particle species selected by the model described above is given an energy randomly according to its extra-dimensional decay spectrum. A different decay spectrum is used for scalars, fermions and vector bosons, i.e. the spin statistics factor is taken into account. Grey-body spectra are used without approximations [30]. The grey-body factors depend on the number of dimensions. The Hawking temperature is updated after each decay. It is assumed the decay is quasi-stationary in the sense that the black hole has time to come into equilibrium at each new temperature before the next particle is emitted. The energy of the particle given by the spectrum must be constrained to conserve energy and momentum at each step.

The evaporation phase ends when the chosen energy for the emitted particle is ruled out by the kinematics of a two-body decay. At this point an isotropic two-body phase-space decay is performed. In our simulation, the decay is performed totally to Standard Model particles and no stable exotic remnants survive.

<sup>4</sup>The main effects of these are to reduce the black hole production cross-section, possibly by as much as a few orders of magnitude. Work is underway to try to estimate the magnitude of this.

<sup>5</sup>Here emissivity is the fractional emission rate per degree of freedom. Mathematically it is ratio of  $dE/dt$  for different species, or roughly speaking the area under the black body distribution for a particular type of particle.

<sup>6</sup>Including a scalar Higgs boson is not significant since it has only one degree of freedom.

Name	Description	Value
MINMSS	Minimum mass of black holes	5 TeV
MAXMSS	Maximum mass of black holes	14 TeV
MPLNCK	Planck scale	1 TeV
MSSDEF	Convention for Planck scale	2
TOTDIM	Total number of dimensions	6
NBODY	Number of particles in remnant decay	2
GTSCA	Black hole mass used as PDF momentum scale	True
TIMVAR	Allow $T_H$ to change with time	True
MSSDEC	Use all Standard Model particles as decay products	True
GRYBDY	Include grey-body effects	True
KINCUT	Use a kinematic cut-off on the decay	True

Table 1: Default parameters used in the CHARYBDIS generator.

Baryon number, colour and electric charge are conserved in the black hole production and decay in this model. Missing transverse energy in the generator comes only from the neutrinos, while in reality missing transverse energy is also possible due to the lost energy in inelastic production, graviton emission, a non-detectable black hole remnant and the possibility that the black hole can leave the Standard Model brane. For the black holes we consider, only a small amount of energy, on average, is lost due to neutrinos. If gravitons were considered, the average energy loss would be approximately 9% [31].

### 3 Monte Carlo Simulations

#### 3.1 Production of Signal and Background Events

The event generator CHARYBDIS [32, 33] version 1.003 was used within the ATLAS software framework to generate Monte Carlo signal samples. It was interfaced via the Les Houches accord [29] to HERWIG [34, 35] which provides the parton evolution and hadronisation, as well as Standard Model particle decays.

Table 1 shows the default CHARYBDIS parameters used, for which approximately 25000 events were generated. Three other black hole signal samples were generated with variations in the number of dimensions and in the black hole minimum mass. In all simulations, the parameter MSSDEF was set equal to 2, setting the Planck scale MPLNCK to be the  $D$ -dimensional Planck scale  $M_{\text{DL}}$  in the convention of Ref. [8]. The above samples subsequently underwent the full ATLAS detector simulation and reconstruction. Fast simulation using ATLFast [36] was employed to widen the range of signal samples studied, enabling investigation of the many theoretical uncertainties modelled by generator parameter switches (see Table 2).

Black holes decay democratically to all particles of the Standard Model, so few Standard Model processes should produce the same particle spectrum. Black hole decays are characterised by a number of high energy and transverse momentum objects, so the primary Standard Model backgrounds are states with high multiplicity or high energy jets. The predominant backgrounds to our signal are described below and their datasets and cross-sections are listed in Table 3. Sizeable samples are required due to their large cross-sections at the LHC.

- $t\bar{t}$  leptonic and hadronic decay modes. This process yields the largest contribution to the background due to its large cross-section at the LHC and the large branching ratio to hadronic final

Table 2: Monte Carlo datasets and their respective cross-sections used in this analysis. The first four samples were simulated using both full and fast simulations; the lower nine samples were simulated using the fast simulation ATLFAST. The final column shows the CHARYBDIS parameter that was changed with respect to the reference set shown in Table 1.

states. The matrix element calculation is done with MC@NLO [37] and HERWIG is used to perform the parton shower evolution, parton decay and their hadronisation.

- QCD dijet production. The requirements placed on the hadronic part of the signal events reduces the contribution from low- $p_T$  QCD jets. This background is generated using PYTHIA 6.4 [38]. Note that the complete QCD inclusive jet production is not fully modelled by the PYTHIA dijet simulation due to the lack of higher-order QCD contributions. Very low-statistics samples of multijet samples generated by ALPGEN [39] were also used.
- $W \rightarrow \ell \nu + \text{jets}$  production. These backgrounds, though coming from the hard process, have cross-sections that rapidly become small compared to the signal as more jets are added. Vector boson plus jets samples were generated using ALPGEN.
- $Z \rightarrow \ell \ell + \text{jets}$  production.
- $\gamma(\gamma) + \text{jets}$  production.

### 3.2 Detector Simulation

The detector simulation and reconstruction of both signal and background Monte Carlo events were performed within the ATLAS offline framework.

Fast simulation (ATLFAST) was used to widen the range of signal samples studied. The primary advantage of this is one of processing rate: since no detector interactions are modelled it requires less than one second per event. In contrast, full simulation requires approximately 15 minutes for typical Standard Model events, and over 30 minutes per black hole event. Despite this advantage, there are drawbacks: the fast simulation does not include a complete treatment of lepton isolation and misidentification nor of photon conversion.

The same generator signal samples were passed through the full and fast simulations in order to understand the differences in black hole events. Variables ranging from simple multiplicities to event

Process	$\sigma$ (pb)
Semi/Fully Leptonic $t\bar{t}$	463
Hadronic $t\bar{t}$	370
QCD dijets	$12.84 \times 10^3$

$Z \rightarrow ee + \text{jets}$	25.8
$Z \rightarrow \mu\mu + \text{jets}$	26.0
$\gamma + \text{jets}$	$5.00 \times 10^3$
$\gamma\gamma + \text{jets}$	67.6

Table 3: Background Monte Carlo datasets and their respective branching ratio times cross-sections.

Figure 1: Total particle multiplicity and missing transverse energy distributions for signal samples from fast and full simulation.

shapes were compared. Sample distributions of particle multiplicity and  $\cancel{E}_T$  are shown in Figure 1. The multiplicity difference is due to differing default jet algorithms; we use a cone algorithm with radius  $\Delta R = 0.4$  in the full simulation, whereas ATLFast uses a  $k_\perp$  algorithm. Using the same algorithm for both samples gives very close agreement, nonetheless this discrepancy will have an effect in analyses dependent purely upon multiplicity information. All other variables investigated showed concordant results.

## 4 Event Properties

The high mass scale, and the thermal nature of the decay process, result in black hole events being characterised by a large number of high- $p_T$  final state particles, including all the Standard Model fields. Graviton emission is also expected, but is not simulated in CHARYBDIS. Of the final state particles, the detector can measure jets, electrons, muons and photons well, and will be able to reconstruct some of the  $Z$  and  $W$  bosons. The missing transverse energy, produced mainly by neutrino and graviton emission, can also be measured. In this section, the data sample with two extra dimensions and black hole masses above 5 TeV is used as the reference signal sample.

A key feature of black hole decays is that the Hawking temperature is higher for larger  $n$ , for a given black hole mass. A higher temperature produces higher energy emissions, with the consequence that the

Figure 2: PDG code of particles emitted from black hole decay for a minimum black hole mass of 5 TeV and  $n = 2, 4$  and 7 and for a minimum black hole mass of 8 TeV and  $n = 2$  ( $|Pdgid| = 1 - 6$  are quarks, 11 – 16 leptons, and 21 – 25 gauge and Higgs bosons). The vertical axis shows multiplicity per black hole decay.

energy is shared between fewer particles. This has a significant effect on the multiplicity and event shape distributions. Similarly, the samples with a higher black hole low-mass cutoff produce more high energy final state particles.

#### 4.1 Particle Types and Multiplicities

Figure 2 shows the types of particles produced directly by black hole decay. The vertical axis shows the average number of particles per black hole decay. From this figure, we see that a heavier black hole has more decay products. The particle-antiparticle balance is broken by the initial state of two protons colliding. Moreover, due to conservation of energy and momentum, colour connection etc., a perfect democratic decay cannot be achieved, e.g., the number of top quarks is smaller than that of lighter quarks. The possibility of identifying fermions and bosons and determining their branching ratios in black hole decays was studied in [40].

Figure 3 shows  $p_T$  and pseudorapidity ( $\eta$ ) distributions of particles produced directly from black hole decays. As expected, the shape depends little on particle type. Figure 4 shows the reconstructed multiplicity of final-state jets, leptons and photons. Four signal samples are shown for  $n = 2, 4$  and 7 with a minimum black hole mass of 5 TeV, and for  $n = 2$  with a minimum black hole mass of 8 TeV. The figure also compares the reference signal to the backgrounds. The multiplicity in the signal falls as  $n$  rises, because the black holes decay at a higher temperature.

#### 4.2 Event Shape

At first sight, one would expect black hole events to be very different from the background in event shape variables [38, 41, 42] such as sphericity, because of the high multiplicity thermal decay. However, the event shape of the black hole events varies considerably with  $n$ , making such variables less useful than could be hoped. Though the background distributions show less variation, when these are scaled by their large cross sections, there is a large degree of overlap, disfavouring their use as a cut variable. Additionally, our ignorance of the decay modes of the final black hole remnant introduces a significant

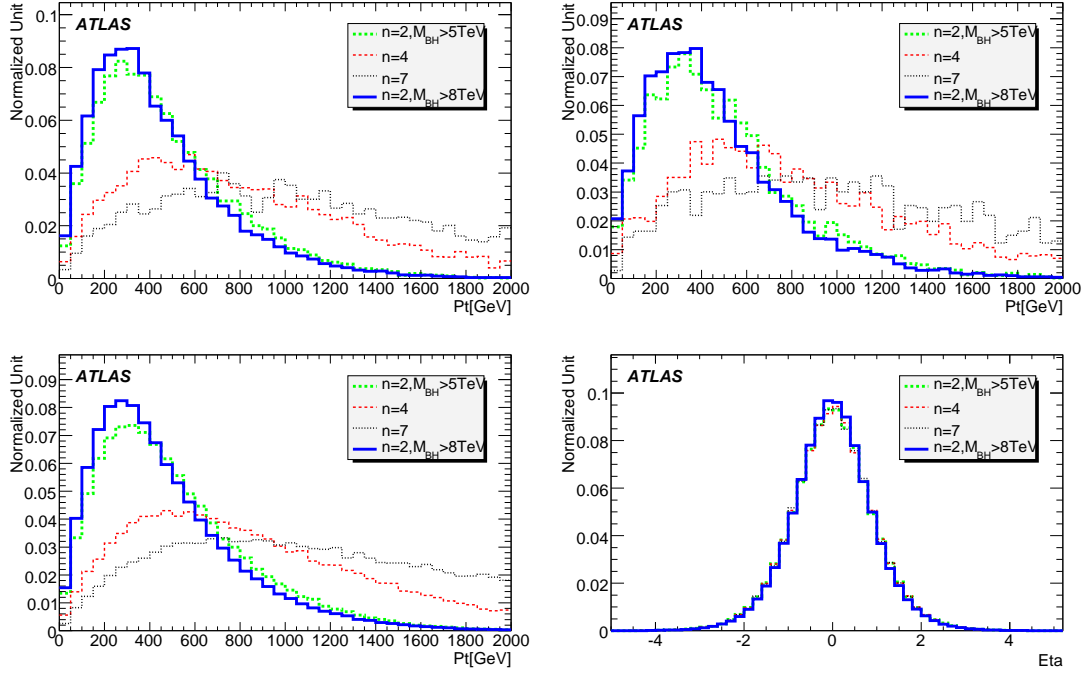

Figure 3: Generator  $p_T$  distributions (top row): leptons (left) and Z bosons (right) emitted from the black hole. The bottom row shows  $p_T$  and  $\eta$  spectra for all particles emitted from the black hole.

Figure 4: Multiplicities of reconstructed objects for (left) black hole samples and (right) backgrounds. They are normalised to the integrated luminosity of  $1 \text{ fb}^{-1}$ .

Figure 5: Circularity calculated from reconstructed objects for (left) black hole samples and (right) backgrounds.

Figure 6: Thrust calculated from reconstructed objects for (left) black hole samples and (right) QCD dijet and  $t\bar{t}$  backgrounds.

systematic effect. In our version of CHARYBDIS, once the mass of the black hole has dropped below the Planck scale, the remnant decays to either 2 or 4 bodies. We have selected the two-body option for our standard samples. This means that at high  $n$ , where events can reach this stage after few emissions, the circularity of the events is reduced, and the thrust increased.

The distinguishing power between signal and backgrounds of a selection of event shape variables was studied; Figure 5 shows the circularity distribution for the same samples as Figure 4; similarly Figs. 6 and 7 show their thrust distributions, sphericity and aplanarity. The expected bias towards more “jet-like” events is clearly seen at high  $n$ . For this reason, we choose not to use event shape variables as a discriminant in this analysis.

## 5 Trigger

The ATLAS trigger and data-acquisition system consists of three levels (L1, L2, EF) of online event selection [43]. Each subsequent trigger level refines the decisions made at the previous level and may apply additional selection criteria. The ATLAS trigger is described in detail in ref. [44].

(b) Thrust minor

(c) Sphericity

(d) Aplanarity

 Figure 7: Different event shape variables for black hole samples and backgrounds. They are normalised to the integrated luminosity of  $1 \text{ fb}^{-1}$ .

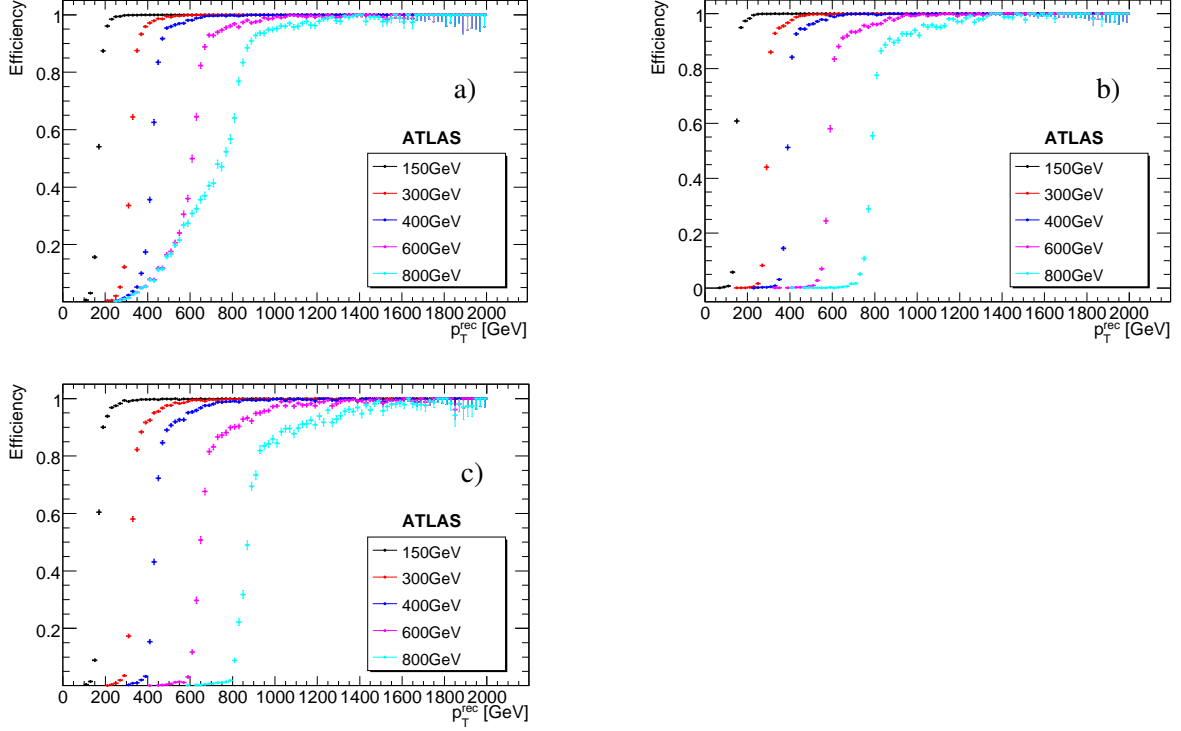

Figure 8: Simulated jet trigger efficiencies as functions of the offline reconstructed jet  $p_T$  for a) L1, b) L2 and c) EF. The efficiencies are determined for different  $p_T$ -thresholds: 150 GeV (black), 300 GeV (red), 400 GeV (blue), 600 GeV (magenta) and 800 GeV (cyan).

### 5.1 Triggering on Black Holes

Each black hole produces multiple decay products, including hadronic jets, leptons and photons, as described in Section 4. The jets typically carry a dominant fraction of the visible decay energy and hence provide the best option for triggering black hole events.

The response of the jet trigger, as simulated in the current version of the ATLAS detector simulation, is demonstrated in Figure 8. The plots show the trigger efficiencies for various  $p_T$ -thresholds as functions of the jet  $p_T$  reconstructed offline. For these plots, a match between the jet reconstructed offline and at the respective trigger level is required. The matching consists of searching for the closest offline jet in  $\Delta R = \sqrt{(\Delta\eta)^2 + (\Delta\phi)^2}$ , where  $\Delta\eta$  and  $\Delta\phi$  are the distances between the reconstructed jet and the trigger jet in pseudorapidity  $\eta$  and azimuth  $\phi$ , respectively. To avoid incorrect matching for L1 jets, a modified criterion is applied: the L1 jet closest in energy to the reconstructed jet is chosen among the jets found within the  $\Delta R = 0.5$  distance around the reconstructed jet. The shape of the L1 efficiency distribution for the 800 GeV threshold is due to the saturation of the L1 trigger tower energies at 255 GeV. Events in which the transverse energy in one trigger tower exceeds 255 GeV are automatically accepted, as larger values fill up the memory of the L1 trigger analog-to-digital converters.

The efficiency at each trigger level is determined independently of the decisions at the other levels. Were the trigger chain to have the same threshold on all levels, the total efficiency would be the convolution of the respective functions. The L2 algorithms are based on regions of interest provided by L1, hence it is not possible to determine their efficiency completely independently of the L1 decisions. The L2 algorithms were run on all L1 jet RoI starting from the lowest L1 jet  $p_T$  threshold of 35 GeV. This is much lower than the thresholds studied, making the L2 decision (shown in Figure 8b) virtually

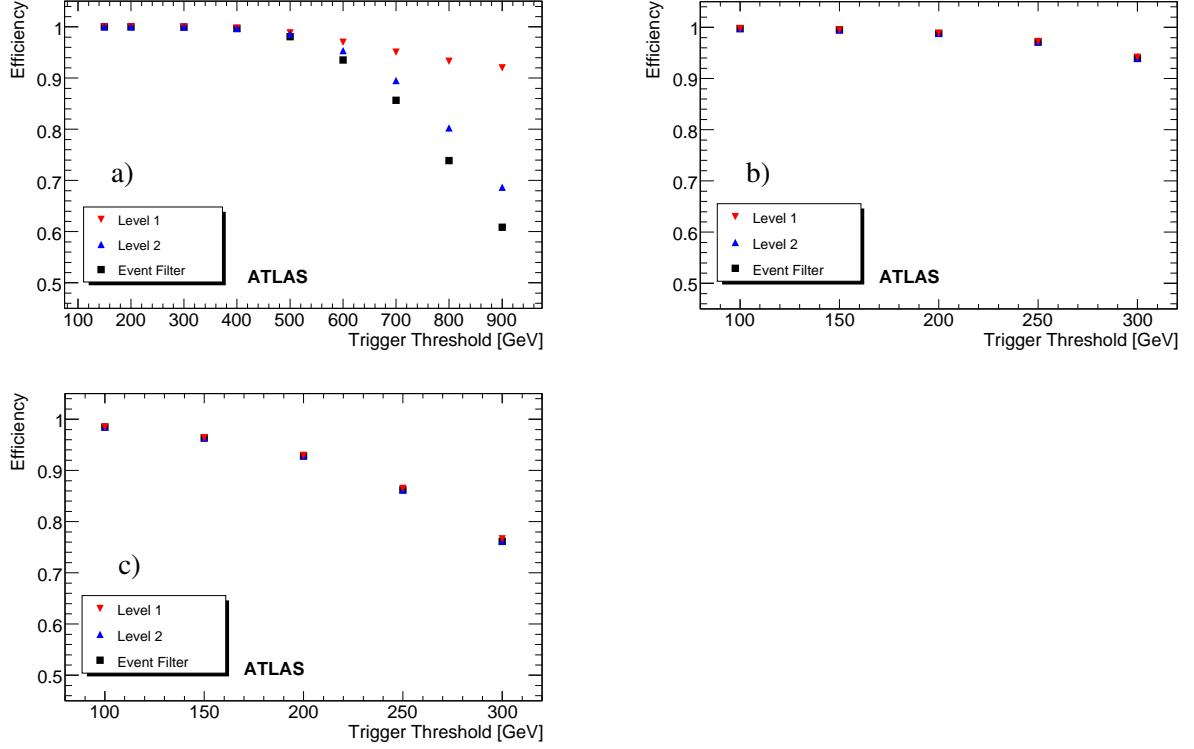

Figure 9: Simulated jet trigger efficiencies for black hole events from the signal sample with  $n = 2$  and  $m > 5$  TeV as functions of the jet  $p_T$  threshold for a) single-jet trigger, b) 3-jet trigger and c) 4-jet trigger. The efficiencies are determined for L1 (black), L2 (red) and EF (blue).

independent of the L1 efficiency.

The total trigger efficiencies are listed in Table 4 for three signal samples and demonstrated in Figure 9 for the signal sample with  $n = 2$  and  $m > 5$  TeV. The highest efficiency is provided by the single-jet trigger, which we consider to be the master trigger for the black hole events. The presence of multiple high- $p_T$  jets per event, each of which is likely to pass the trigger, results in very high total efficiencies. Setting this trigger threshold at 400 GeV will provide greater than 99% efficiency at all trigger levels. The Standard Model process rate at this threshold is expected to be less than 0.1 Hz at an instantaneous luminosity of  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ , which should allow this trigger to run at this threshold without prescaling for the first few years of LHC data taking. The rate of black hole events is expected to be less than 5 mHz at the  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  luminosity. For the start-up running at the luminosity of  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ , it is planned to set the highest threshold for the single-jet trigger at 120 GeV, guaranteeing an efficiency of almost 100% for black hole events.

Alternatively, a trigger based on the scalar sum of transverse energies of all recorded decay products (“sum- $E_T$  trigger”) can be used. No simulation of this trigger is available in the samples used in this study. Looking at this sum in the offline reconstruction suggests that this trigger would collect nearly 100% of black hole events for Planck scales above 1 TeV. It is foreseen to run this trigger in the start-up data taking, unprescaled at the threshold of 650 GeV.

Based on experience from previous collider experiments, one may expect detector hardware problems at the beginning of data taking. In particular, noisy channels in the calorimeter or trigger electronics may cause high trigger rates for the single-jet trigger and for the sum- $E_T$  trigger, such that even the highest threshold triggers have to be prescaled. In such cases, a multijet (3- or 4-jet) trigger is considered for use

 Table 4: Simulated jet trigger efficiencies for black hole events as functions of the jet- $p_T$  threshold for different simulation samples.

until the detector problems are resolved. The efficiencies of such triggers are listed in Table 4.

In the present study, the minimum mass of a black hole is set at 5 TeV or more in order to be safely above the Planck scale. At lower masses one may expect an increased rate of dijet events described by a contact interaction. The single-jet trigger or the sum- $E_T$  trigger at the thresholds considered above are well suited for detecting such signatures. Such events may not, however, be selected by multijet triggers.

The trigger efficiencies, studied here in the simulation, have to be determined from data. An unbiased determination requires an “orthogonal” trigger, e.g. a trigger based on fully independent information from that used by the master trigger. A muon trigger which is based solely on signals in the muon detector should be well suited for such studies.

## 6 Signal Selection and Background Rejection

### 6.1 Event Selection

Since all types of Standard Model particles are produced from black hole decay, we make full use of particle identification information (PID) from our detectors. First we select muons, electrons, photons and jets, which are called *objects* in this section. Table 5 shows the details of their selection criteria.

The identification of objects is sometimes ambiguous: e.g., an electron could be simultaneously reconstructed as a jet. To resolve this, we apply PID to each object, selecting muons, electrons, photons and jets in that order of priority. Once an object passes the PID criteria in a given category, any remaining ambiguous assignments are removed if they match the chosen object within a  $\Delta R$  of less than 0.1.

Next we select black hole events using these objects as described below. Then we reconstruct a black hole from all the identified objects for the selected event. The mass of the black hole in an event is calculated from the four-momenta of the reconstructed final state objects and missing  $E_T$ , which is

included in the calculation to improve the reconstructed mass resolution:

$$p_{\text{BH}} = \sum_{i=\text{objects}} p_i + (\cancel{E}_T, \cancel{E}_{Tx}, \cancel{E}_{Ty}, 0), \quad (2)$$

$$m_{\text{BH}} = \sqrt{p_{\text{BH}}^2}. \quad (3)$$

We present two methods to select black hole events. One is based on the scalar summation of  $p_T$  and the other on the multiplicity of high- $p_T$  objects. Both make use of the characteristic of a black hole having large mass. After that, we require a high- $p_T$  lepton to reject backgrounds further.

Figure 10 shows the scalar summation of the  $p_T$  of each object,  $\sum |p_T|$ , which demonstrates good background discrimination and high signal efficiency for all black hole samples. We require  $\sum |p_T|$  to be larger than 2.5 TeV to reject backgrounds. This requirement is relatively unaffected by changes in the model, in particular by changes to the number of extra dimensions  $n$ . Figure 11 shows  $m_{\text{BH}}$  distributions after this requirement. The QCD dijet background is already well suppressed, but we also investigated the effect of a further selection, requiring a lepton with a  $p_T > 50$  GeV. This resulted in the QCD dijet background being rejected by a factor greater than  $10^6$  as shown in Table 6, which summarises the event numbers for an integrated luminosity of  $1 \text{ fb}^{-1}$ . Though the high statistics QCD samples used were generated with PYTHIA, a leading order generator, there were also  $p_T$ -sliced small ALPGEN multijet samples available. When investigated using the  $\sum |p_T|$  and lepton cut method, a very similar, marginally lower number of background events was predicted according to the very limited statistics available. Larger scale studies would be needed to conclude anything more concrete. Poisson confidence limits are used for samples where fewer than 20 events passed the requirements. Signal cross-section errors are statistical only; the theoretical uncertainties are large as discussed in Section 2.<sup>7</sup>

An alternative selection procedure was also used. Figure 12 shows the  $p_T$  distributions of the leading, 2nd-, 3rd- and 4th-leading objects out of all the selected objects. The 4th-leading object still has larger  $p_T$  in the signal events than in the background events. We require the number of objects with  $p_T > 200$  GeV to be equal to or greater than four. Figure 14 (left) shows  $m_{\text{BH}}$  distributions after this requirement. Since QCD processes still remain large, a lepton requirement is again used to decrease it. Figure 13 shows the distribution of the highest  $p_T$  lepton (muon or electron). As expected, the number of leptons from QCD processes is small. Requiring the number of leptons (muons or electrons) with  $p_T > 200$  GeV to be equal to or greater than one results in the  $m_{\text{BH}}$  distributions shown in Figure 14(right).

The shape of the background in the region of high  $m_{\text{BH}}$  was fitted with a gaussian plus an asymmetric gaussian (Figure 15) and that function is used to estimate the number of background events.

CHARYBDIS does not include graviton emission. In practice this, and the energy lost in gravitational interactions during the balding phase, would be another source of  $\cancel{E}_T$ . Consequently we expect

<sup>7</sup>In the case of two hadronic subsamples ( $t\bar{t}$  and dijets) where very few events passed the  $\sum |p_T|$  requirement, the lepton requirement rejection factor was applied to the  $\sum |p_T|$  requirement's Poisson bound to estimate the background distribution error.

Table 7: Acceptance of the 4-object requirements for each dataset in fb. 90% confidence limits are used when no events passed the requirements.

Figure 15: The background shape after the 4-object and lepton requirements is shown (data points). The points were fitted by the sum (black line) of a gaussian (red line) and an asymmetric gaussian (green line).

CHARYBDIS to underestimate this for black hole events. Nonetheless, each of the black hole samples studied in this analysis often have very wide distributions of  $\cancel{E}_T$ , with tails extending out to several TeV. This property of models with black holes is most unusual and hard to reproduce in other new physics scenarios, and should make it possible to distinguish between Black Holes and the majority of SUSY models for example.

A requirement on  $\cancel{E}_T$  above  $\sim 500 - 600$  GeV was studied as an alternative to a lepton requirement for black hole signal selection. Figure 16 shows the potential of this method, and contrasts these models with three common supersymmetric models of different cross-section and mass scale. Despite the possibility of early evidence for the presence of black holes, there are disadvantages to relying on such a selection. Firstly, our ability to reconstruct the black hole’s mass is aided by limiting  $\cancel{E}_T$  to be under 100 GeV (Figure 22). Such a signal from high  $\cancel{E}_T$  events would be dominated by those events reconstructed most poorly, limiting their use for cross-section measurement and discovery. The theoretical uncertainties are large and difficult to quantify, and finally there are experimental difficulties in calibrating and accurately measuring this variable across a wide energy range.

## 6.2 Discovery Reach

Making a robust discovery potential for black hole events is difficult, because the semi classical assumptions used to model them are only valid well above the Planck scale. Close to the Planck scale, events may occur due to gravitational effects with lower multiplicities, but without the signatures anticipated by our event selections. As the energy rises above the threshold needed for black hole creation, our requirements should become more efficient. Lack of theoretical understanding makes it impossible to model this threshold region.

To account for this, we impose a lower requirement on the true mass of black holes created in our simulated samples,  $BH_{thresh}$ , normally set at 5 TeV, and we do not attempt to account for any additional signal from lower masses. In order to estimate the discovery potential, two methods have been consid-

Figure 16: The left hand plot shows the missing transverse energy distributions after a  $\sum |p_T| > 2.5$  TeV requirement. A requirement of  $\cancel{E}_T > 500$  GeV would leave negligible background and a large number of signal events for all samples. The right hand plot compares two black hole samples with three supersymmetric models with a range of mass scales; the two classes of models can easily be distinguished by their differing cross-sections and the extent of the  $\cancel{E}_T$  tail.

ered:

1. we keep our signal selection requirements constant, and increase the value of  $BH_{thresh}$ . Since the analysis requirements are unchanged, the background remains constant, while the signal drops as the production of events occurs at higher mass. We then evaluate the luminosity required to detect a minimum of 10 signal events, with  $S/\sqrt{B} > 5$ , assuming the production cross-section is as high as predicted. Such a study is shown in Figure 17, using the  $\sum |p_T|$  and lepton requirements. This method produces conservative limits, taking some account of the uncertainty in the production cross-section near the threshold.
2. We keep the production model unchanged with  $BH_{thresh} = 5$  TeV, but apply an additional requirement on the reconstructed black hole mass. This requirement reduces substantially background events, while allowing the higher mass signal to pass unchanged. This is less conservative, since it allows black hole signal events to be produced at low mass, but to migrate above the reconstructed mass requirement because of the detector mass resolution, hence increasing the signal. As before, we use the nominal value of the production cross-section, and evaluate the luminosity needed to meet our discovery criteria, this time as a function of reconstructed mass. A study using this method is shown in Figure 18 using the 4-object and lepton requirements.

The two approaches are complementary and illustrate the uncertainties in different ways. We observe that the search reach is limited eventually at high mass by the falling production cross-section, reflecting the falling parton luminosity and the limited energy of the LHC. We conclude that, if the semi classical cross-section estimates are valid, black holes can be discovered above a 5 TeV threshold with a few  $\text{pb}^{-1}$  of data, while  $1 \text{ fb}^{-1}$  would allow a discovery to be made even if the production threshold was at 8 TeV.

## 7 Systematic Uncertainties

### 7.1 Signal uncertainties

We have investigated the systematic uncertainties using fast simulation runs, having checked that the full and fast simulations agree well for this purpose.

Figure 17: Discovery potential using  $\sum |p_T|$  and lepton selections: required luminosity as a function of black hole mass threshold. Error bars reflect statistical uncertainties only.

Figure 18: Discovery potential for black holes using four-object and lepton requirements. The required luminosity is shown as a function of the requirement on the reconstructed black hole mass. The error bars correspond to experimental systematic uncertainties. (See text for constraints.)

There are a number of theoretical parameters associated with CHARYBDIS which can generate systematic errors in the estimates of the acceptance for signal events. These are:

- The kinematic cutoff. This parameter is normally true, and causes the generator to end thermal emission if an unphysical emission is randomly selected. The generator moves immediately to the final remnant decay phase. This approximation deteriorates at high numbers of extra dimensions because of the high temperature and emitted particle energies. We have investigated the alternative, where a new emission is selected until a physical one is chosen. In this case, thermal emission will continue until the black hole mass falls below  $M_{DL}$ .
- Temperature variation. The Hawking temperature of the black hole is normally allowed to increase as its mass decreases, as expected if the black hole has time to equilibrate between decays. We have investigated the alternative of keeping the temperature fixed at the initial value, as would be the case if the black hole decayed very quickly or “suddenly” (see Table 8).
- Number of extra dimensions. In addition to our full simulation samples with  $n = 2, 4$  and  $7$ , we have simulated  $n = 3$  and  $5$  with the fast simulation. As noted above, the events become more jet-like at high  $n$  and the particle multiplicity drops (see Figure 20), due to the increased Hawking temperature. Our signal selection remains robust, as shown in Table 8.
- Planck scale. We have investigated changing the Planck scale from its default value of  $M_{DL} = 1$  TeV to 2 TeV. We note that, since the model is only valid for black hole masses much larger than the Planck scale, this scenario is not well modelled in the range of masses accessible at the LHC.
- Remnant decay. We have investigated changing the remnant decay model from a two-body to a four-body mode (see Figure 20).

Figure 19 shows the effect of changing the kinematic cutoff on the particle multiplicity and  $\sum |p_T|$  distributions. Since the black hole is forced to decay thermally until it falls below  $M_{DL}$ , the multiplicity is higher, and the events have lower energy emissions. The total energy remains constant, however so the  $\sum |p_T|$  distribution is relatively stable.

Figure 19: Particle multiplicity and  $\sum |p_T|$  distributions, showing the variation when the kinematic cut-off parameter is changed.

The acceptance of the signal for various parameter choices are shown in Table 8. Compared to the standard full simulation, the largest effect is observed for high  $n$ , when the kinematic cut-off parameter is changed. This is as expected, since this parameter has a large effect on the evolution of the black hole during its decay. Similarly changing the remnant decay from 2 to 4 bodies has a large effect at high  $n$ ; the effect of this, and of changing number of extra dimensions is shown in Figure 20.

Figure 20: Particle multiplicity distributions, showing the variation produced by a change in the number of extra dimensions, or the number of particles produced by remnant decay.

$n$	Full Sim	Fast Sim	Kin. Cut off	$T_H$ -variation off	4-body remnant
2	45.8	42.9	47.2	48.7	47.9
3	-	33.2	-	-	-
4	27.4	26.6	-	-	-
5	-	21.7	-	-	-
7	16.1	15.9	29.2	16.6	27.4

Table 8: Signal acceptance (%) for different model assumptions.

## 7.2 Uncertainties on detector performance

Two kinds of systematic uncertainties on detector performance were studied. One is an uncertainty on lepton identification efficiency. To estimate this effect, we loosened and tightened particle identification selections, by changing the hadronic leakage for electrons and the isolation cut for muons. The changes in signal efficiencies are around 2%.

The effect of a 5% error in the jet energy scale (JES) was also considered. The effect of these uncertainties on the discovery potential is shown in Figure 18.

# 8 Results

## 8.1 Search Reach for Black Hole Production at the LHC

The studies presented show that the ATLAS detector is capable of discovering the production of black holes up to the kinematic limit of the LHC, assuming that the signal is correctly modelled. This conclusion is largely based on the predicted huge production cross-section, and the small background from QCD dijets at very high- $p_T$ , especially when the presence of a high energy lepton is required. However, both of these assumptions are suspect. The high production cross-section is subject to considerable discussion in the literature, as discussed in Section 2. Moreover, until the LHC has measured the QCD cross-section at 14 TeV, we cannot be certain of the tails of the QCD distributions. The Monte Carlo simulations of these tails are working at the limit of their validity, given the high energies and large multiplicities involved.

For these reasons, we prefer not to place too much weight on the detailed search reach limits. Instead, we confine ourselves to the statement that, with current understanding, the black hole signature

considered should be clearly visible if it exists.

## 8.2 Determination of Model Parameters

We have considered the possibility of extracting model parameters from the data, should a signal be observed. There are two key parameters: the Planck scale  $M_D$  (or  $M_{DL}$  depending on the convention) and the number of extra dimensions  $n$ . In Ref. [46, 47] a method was proposed to extract  $M_D$  from the cross-section data, which fixes the Planck scale (within the model assumptions), and from events with high energy emissions.

The Hawking temperature  $T_H$  of the black hole depends on  $n$ . If we detect events with emissions near  $m_{BH}/2$ , the energy of those emissions is a measure of the initial  $T_H$ . Hence, over the sample of black holes, the probability of such emissions is a measure of the characteristic temperature, and can be used to extract  $n$ . This method was first put forward in Ref. [46], and here is made compatible with the need for background rejection requirements. The requirements described in Section 6 are not appropriate: the lepton requirement biases the selected events in favour of final states with many particles, and hence against those events with a single high energy emission. A suitable requirement was found to be  $\sum |p_T| > 3.5$  TeV; this removes the background without biasing the signal events selected.

Figure 21 shows the probability of a hard emission for two samples, compared to the predictions. The method requires accurate mass resolution, and so an additional requirement on  $\cancel{E}_T < 100$  GeV is applied. The addition of this requirement lowers the efficiency noticeably, but does improve the black hole mass reconstruction; details of the resolution and efficiency can be found in Figure 22. The data are consistent with the expected value of  $n$ , but due to this reduction in signal efficiency, more data would be required to make a definitive measurement. It should be noted that this measurement requires the Planck scale to be known. If this cannot be determined from the production cross-section, it is likely that the threshold behaviour near the Planck scale would provide an indication of its value. At present, no theoretical model exists to allow us to make predictions in this region.

Figure 21: The probability of a hard emission near  $m_{BH}/2$  for  $n = 7$  and  $n = 4$ . The bands show the expected range for  $n = 7$  and  $n = 6$ , and for  $n = 5$  and  $n = 4$ , respectively, for a luminosity of approximately  $0.75 \text{ fb}^{-1}$ .

## 9 Summary

The search for black holes in the first  $100 \text{ pb}^{-1}$  of LHC data with the ATLAS detector and software framework was simulated.

		Normalisation	Mean (GeV)	Resolution (GeV)
Without $\cancel{E}_T$ requirement	Narrow	$1018 \pm 26$	$-217 \pm 5$	$276 \pm 9$
	Wide	$276 \pm 30$	$-148 \pm 9$	$722 \pm 13$
With $\cancel{E}_T$ requirement	Narrow	$318 \pm 12$	$-116 \pm 8$	$215 \pm 9$
	Wide	$108 \pm 7$	$118 \pm 18$	$635 \pm 16$

Figure 22: Black hole mass resolution distributions and their fits to double Gaussian functions, using a  $\sum |p_T|$  and lepton requirement ( $1 \text{ fb}^{-1}$ ). The upper curve is without a  $\cancel{E}_T$  cut. The lower curve has an additional requirement on  $\cancel{E}_T < 100 \text{ GeV}$ .

We summarised the current experimental limits on black hole production and studied, with the help of the black hole event generator CHARYBDIS and Standard Model Monte Carlo data sets, the basic event properties, trigger and selection efficiencies, theoretical and experimental uncertainties of black hole production at the LHC for a flat ADD extra dimension scenario with the Planck scale  $M_{\text{DL}} = 1 \text{ TeV}$ . We have explored the uncertainties inherent in the theoretical modelling and our understanding of the detector. We conclude that, if the semi-classical cross section estimates are valid, black holes above a 5 TeV threshold can be discovered with a few  $\text{pb}^{-1}$  of data, while  $1 \text{ fb}^{-1}$  would allow a discovery to be made even if the production threshold was 8 TeV.
