# **Expected Performance of the ATLAS Experiment**

## **Detector, Trigger and Physics**

### **The ATLAS Collaboration**

A detailed study is presented of the expected performance of the ATLAS detector. The reconstruction of tracks, leptons, photons, missing energy and jets is investigated, together with the performance of  $b$ -tagging and the trigger. The physics potential for a variety of interesting physics processes, within the Standard Model and beyond, is examined. The study comprises a series of notes based on simulations of the detector and physics processes, with particular emphasis given to the data expected from the first years of operation of the LHC at CERN.

Display of a high- $p_T$   $H \rightarrow ZZ^* \rightarrow ee\mu\mu$  decay ( $m_H = 130$  GeV), after full simulation and reconstruction in the ATLAS detector. The four leptons and the recoiling jet with  $E_T = 135$  GeV are clearly visible. Hits in the Inner Detector are shown in green for the four reconstructed leptons, both for the precision tracker (pixel and silicon micro-strip detectors) at the inner radii and for the transition radiation tracker at the outer radii. The other tracks reconstructed with  $p_T > 0.5$  GeV in the Inner Detector are shown in blue. The two electrons are depicted as reconstructed tracks in yellow and their energy deposits in each layer of the electromagnetic LAr calorimeter are shown in red. The two muons are shown as combined reconstructed tracks in orange, with the hit strips in the resistive-plate chambers and the hit drift tubes in the monitored drift-tube chambers visible as white lines in the barrel muon stations. The energy deposits from the muons in the barrel tile calorimeter can also be seen in purple.

# Acknowledgements

We are greatly indebted to all CERN's departments and to the LHC project for their immense efforts not only in building the LHC, but also for their direct contributions to the construction and installation of the ATLAS detector and its infrastructure. We acknowledge equally warmly all our technical colleagues in the collaborating Institutions without whom the ATLAS detector could not have been built. Furthermore we are grateful to all the funding agencies which supported generously the construction and the commissioning of the ATLAS detector and also provided the computing infrastructure.

The ATLAS detector design and construction has taken about fifteen years, and our thoughts are with all our colleagues who sadly could not see its final realisation.

We acknowledge the support of ANPCyT, Argentina; Yerevan Physics Institute, Armenia; ARC and DEST, Australia; Bundesministerium für Wissenschaft und Forschung, Austria; National Academy of Sciences of Azerbaijan; State Committee on Science & Technologies of the Republic of Belarus; CNPq and FINEP, Brazil; NSERC, NRC, and CFI, Canada; CERN; NSFC, China; Ministry of Education, Youth and Sports of the Czech Republic, Ministry of Industry and Trade of the Czech Republic, and Committee for Collaboration of the Czech Republic with CERN; Danish Natural Science Research Council; European Commission, through the ARTEMIS Research Training Network; IN2P3-CNRS and Dapnia-CEA, France; Georgian Academy of Sciences; BMBF, DESY, DFG and MPG, Germany; Ministry of Education and Religion, through the EPEAEK program PYTHAGORAS II and GSRT, Greece; ISF, MINERVA, GIF, DIP, and Benoziyo Center, Israel; INFN, Italy; MEXT, Japan; CNRST, Morocco; FOM and NWO, Netherlands; The Research Council of Norway; Ministry of Science and Higher Education, Poland; GRICES and FCT, Portugal; Ministry of Education and Research, Romania; Ministry of Education and Science of the Russian Federation, Russian Federal Agency of Science and Innovations, and Russian Federal Agency of Atomic Energy; JINR; Ministry of Science, Serbia; Department of International Science and Technology Cooperation, Ministry of Education of the Slovak Republic; Slovenian Research Agency, Ministry of Higher Education, Science and Technology, Slovenia; Ministerio de Educación y Ciencia, Spain; The Swedish Research Council, The Knut and Alice Wallenberg Foundation, Sweden; State Secretariat for Education and Science, Swiss National Science Foundation, and Cantons of Bern and Geneva, Switzerland; National Science Council, Taiwan; TAEK, Turkey; The Science and Technology Facilities Council, United Kingdom; DOE and NSF, United States of America.

# **Introduction**

## Preface

The Large Hadron Collider (LHC) at CERN promises a major step forward in the understanding of the fundamental nature of matter. The ATLAS experiment is a general-purpose detector for the LHC, whose design was guided by the need to accommodate the wide spectrum of possible physics signatures. The major remit of the ATLAS experiment is the exploration of the TeV mass scale where ground-breaking discoveries are expected. In the focus are the investigation of the electroweak symmetry breaking and linked to this the search for the Higgs boson as well as the search for Physics beyond the Standard Model.

In this report a detailed examination of the expected performance of the ATLAS detector is provided, with a major aim being to investigate the experimental sensitivity to a wide range of measurements and potential observations of new physical processes. An earlier summary of the expected capabilities of ATLAS was compiled in 1999 [1]. A survey of physics capabilities of the CMS detector was published in [2].

The design of the ATLAS detector has now been finalised, and its construction and installation have been completed [3]. An extensive test-beam programme was undertaken. Furthermore, the simulation and reconstruction software code and frameworks have been completely rewritten. Revisions incorporated reflect improved detector modelling as well as major technical changes to the software technology. Greatly improved understanding of calibration and alignment techniques, and their practical impact on performance, is now in place.

The studies reported here are based on full simulations of the ATLAS detector response. A variety of event generators were employed. The simulation and reconstruction of these large event samples thus provided an important operational test of the new ATLAS software system. In addition, the processing was distributed world-wide over the ATLAS Grid facilities and hence provided an important test of the ATLAS computing system – this is the origin of the expression “CSC studies” (“computing system commissioning”), which is occasionally referred to in these volumes.

The work reported does generally assume that the detector is fully operational, and in this sense represents an idealised detector: establishing the best performance of the ATLAS detector with LHC proton-proton collisions is a challenging task for the future. The results summarised here therefore represent the best estimate of ATLAS capabilities before real operational experience of the full detector with beam. Unless otherwise stated, simulations also do not include the effect of additional interactions in the same or other bunch-crossings, and the effect of neutron background is neglected. Thus simulations correspond to the low-luminosity performance of the ATLAS detector.

This report is broadly divided into two parts: firstly the performance for identification of physics objects is examined in detail, followed by a detailed assessment of the performance of the trigger system. This part is subdivided into chapters surveying the capabilities for charged particle tracking, each of electron/photon, muon and tau identification, jet and missing transverse energy reconstruction, b-tagging algorithms and performance, and finally the trigger system performance. In each chapter of the report, there is a further subdivision into shorter notes describing different aspects studied. The second major subdivision of the report addresses physics measurement capabilities, and new physics search sensitivities. Individual chapters in this part discuss ATLAS physics capabilities in Standard Model QCD and electroweak processes, in the top quark sector, in b-physics, in searches for Higgs bosons, supersymmetry searches, and finally searches for other new particles predicted in more exotic models.

# Cross-Sections, Monte Carlo Simulations and Systematic Uncertainties

## Abstract

The studies presented in this volume share several common features, including use of the same event samples for Standard Model processes, and the same detector description and simulation framework for all samples. Common cross-section assumptions were made. These assumptions, and the Monte Carlo generator programs employed, are listed. Information is also given on the different detector configurations and geometries simulated, and on the consistent treatment of systematic uncertainties.

## 1 Introduction

The studies presented in this volume have many shared features starting from a common simulation framework of the ATLAS detector, and the same detector description. They are based on a full simulation of the ATLAS detector using the GEANT4 [1] program and the event samples produced were shared by the various analysis groups. For the simulation of the physics events standard event generators for high energy proton-proton collisions were used and interfaced to the ATLAS simulation framework.

In many searches for new particles at the LHC Standard Model processes represent important backgrounds and the signal significance depends on the precise knowledge of these backgrounds. As discussed in several studies presented in this book, methods were investigated on how to determine these cross-sections from the data themselves. However, this will not be always possible, and reliable theoretical predictions must be used to estimate these backgrounds. In addition, the Standard Model cross-sections are relevant for the estimate of signal rates and consequent measurement precision for Standard Model parameters, or for tests of the Standard Model. All studies presented in this book made common assumptions on the cross-sections for Standard Model processes.

In this introductory note features common to the simulations used in these studies are discussed. After reviewing the cross-section assumptions and models used for different processes, the Monte Carlo generator programs employed are summarised. Information is given, next, on the different detector configurations and geometries simulated. Finally, a common treatment is described of systematic uncertainties which affect many analyses.

## 2 Cross-Sections of Physical Processes

A consistent set of cross-sections for Standard Model processes was used in all studies reported in this volume. Over recent years considerable progress has been made in the calculation of higher-order QCD corrections (often expressed as “K-factors”) for many physics processes at the LHC. Wherever these corrections are known for both the signal and the dominant background processes, they were included in the analyses. In case the K-factors are not known for the dominant background processes, the studies have consistently refrained from using K-factors and resorted to Born-level predictions for both signal and backgrounds. In this note we detail the values of cross-sections that were used in the different studies reported in this volume: we do not discuss the uncertainties, such as those from missing higher order corrections.

For the simulation of physics processes both leading order (LO) and next-to-leading order (NLO) Monte Carlo programs were used. For the simulation of several processes tree-level matrix element calculations with parton shower matching were adopted. Unless otherwise stated, all tree-level Monte

Carlo calculations were normalized to the NLO cross-section calculation. In the case of parton shower matching several final state parton multiplicities were simulated for predefined shower matching cuts and the sum of the exclusive cross-sections was normalized to the result of the higher-order calculation. By applying this procedure, it is expected that the shapes of inclusive distributions are reasonably well described. However, large uncertainties are expected in the absolute cross-section predictions in extreme phase-space regions such as, for example, final states with high jet multiplicities.

Table 1: Leading order (LO) and higher order (N)NLO cross-sections for some important Standard Model production processes for pp collisions at a centre-of-mass energy of 14 TeV. In the calculation of all cross-sections the CTEQ6L and CTEQ6M structure function parametrizations have been used. For inclusive  $W$  and  $Z$  production, the cross-section quoted includes the branching ratio into one lepton generation.

Process	Comments	Reference	Order in pert. theory	$\sigma$ (nb)
Total inelastic pp		PYTHIA [2]		$79 \cdot 10^6$

$\gamma\gamma$ ( $qq, qg \rightarrow \gamma\gamma$ )	$80 < m_{\gamma\gamma} < 150 \text{ GeV}$	RESBOS [15]	NLO	0.0209
( $gg \rightarrow \gamma\gamma$ )	$80 < m_{\gamma\gamma} < 150 \text{ GeV}$	RESBOS [15]	NLO	0.0080

The cross-sections for the most relevant Standard Model production processes are summarised in Table 1. The cross-sections for new physics signal processes are presented in the respective sub-chapters of this book. For the calculation of the leading order cross-sections the CTEQ6L [16, 17] set of structure function parametrizations was used. Processes available at (N)NLO were calculated by using the

CTEQ6M [16, 17] parametrizations. The following comments concern the various cross-sections:

- The total pp cross-section at a centre-of-mass energy of 14 TeV is predicted by PYTHIA [2] to be 102 mb. This is split into elastic (23 mb) and inelastic (79 mb) parts. The total inelastic pp cross-section includes contributions from single and double-diffractive scattering which are estimated to be 14 and 10 mb, respectively. The non-single diffractive cross-section, which is usually also denoted as the *minimum bias* cross-section, is given by  $\sigma_{\text{NSD}} = \sigma_{\text{inel.}} - \sigma_{\text{SD}} = 65$  mb.
- Multijet production via QCD processes is the dominant high- $p_T$  process at the LHC and is an important background in many physics studies. Even if next-to-leading order corrections are partially known, the remaining uncertainties from missing higher-order corrections remain large. We therefore used leading-order estimates in most physics studies and large errors were assigned to cover the uncertainty.
- The pair production of  $b$ -quarks provides a copious source of leptons at the LHC. The single and dimuon cross-sections from  $b\bar{b}$  production were calculated with  $p_T$  thresholds as expected at the trigger level. A leading order PYTHIA calculation has been used in the present studies. Even if the higher-order corrections are known [18], large uncertainties remain.
- For the  $t\bar{t}$  production cross-section several calculations beyond leading order exist. In the studies presented in this volume the NLO calculation including a next-to-leading log (NLL) resummation [5] was used. The cross-sections for the three relevant sub-processes for single-top production were calculated at NLO.
- The inclusive production cross-sections of  $W$  and  $Z$  bosons are known at next-to-next-to-leading order (NNLO) and these values were used in the studies. The residual uncertainties from variations of the renormalization and factorization scales are estimated to be at the level of a few percent [13]. In many cases the production of  $W$  and  $Z$  bosons with jets constitutes an important background to searches. Exclusive  $W/Z$  + jet cross sections have in general been calculated with leading order Monte Carlos, such as PYTHIA, or the parton shower matched Monte Carlos ALPGEN or Sherpa. These calculations were normalized to the inclusive NNLO cross-sections. Only in case of the  $Wb\bar{b}$  and  $Zb\bar{b}$  production were exclusive NLO cross-sections calculated, to which the tree-level Monte Carlo generator results were normalized. The results of these calculations for a few relevant phase space regions are:

Process	Comments	Reference	Order in pert. theory	$\sigma$ (pb)
$Wb\bar{b}$	$p_T^b > 10$ GeV, $ \eta_b  < 2.5$ , $\Delta R_{b\bar{b}} > 0.7$ $m_W^{(*)} > 30$ GeV, $m_{b\bar{b}} > 9.24$ GeV	ALPGEN [19]	LO	68.7
		MCFM [14]	NLO	176.9
$Zb\bar{b}$	$p_T^b > 10$ GeV, $ \eta_b  < 2.5$ , $\Delta R_{b\bar{b}} > 0.7$ $m_Z^{(*)} > 30$ GeV, $m_{b\bar{b}} > 9.24$ GeV	AcerMC [6]	LO	60.7
		MCFM [14]	NLO	86.4
$Zb\bar{b}$	$p_T^b > 5$ GeV, $ \eta_b  < 2.5$ , $\Delta R_{b\bar{b}} > 0.7$ $m_Z^{(*)} > 60$ GeV, $m_{b\bar{b}} > 9.24$ GeV	AcerMC [6]	LO	27.9
		MCFM [14]	NLO	44.8

- The cross-sections for diboson production are available at NLO. In addition to the  $q\bar{q}$ -initiated processes, the  $gg$  box-diagram contributions are sizeable, and both have been taken into account in the analyses. For  $ZZ$  production the  $gg$  box contributions were estimated to be at the level of 30% [20] and the NLO result was scaled accordingly. A re-evaluation of this contribution using the program of Ref. [21] yielded a contribution of 23.8%. For the  $\gamma\gamma$  production process the box contribution was calculated using the RESBOS Monte Carlo program [15].

### 3 Monte Carlo Simulation

The samples of fully simulated events were made using a variety of Monte Carlo generators. Interfaces in the ATLAS software framework provided mechanisms to feed the particle-level events generated into the ATLAS simulation software packages. The production of these events was a major effort: a plethora of physics processes were simulated, and over 1300 different data sets were produced. Unless otherwise stated, samples were produced simulating only one proton-proton interaction: the effect of additional interactions was neglected.

The principal general-purpose Monte Carlo generators employed were PYTHIA, HERWIG, Sherpa, AcerMC, ALPGEN, MadGraph/MadEvent and MC@NLO. In addition to these, further generators were used for specific processes: Charybdis, CompHEP, TopReX and WINHAC. The versions of the generators used are summarised in Table 2. Parton-level Monte Carlo generators used either PYTHIA or HERWIG/JIMMY for hadronisation and underlying event modelling. HERWIG hadronisation was complemented by an underlying event simulation from the JIMMY program [22] (versions 4.2 and 4.31). The underlying event model parameters were tuned, for PYTHIA and HERWIG/JIMMY, to published data from Tevatron and other experiments, as described in Ref. [23] and references therein. For Sherpa, the default parton shower and underlying event modelling was used. Examples of the specific processes generated with each program are given in the Appendix.

Table 2: Monte Carlo event generators used for the production of event samples for the studies reported here. The fourth column shows, for the parton-level event generators, which software was used for the hadronisation and underlying event (UE) simulation.

Generator	Versions	Reference	Hadronisation+UE
PYTHIA	6.323-6.411	[2]	JIMMY for UE
HERWIG	6.508-6.510	[24]	
Sherpa	1.008-1.011	[25]	
AcerMC	3.1-3.4	[26]	PYTHIA,HERWIG
ALPGEN	2.05-2.13	[19]	HERWIG/JIMMY
MadGraph/MadEvent	3.X-4.15	[27]	PYTHIA
MC@NLO	3.1-3.3	[28]	HERWIG/JIMMY
Charybdis	1.001-1.003	[29]	HERWIG/JIMMY
CompHEP	–	[30]	PYTHIA
TopReX	4.11	[31]	PYTHIA
WINHAC	1.21	[32]	PYTHIA

The decay of  $\tau$  leptons was normally not treated by the main Monte Carlo generators themselves, but rather via the TAUOLA package [33], version 2.7. The radiation of photons from charged leptons was also treated specially, using the PHOTOS QED radiation package, version 2.15 [34]. These two packages were used for a range of processes and generators: this required implementation of new interfaces for HERWIG and Sherpa. When simulating specific b-hadron decays for B-physics analyses [35], the EvtGen [36] dedicated b-hadron decay package was used in combination with PYTHIA.

The Monte Carlo tools in ATLAS are taken, where available, from the LHC Computing Grid GENSER (generator services) sub-project [37]. These are modified with custom ATLAS software patches when needed. For most Monte Carlo programs more than one version was employed during the long series of simulations: changes in version were motivated by physical model, or technical improvements to the package. Common particle mass definitions were also used where relevant (for example, the top mass was taken to be 175 GeV, unless otherwise stated). The Monte Carlo tools are then either wrapped in-

side the ATLAS Athena environment [38], or interfaced via the Les Houches accord event format [39], depending on the implementation simplicity. The latter interfaces were used for the Sherpa, AcerMC, ALPGEN, MadGraph/MadEvent, MC@NLO and CompHEP event generation. These interfaces rely on widespread use of the HepMC C++-based event record format [40]: several improvements were made during the series of event production processings.

LHAPDF, the Les Houches accord PDF interface library [41], was used throughout, and was linked to all Monte Carlo event generators to provide the PDF set values. The PDF sets [16] used were CTEQ6L for leading order (LO) Monte Carlo event generators, and CTEQ6M for the next-to-leading order (NLO) Monte Carlo event generator MC@NLO.

## 4 Detector Description

One important aspect of the Computing Commissioning Challenge was the test of the alignment and calibration procedures with an imperfect, *i.e.* more realistic, description of the ATLAS detector. In particular, misalignments were introduced for the inner detector and additional material was added in the inner detector and in front of the calorimeters. In addition, distorted magnetic field configurations were introduced, where the symmetry axis of the field did not coincide with the beam axis.

The goal was to establish and validate the alignment and calibration procedures and to determine the known distortions. This has a strong physics motivation: for example, a knowledge of the energy scale of the electromagnetic calorimeter with a precision of 0.02%, as required for a precise measurement of the W mass, requires knowledge of the total radiation length of the material in the inner detector with a precision at the level of 1%.

Two different geometries were used in the simulations. In a so-called *as-built geometry* realistic alignment shifts and distortions of the magnetic field were introduced. In the *distorted geometry* additional material was added. The calibration samples were simulated and calibration constants determined with the *as-built geometry*. All physics samples were, however, simulated with the *distorted geometry* and the calibrations constants as determined from the *as-built geometry* were applied.

**As-built geometry** The *as-built geometry* includes misalignments of the main subdetectors (pixel detector, silicon microstrip tracker (SCT), and transition radiation tracker (TRT)) of the inner detector. The misalignments were introduced as independent translations and rotations at three levels: (i) of the main subdetector parts (pixel detector, SCT barrel, two SCT endcaps, TRT barrel and two TRT endcaps), (ii) of major detector sub-units, like pixel and SCT barrel layers, pixel and SCT endcap disks and TRT barrel modules and (iii) of individual silicon detector modules. The sizes of displacements were chosen to lie within the expected build tolerances. The actual displacements were assigned randomly in most cases.

The shifts described in the following were applied for the levels (i) and (ii) in the global ATLAS coordinate system, defined as a right-handed system with the  $x$ -axis pointing to the centre of the LHC ring, the  $y$ -axis in the vertical direction and the  $z$ -axis along the beam direction. The level (iii) misalignments refer to the local coordinate system of individual detector modules.

At level (i), the whole subdetector parts were displaced in the three spatial coordinates at the level of 1-2 mm followed by rotations around the three axes at the level of 10-50 mrad.

The alignments of the endcap detector sub-units include additional in-plane ( $x$ - $y$ ) displacements and rotations around the  $z$ -axis. They were generated randomly from uniform distributions centred around zero with a width of  $\pm 150 \mu\text{m}$  and  $\pm 1$  mrad, respectively. For the TRT barrel modules the translations are generated randomly from uniform distributions around zero, with widths of  $\pm 200 \mu\text{m}$ ,  $\pm 100 \mu\text{m}$  and  $\pm 300 \mu\text{m}$  respectively for modules of the three TRT layers. In addition, a systematic radial shift of +1.0,

-0.5 and +1.5 mm is applied for all modules of the respective layers. No rotations nor displacements were applied to the TRT endcap modules.

For the individual pixel and SCT detector modules individual position displacements were applied randomly from uniform distributions with widths of 30-50  $\mu\text{m}$  for pixel and 100-150  $\mu\text{m}$  for SCT modules, followed by rotations around the three axes, also randomly chosen from uniform distributions with widths of  $\pm 1$  mrad.

**Distorted geometry** The *distorted geometry* is based on the *as-built geometry* with additional material added in different locations of the inner detector and in front of the electromagnetic calorimeter. Material corresponding to an increase of 1-3% of a radiation length was added just behind the first pixel layer, and just behind the second SCT layer, and in the endcaps adjacent to one of the endcap pixel disks and adjacent to two of the endcap SCT disks. This amount of additional material is considered to be much larger than the uncertainty on the knowledge of the exact amount of the material. Within the active tracking volume the material in regions of service routing was increased by 1-5% of a radiation length. For services outside the active tracking volume the material was increased by up to 15% of a radiation length. These increases are also expected to be larger than the uncertainties. It should be noted that for the inner detector the extra material was only added in one half of the azimuthal angle ( $0 < \phi < \pi$ ) to allow for a straightforward study of the difference in calibration and performance with single particles.

Additional material was also added in a  $\phi$ -asymmetric way in front of the calorimeter. In the region  $\eta > 0$  additional material corresponding to 8-11%  $X_0$  were added in front of the barrel cryostat, 5%  $X_0$  between the barrel presampler and strip layers (in  $\pi/2 < \phi < 3\pi/2$ ), and 7-11%  $X_0$  behind the cryostat. In the region  $\eta < 0$ , additional material corresponding to 5%  $X_0$  was added between the barrel presampler and the strip layer in the region  $-\pi/2 < \phi < \pi/2$ . The density of material in the gap between the barrel and the endcap cryostat was increased by 70%. Again, this is considered to be conservative and larger than the uncertainties on the precise knowledge of the material distribution in this region of the detector.

**Applications in performance of physics studies** Several performance studies were carried out using the as-built and distorted geometries in simulation and the impact is documented elsewhere in this volume. Among the important studies is the impact of the misalignments on the b-tagging performance or on the reconstructed resolution of the Z resonance in muon final states. In addition the impact on the mass resolution and reconstruction efficiencies was studied for  $H \rightarrow \gamma\gamma$ ,  $H \rightarrow ZZ \rightarrow 4\ell$  and  $Z \rightarrow ee$  samples.

## 5 Treatment of systematic uncertainties

The results of the physics and performance studies are affected by systematic uncertainties, some of which are common to many studies. To allow a uniform treatment of these uncertainties across the various analyses, the following effects and prescriptions were applied.

There are detector-related uncertainties, such as those on particle identification efficiencies, on background rejections, and on the precise knowledge of energy scales and resolution functions. These uncertainties can be largely constrained and determined from the data themselves. However, this can only be done with a finite, and integrated luminosity-dependent, accuracy. In the present studies, rough estimates of these uncertainties were used, considering three canonical integrated luminosity values: 0.1, 1 and 10  $\text{fb}^{-1}$ . Detector-related systematic uncertainties were applied to signal and background samples by varying the energy scale, resolution, or efficiency or rejections.

In addition, uncertainties come from the approximations made in Monte Carlo generators, modelling and from the theoretical calculation of cross-sections. Unless stated otherwise when discussing individual analyses, the following assumptions were applied, for the various systematic uncertainties.

### 5.1 Uncertainties on the detector performance

**Electrons and photons** For electrons and photons, uncertainties on the identification efficiency of 1.0%, 0.5% and 0.2% were assumed for the three values of integrated luminosity, 0.1, 1 and 10 fb<sup>-1</sup>, respectively. These values can be determined from data by applying the so called tag-and-probe methods [42, 43] to known resonance decays, like  $Z \rightarrow ee$ . The uncertainty on the energy scale was assumed to be 1% (0.1%) for integrated luminosities below (above) 1 fb<sup>-1</sup>. The electron and photon resolutions were estimated to be known with precisions of 20%, 10% and 5% at the three values of integrated luminosity. The electron fake rates were assumed to have overall uncertainties of 50%, 20% and 10% at the three integrated luminosity values. All uncertainties were assumed to be independent of  $p_T$  and  $\eta$ .

**Muons** Uncertainties on the identification efficiency of 1%, 0.3% and 0.1% were used for muons with  $p_T < 100$  GeV for the three integrated luminosity values. As for electrons, it should be noted that these numbers are expected to be conservative, since the statistical precision that can be obtained from studies of  $Z \rightarrow \mu\mu$  decays amounts to 0.2% for an integrated luminosity of 0.1 fb<sup>-1</sup>. For higher muon momenta the efficiencies must be estimated using extrapolations based on Monte Carlo and therefore larger values were assumed: for muons with a  $p_T$  of 1 TeV, for example, the uncertainties were assumed to be 5%, 3% and 1%, respectively.

The muon energy scale was assumed to be known with precisions of 1%, 0.3% and 0.1% for the three integrated luminosity values. Furthermore, uncertainties of 12%, 4% and 1% were assumed on the muon momentum resolution below 100 GeV, whereas a value of 100% was used for muons with  $p_T$  of 1 TeV. All these uncertainties were considered to be independent of  $\eta$ .

**Jets and Missing  $E_T$**  Unless otherwise stated, the overall uncertainty on the jet energy scale was assumed to  $\pm 5\%$  over the pseudorapidity region  $|\eta| < 3.2$  and  $\pm 10\%$  for jets in the forward calorimeters,  $3.2 < |\eta| < 4.9$ . This scale uncertainty is applied, independently of jet  $p_T$ , for both light-quark jets and jets from  $b$ -quarks. In addition, unless stated otherwise, an uncertainty of 10% on the jet energy resolution was considered.

The missing transverse energy,  $E_T^{\text{miss}}$ , is calculated by summing high- $p_T$  objects like leptons and jets, in addition a component from unclustered energy is added. Part of the uncertainty in  $E_T^{\text{miss}}$  is thus correlated with the jet and lepton energy scale uncertainties, but also a wrong calibration of unclustered energy can affect  $E_T^{\text{miss}}$ .

After identified objects were rescaled or smeared, the  $E_T^{\text{miss}}$  was re-calculated with the corrected energies. In most of the studies also the low  $p_T$  part of the unclustered energy was modified. In this procedure, the momenta of the leptons and jets with  $p_T > 20$  GeV were subtracted first from the  $E_T^{\text{miss}}$ , a 10% uncertainty on the remainder was applied, and then the effects of the leptons and jets were added back in.

**Heavy-flavour tagging** For the  $b$ -tagging efficiency a 5% relative uncertainty was assumed, independently of luminosity. This is considered to be a conservative estimate for integrated luminosities of 1 fb<sup>-1</sup> or higher. For the mistag rate of light and  $c$ -jets an integrated-luminosity independent uncertainty of 10% was assumed. It is expected that the mistag rates can be measured with this precision or better from data sets exceeding an integrated luminosity of 0.1 fb<sup>-1</sup>. The efficiency and mistag variations were

implemented in analyses by randomly rejecting 5% of the jets tagged as  $b$ -jets or by randomly changing the tag status of light and  $c$ -jets.

## 5.2 Uncertainties on cross-sections and Monte Carlo modelling

Several theoretical uncertainties affect the predicted cross-sections. The details and the size of the uncertainty depend on the signal and background processes considered and no general numbers can be quoted. They are therefore usually addressed in the respective studies presented in this volume. The main effects can be classified as follows:

- The theoretical calculations are affected by missing unknown higher-order corrections. These uncertainties are usually estimated by varying the renormalization and factorization scales within factors of two around the nominal scale chosen.
- Despite the normalization of tree-level Monte Carlo programs – with or without parton shower matching – to the (N)NLO cross sections, large uncertainties remain, in particular for exclusive final states in specific phase space regions after the application of cuts. These uncertainties have been estimated either by varying parton-shower matching cuts or by comparisons with different Monte Carlo event generators.
- Uncertainties in the parton distribution functions result in uncertainties on the calculated cross-sections which are typically of the order of 10%. These uncertainties have either been addressed by varying the eigenvalues of the CTEQ parametrization parameters [17] within the suggested values or by comparing the CTEQ and MRST2001 [44] parametrizations.

## Appendix

In the following, additional technical information is given on some of the Monte Carlo event generators employed, together with example processes.

### PYTHIA

The PYTHIA Monte Carlo event generator [2] was employed for the event simulation of many samples. The new implementation of parton showering, commonly known as  $p_T$ -ordered showering, was used, as was the new underlying event model where the phase-space is interleaved/shared between initial-state radiation (ISR) and the underlying event. In addition to the standard processes implemented in PYTHIA, two extensions were implemented containing a chiral lagrangian model [45], and an R-hadron model.

### HERWIG and JIMMY

HERWIG [24] was used, for example, for simulation of SUSY signal processes [46]. The pre-generated input tables for these processes were provided by ISAJET and ISAWIG [47].

### Sherpa

The Sherpa Monte Carlo event generator [25], was used for several processes, most notably for the production of electroweak bosons in association with jets: these profited from the implemented CKKW parton-showering and matrix-element matching technique. Some representative processes for which Sherpa was used are: a  $W$  or  $Z$  produced in association with up to four light jets; Higgs boson production via vector boson fusion; and associated production of  $b\bar{b}A$ .

### AcerMC

Some processes for which AcerMC [26] was used were:  $Zb\bar{b}$  production;  $Zt\bar{t}$  production;  $t\bar{t}$  production; single top processes;  $t\bar{t}b\bar{b}$  production; and  $t\bar{t}t\bar{t}$  production. The AcerMC program was used both with PYTHIA and HERWIG hadronisation, to allow tests of systematic uncertainties related to parton shower modelling.

A procedure was developed for combining samples with  $t\bar{t}$  production modelled with MC@NLO with samples from the AcerMC  $t\bar{t}b\bar{b}$  process. There is an overlap of the two samples since the extra gluon in the NLO  $t\bar{t}$  calculation can split into a  $b\bar{b}$  pair during parton showering. For studies where this channel was relevant [48], events with additional  $b\bar{b}$  pairs in the MC@NLO samples were rejected, since the matrix-element  $t\bar{t}b\bar{b}$  generation is expected to describe such events better in the region of the phase space selected by the analysis (especially for relatively large opening angle between the two quarks of the  $b\bar{b}$  pair). The corresponding number of events (10% of the total) was also removed from the high jet-multiplicity  $t\bar{t}$  sample for normalization purposes.

### ALPGEN

The ALPGEN Monte Carlo event generator [19] was used for several processes, most notably for the production of electroweak bosons in association with jets, in order to profit from the implemented MLM parton-showering and matrix-element matching technique. Some processes for which ALPGEN was used were:  $W$  or  $Z$  production in association with up to five light jets;  $t\bar{t}$  production with up to three additional light jets;  $b\bar{b}$  or  $c\bar{c}$  production with up to three additional light jets; electroweak boson pair production in association with up to three jets Higgs production via vector boson fusion; and photon pair production in association with up to three jets.

### MadGraph/MadEvent

The MadGraph/MadEvent Monte Carlo event generator [27] was used for a selection of processes, for example for exclusive final states involving multiple electroweak bosons and associated light jets, as well as some Standard Model Higgs boson production channels. Although MadGraph/MadEvent processes in the 4.X versions can be combined with a native version of parton-showering and matrix-element matching technique, this functionality was not used here. Some representative processes for which MadGraph/MadEvent was used are:  $W$  or  $Z$  production in association with four light partons;  $WW$ ,  $WZ$  or  $ZZ$  pair production in association with two light partons; electroweak boson production in association with two photons; and photon pair production in association with two additional partons.

### MC@NLO

The MC@NLO event generator [28] is one of the few Monte Carlo tools incorporating full NLO QCD corrections to a selected set of processes in a consistent way. It was used to simulate a number of processes, including: inclusive  $W$  or  $Z$  production;  $t\bar{t}$  production; electroweak boson pair production; and Higgs boson production and decay, for the  $W^+W^-$  and  $\gamma\gamma$  Higgs boson decay modes.

### Charybdis

The Charybdis Monte Carlo event generator [29] is a special-purpose program implementing production and decay of microscopic black holes in models with TeV-scale gravity.

### CompHEP

The CompHEP Monte Carlo event generator [30] was used for a small set of processes: excited electron production,  $Z' \rightarrow e^+ e^- \gamma$ , and the production of E6 heavy iso-singlet D quarks decaying to  $Z$  or  $W$  pairs, or to a  $ZH$  pair in association with additional quarks.

### TopReX

The TopReX Monte Carlo event generator [31] was used for top pair or single top production involving flavour-changing neutral current (FCNC) couplings in top quark decays, explicitly:  $t\bar{t}$  production where one top quark decays conventionally (to  $bW$ ), and the other to either  $q\gamma$  or  $qZ$ ; and single top production and decay to either  $q\gamma$  or  $qZ$ . TopReX was interfaced directly with PYTHIA for parton showering, hadronisation and the underlying event: a point to note is that TopReX single top generation is intimately interfaced with the PYTHIA old (virtuality-ordered) parton showering model and thus cannot be used with the new PYTHIA  $p_T$ -ordered showering.

### WINHAC

WINHAC [32] is a Monte Carlo event generator dedicated to the hadro-production of single  $W$  bosons decaying into leptons. Comparisons done within ATLAS have shown that the WINHAC predictions match well the predictions of PHOTOS for radiative corrections to  $W$  boson leptonic decays. PHOTOS was used throughout this work.

# Tracking

# The Expected Performance of the Inner Detector

## Abstract

The ATLAS inner detector will see of the order of 1000 charged particle tracks for every beam crossing at the design luminosity of the CERN Large Hadron Collider (LHC). This paper summarizes the design of the detector and outlines the reconstruction software. The expected performance for reconstructing single particles is presented, along with an indication of the vertexing capabilities. The effect of the detector material on electrons and photons is discussed along with methods for improving their reconstruction. The studies presented focus on the performance expected for the initial running at the start-up of the LHC.

## 1 Introduction

In ATLAS, at the LHC design luminosity of  $10^{34} \text{ cm}^{-2}\text{s}^{-1}$ , approximately 1000 particles will emerge from the collision point every 25 ns within  $|\eta| < 2.5$ , creating a very large track density in the detector. To achieve the momentum and vertex resolution requirements imposed by the benchmark physics processes, high-precision measurements will be made in the inner detector (ID), shown in Fig. 1. Pixel and silicon microstrip (SCT) trackers, used in conjunction with the straw tubes of the transition radiation tracker (TRT), will make high-granularity measurements. The original performance specifications were set out in 1994 and are detailed in [1] – the focus being on challenging physics channels such as the measurement of leptons from the decays of heavy gauge bosons and the tagging of  $b$ -quark jets.

Figure 1: Cut-away view of the ATLAS inner detector.

The ID surrounds the LHC beam-pipe which is inside a radius of 36 mm. The layout of the detector is illustrated in Fig. 2 and detailed in [2]. Its basic parameters are summarised in Table 1. The ID is

immersed in a 2 T magnetic field generated by the central solenoid, which extends over a length of 5.3 m with a diameter of 2.5 m.

Figure 2: Plan view of a quarter-section of the ATLAS inner detector showing each of the major elements with its active dimensions.

Item		Radial extension (mm)	Length (mm)
<b>Pixel</b>	Overall envelope	$45.5 < R < 242$	$0 <  z  < 3092$
	3 cylindrical layers	$50.5 < R < 122.5$	$0 <  z  < 400.5$
	$2 \times 3$ disks	$88.8 < R < 149.6$	$495 <  z  < 650$
<b>SCT</b>	Overall envelope	$255 < R < 549$ (barrel) $251 < R < 610$ (end-cap )	$0 <  z  < 805$ $810 <  z  < 2797$
	4 cylindrical layers	$299 < R < 514$	$0 <  z  < 749$
	$2 \times 9$ disks	$275 < R < 560$	$839 <  z  < 2735$
<b>TRT</b>	Overall envelope	$554 < R < 1082$ (barrel) $617 < R < 1106$ (end-cap )	$0 <  z  < 780$ $827 <  z  < 2744$
	73 straw planes	$563 < R < 1066$	$0 <  z  < 712$
	160 straw planes	$644 < R < 1004$	$848 <  z  < 2710$

Table 1: Main parameters of the inner detector.

The precision tracking detectors (pixels and SCT) cover the region  $|\eta| < 2.5$ . In the barrel region, they are arranged on concentric cylinders around the beam axis while in the end-cap regions, they are located on disks perpendicular to the beam axis. The highest granularity is achieved around the vertex region using silicon pixel sensors. All pixel modules are identical and the minimum pixel size on a sensor is  $50 \times 400 \mu\text{m}^2$ . The pixel layers are segmented in  $R - \phi$  and  $z$  with typically three pixel layers crossed by each track. The first layer, called the “vertexing layer”, is at a radius of 51 mm. The intrinsic accuracies in the barrel are  $10 \mu\text{m}$  ( $R - \phi$ ) and  $115 \mu\text{m}$  ( $z$ ) and in the disks are  $10 \mu\text{m}$  ( $R - \phi$ ) and  $115 \mu\text{m}$  ( $R$ ). The pixel detector has approximately 80.4 million readout channels.

For the SCT, eight strip layers (four space points) are crossed by each track. In the barrel region, this detector uses small-angle (40 mrad) stereo strips to measure both coordinates, with one set of strips in

each layer parallel to the beam direction, measuring  $R - \phi$ . Each side of a detector module consists of two 6.4 cm long, daisy-chained sensors with a strip pitch of  $80 \mu\text{m}$ . In the end-cap region, the detectors have a set of strips running radially and a set of stereo strips at an angle of  $40 \text{ mrad}$ . The mean pitch of the strips is also approximately  $80 \mu\text{m}$ . The intrinsic accuracies per module in the barrel are  $17 \mu\text{m}$  ( $R - \phi$ ) and  $580 \mu\text{m}$  ( $z$ ) and in the disks are  $17 \mu\text{m}$  ( $R - \phi$ ) and  $580 \mu\text{m}$  ( $R$ ). The total number of readout channels in the SCT is approximately 6.3 million.

A large number of hits (typically 30 per track, with a maximum of 36, see Fig. 34) is provided by the 4 mm diameter straw tubes of the TRT, which enables track-following up to  $|\eta| = 2.0$ . The TRT only provides  $R - \phi$  information, for which it has an intrinsic accuracy of  $130 \mu\text{m}$  per straw. In the barrel region, the straws are parallel to the beam axis and are 144 cm long, with their wires divided into two halves, approximately at  $\eta = 0$ . In the end-cap region, the 37 cm long straws are arranged radially in wheels. The total number of TRT readout channels is approximately 351,000.

Item	Intrinsic accuracy ( $\mu\text{m}$ )	Alignment tolerances ( $\mu\text{m}$ )		
		Radial (R)	Axial (z)	Azimuth (R- $\phi$ )
<b>Pixel</b>				
Layer-0	10 ( $R - \phi$ ) 115 ( $z$ )	10	20	7
Layer-1 and -2	10 ( $R - \phi$ ) 115 ( $z$ )	20	20	7
Disks	10 ( $R - \phi$ ) 115 ( $R$ )	20	100	7
<b>SCT</b>				
Barrel	17 ( $R - \phi$ ) 580 ( $z$ ) <sup>1</sup>	100	50	12
Disks	17 ( $R - \phi$ ) 580 ( $R$ ) <sup>1</sup>	50	200	12
<b>TRT</b>	130			30 <sup>2</sup>
1. Arises from the 40 mrad stereo angle between back-to-back sensors on the SCT modules with axial (barrel) or radial (end-cap) alignment of one side of the structure. The result is pitch-dependent for end-cap SCT modules. 2. The quoted alignment accuracy is related to the TRT drift-time accuracy.				

Table 2: Intrinsic measurement accuracies and mechanical alignment tolerances for the inner detector sub-systems, as defined by the performance requirements of the ATLAS experiment. The numbers in the table correspond to the single-module accuracy for the pixels, to the effective single-module accuracy for the SCT and to the drift-time accuracy of a single straw for the TRT.

The combination of precision trackers at small radii with the TRT at a larger radius gives very robust pattern recognition and high precision in both  $R - \phi$  and  $z$  coordinates. The straw hits at the outer radius contribute significantly to the momentum measurement, since the lower precision per point compared to the silicon is compensated by the large number of measurements and longer measured track length.

The inner detector system provides tracking measurements in a range matched by the precision measurements of the electromagnetic calorimeter [2]. The electron identification capabilities are enhanced by the detection of transition-radiation photons in the xenon-based gas mixture of the straw tubes. The semiconductor trackers also allow impact parameter measurements and vertex reconstruction (“vertexing”) for heavy-flavour and  $\tau$ -lepton tagging. The secondary vertex measurement performance is enhanced by the innermost layer of pixels, at a radius of about 5 cm.

Charged particle tracks with transverse momentum  $p_T > 0.5 \text{ GeV}$  and  $|\eta| < 2.5$  are reconstructed and measured in the inner detector and the solenoid field. However, the efficiency at low momentum is limited because of the large material effect in the inner detector (see Fig. 3). The intrinsic measurement performance expected for each of the inner detector sub-systems is summarised in Table 2. This performance has been studied extensively over the years [1], both before and after irradiation of production

modules, and also, more recently, during the combined test beam (CTB) runs in 2004 [2,3] and in a series of cosmic-ray tests in 2006 [2,4]. The results have been used to update and validate the modelling of the detector response in the Monte-Carlo simulation. This paper describes the expected performance of the inner detector in terms of tracking, vertexing and particle identification. The alignment of the inner detector is described elsewhere ([2] and the references therein).

Figure 3: Material distribution ( $X_0$ ,  $\lambda$ ) at the exit of the ID envelope, including the services and thermal enclosures. The distribution is shown as a function of  $|\eta|$  and averaged over  $\phi$ . The breakdown indicates the contributions of external services and of individual sub-detectors, including services in their active volume.

## 2 Track reconstruction

The inner detector track reconstruction software [5] follows a modular and flexible software design, which includes features covering the requirements of both the inner detector and muon spectrometer [2] reconstruction. These features comprise a common event data model [6] and detector description [7], which allow for standardised interfaces to all reconstruction tools, such as track extrapolation, track fitting including material corrections and vertex fitting. The extrapolation package combines propagation tools with an accurate and optimised description of the active and passive material of the full detector [8] to allow for material corrections in the reconstruction process. The suite of track-fitting tools includes global- $\chi^2$  and Kalman-filter techniques, and also more specialised fitters such as dynamic noise adjustment (DNA) [9], Gaussian-sum filters (GSF) [10] and deterministic annealing filters [11]. Optimisation of these tools continues and their performance will need to be evaluated on real data. The tools intended to cope with electron bremsstrahlung (DNA and GSF – see Section 5.1) will be run after the track reconstruction, as part of the electron-photon identification. Other common tracking tools are provided, including those to apply calibration corrections at later stages of the pattern recognition, to correct for module deformations or to resolve hit-association ambiguities.

Track reconstruction in the inner detector is logically sub-divided into three stages:

1. A pre-processing stage, in which the raw data from the pixel and SCT detectors are converted into clusters and the TRT raw timing information is translated into calibrated drift circles. The SCT clusters are transformed into space-points, using a combination of the cluster information from opposite sides of a SCT module.
2. A track-finding stage, in which different tracking strategies [5, 12], optimised to cover different applications, are implemented. (The results of studies of the various algorithms are reported else-

where [13].) The default tracking exploits the high granularity of the pixel and SCT detectors to find prompt tracks originating from the vicinity of the interaction region. First, track seeds are formed from a combination of space-points in the three pixel layers and the first SCT layer. These seeds are then extended throughout the SCT to form track candidates. Next, these candidates are fitted, “outlier” clusters are removed, ambiguities in the cluster-to-track association are resolved, and fake tracks are rejected. This is achieved by applying quality cuts. For example, a cut is made on the number of associated clusters, with explicit limits set on the number of clusters shared between several tracks and the number of holes per track (a hole is defined as a silicon sensor crossed by a track without generating any associated cluster). The selected tracks are then extended into the TRT to associate drift-circle information in a road around the extrapolation and to resolve the left-right ambiguities. Finally, the extended tracks are refitted with the full information of all three detectors. The quality of the refitted tracks is compared to the silicon-only track candidates and hits on track extensions resulting in bad fits are labelled as outliers (they are kept as part of the track but are not included in the fit).

A complementary track-finding strategy, called back-tracking, searches for unused track segments in the TRT. Such segments are extended into the SCT and pixel detectors to improve the tracking efficiency for secondary tracks from conversions or decays of long-lived particles.

3. A post-processing stage, in which a dedicated vertex finder is used to reconstruct primary vertices. This is followed by algorithms dedicated to the reconstruction of photon conversions and of secondary vertices.

### 3 Tracking performance

#### 3.1 Introduction to performance studies

The expected performance of the tracking system for reconstructing single particles and particles in jets is determined using a precise modelling of the individual detector response (including electronic noise and inefficiencies), geometry and passive material in the simulation. In this paper, a consistent set of selection cuts for reconstructed tracks has been used. Generally, only prompt particles (those originating from the primary vertex) with  $p_T > 1$  GeV and  $|\eta| < 2.5$  are considered. Standard quality cuts require reconstructed tracks to have at least seven precision hits (pixels and SCT). In addition, the transverse and longitudinal impact parameters at the perigee must fulfil respectively  $|d_0| < 2$  mm and  $|z_0 - z_v| \times \sin \theta < 10$  mm, where  $z_v$  is the position of the primary vertex along the beam and  $\theta$  is the polar angle of the track. Stricter selection cuts, called  $b$ -tagging cuts, are defined by: at least two hits in the pixels, one of which should be in the vertexing layer, as well as  $|d_0| < 1$  mm and  $|z_0 - z_v| \times \sin \theta < 1.5$  mm. A reconstructed track is matched to a Monte-Carlo particle if at least 80% of its hits were created by that particle. The efficiency is defined as the fraction of particles which are matched to reconstructed tracks passing the quality cuts, and the fake rate is defined as the fraction of reconstructed tracks passing the quality cuts which are not matched to a particle.

#### 3.2 Track parameter resolutions

The resolution of a track parameter  $X$  can be expressed as a function of  $p_T$  as:

$$\sigma_X(p_T) = \sigma_X(\infty)(1 \oplus p_X/p_T) \quad (1)$$

where  $\sigma_X(\infty)$  is the asymptotic resolution expected at infinite momentum,  $p_X$  is a constant representing the value of  $p_T$  for which the intrinsic and multiple-scattering terms in the equation are equal for the

parameter  $X$  under consideration and  $\oplus$  denotes addition in quadrature. This expression is approximate, working well at high  $p_T$  (where the resolution is dominated by the intrinsic detector resolution) and at low  $p_T$  (where the resolution is dominated by multiple scattering).  $\sigma_X(\infty)$  and  $p_X$  are implicitly functions of the pseudorapidity. Figures 4, 5 and 6 show the momentum resolution for isolated muons and the transverse and longitudinal impact parameter resolutions for isolated pions<sup>1</sup>, all without a beam constraint and assuming the effects of misalignment, miscalibration and pile-up to be negligible. The resolutions are taken as the RMS evaluated over a range which includes 99.7% of the data (corresponding to  $\pm 3\sigma$  for a Gaussian distribution). The TRT measurements are included in the track fits for tracks with  $|\eta| < 2.0$ , beyond which there are no further TRT measurements. Table 3 shows the values of  $\sigma_X(\infty)$  and  $p_X$  for tracks in two  $\eta$ -regions, corresponding to the barrel and end-caps. The use of the beam-spot constraint in the track fit improves the momentum resolution for high-momentum tracks by about 5%. The impact parameter resolutions are quoted only for tracks with a hit in the vertexing layer (this requirement has a very high efficiency, as illustrated in Fig. 14 by the small difference between the standard quality and the  $b$ -tagging quality tracks). Figure 7 shows the comparison of the impact parameter resolutions for pions and muons. The muon distributions are very close to Gaussian, while those for the pions are slightly broader and have small tails, in addition. The tails are even larger for electrons, and this is discussed in Section 5.

Track parameter	$0.25 <  \eta  < 0.50$		$1.50 <  \eta  < 1.75$	
	$\sigma_X(\infty)$	$p_X$ (GeV)	$\sigma_X(\infty)$	$p_X$ (GeV)
Inverse transverse momentum ( $q/p_T$ )	$0.34 \text{ TeV}^{-1}$	44	$0.41 \text{ TeV}^{-1}$	80
Azimuthal angle ( $\phi$ )	$70 \mu\text{rad}$	39	$92 \mu\text{rad}$	49
Polar angle ( $\cot \theta$ )	$0.7 \times 10^{-3}$	5.0	$1.2 \times 10^{-3}$	10
Transverse impact parameter ( $d_0$ )	$10 \mu\text{m}$	14	$12 \mu\text{m}$	20
Longitudinal impact parameter ( $z_0 \times \sin \theta$ )	$91 \mu\text{m}$	2.3	$71 \mu\text{m}$	3.7

Table 3: Expected track-parameter resolutions (RMS) at infinite transverse momentum,  $\sigma_X(\infty)$ , and transverse momentum,  $p_X$ , at which the multiple-scattering contribution equals that from the detector resolution (see Eq. (1)). The momentum and angular resolutions are shown for muons, whereas the impact-parameter resolutions are shown for pions (see text). The values are shown for two  $\eta$ -regions, one in the barrel inner detector where the amount of material is close to its minimum and one in the end-cap where the amount of material is close to its maximum. Isolated, single particles are used with perfect alignment and calibration in order to indicate the optimal performance.

The consequences of the pseudorapidity variation of the track parameter resolutions can be seen from the reconstructed  $J/\psi \rightarrow \mu\mu$  masses in the barrel and end-caps. This is shown in Fig. 8 where both muons are either in the barrel or the end-caps.

The determination of the lepton charge at high  $p_T$  is particularly important for measuring charge asymmetries arising from the decays of possible heavy gauge bosons ( $W'$  and  $Z'$ ). Typically, such measurements require that the charge of the particle be determined to better than  $3\sigma^2$ . Whereas the charge of high-energy muons will be measured precisely in the muon system, the charge of high-energy electrons can only be measured by the inner detector. Figure 9 shows the reconstructed values of  $q/p_T$  for negatively charged isolated muons and electrons with  $p_T = 0.5 \text{ TeV}$  and  $p_T = 2 \text{ TeV}$ . The peaks of the distributions are at negative values, reflecting the negative charges of the simulated particles. It can be seen that the shape of the muon distributions is unchanged in going from 0.5 to 2 TeV – at high momen-

<sup>1</sup>Muons suffer less from interactions and hence provide the best reference; impact parameter determination is important for vertexing, and this is more commonly required for hadrons, for example when  $b$ -tagging.

<sup>2</sup>The charge of a particle is considered well measured if it is at least  $3\sigma$  from 0 in the variable  $q/p$ .

Figure 4: Relative transverse momentum resolution (left) as a function of  $|\eta|$  for muons with  $p_T = 1, 5$  and 100 GeV. Transverse momentum, at which the multiple-scattering contribution equals the intrinsic resolution (corresponding to  $p_X$  in Eq. (1)), as a function of  $|\eta|$  (right).

Figure 5: Transverse impact parameter,  $d_0$ , resolution (left) as a function of  $|\eta|$  for pions with  $p_T = 1, 5$  and 100 GeV. Transverse momentum, at which the multiple-scattering contribution equals the intrinsic resolution (corresponding to  $p_X$  in Eq. (1)), as a function of  $|\eta|$  (right).

Figure 6: Modified longitudinal impact parameter,  $z_0 \times \sin \theta$ , resolution (left) as a function of  $|\eta|$  for pions with  $p_T = 1, 5$  and  $100$  GeV. Transverse momentum, at which the multiple-scattering contribution equals the intrinsic resolution (corresponding to  $p_X$  in Eq. (1)), as a function of  $|\eta|$  (right).

Figure 7: Resolution of the transverse impact parameter,  $d_0$  (left) and the modified longitudinal impact parameter,  $z_0 \times \sin \theta$  (right) for  $5$  GeV muons and pions with  $|\eta| \leq 0.5$  – corresponding to the first two bins of the previous two figures.

Figure 8: Probability for the reconstructed invariant mass of muon pairs from  $J/\psi \rightarrow \mu\mu$  decays in events with prompt  $J/\psi$  production. Distributions are shown for both muons with  $|\eta| < 0.8$  (left) and  $|\eta| > 1.5$  (right).

tum, the resolution of  $q/p_T$  is independent of the true momentum of the muon and determined by the intrinsic resolution of the detector.

For electrons, things are more complicated. As well as the intrinsic resolution, there are competing effects from bremsstrahlung (which lowers the track momentum and makes the charge easier to measure) and the conversion of bremsstrahlung photons (leading to pattern-recognition problems and degraded charge determination). At 0.5 TeV, the effects of the conversions are significant, causing the electrons to be measured worse than the corresponding muons. However, at 2 TeV, the intrinsic resolution dominates the electron charge misidentification, and this is partially compensated for by the bremsstrahlung. The fractions of muons and electrons for which the sign of the charge is incorrectly determined are shown in Fig. 10. For these plots, perfect alignment has been assumed; any misalignment will degrade the charge sign determination.

### 3.3 Track reconstruction efficiency

Figures 11, 12 and 13 show the efficiencies for reconstructing isolated muons, pions and electrons. In addition to multiple-scattering, pions are affected by hadronic interactions in the inner detector material, while electrons are subject to even larger reconstruction inefficiencies which arise from the effects of bremsstrahlung. As a result, the efficiency curves as a function of  $|\eta|$  for pions and electrons reflect the shape of the amount of material in the inner detector (see Fig. 3). As expected, the efficiency becomes larger and more uniform as a function of  $|\eta|$  at higher energies.

Previous studies [1] have shown that the reconstruction efficiency is little affected by the “pile-up” of additional minimum bias events at high luminosity ( $10^{34} \text{ cm}^{-2}\text{s}^{-1}$ ). A more challenging environment is found in the core of an energetic jet. Figure 14 shows the track reconstruction efficiency for prompt pions (produced before the vertexing layer) and the fake rate for tracks in jets in  $t\bar{t}$  events as a function of  $|\eta|$ . For these events, the mean jet  $p_T$  is 55 GeV, and the mean  $p_T$  of the accepted tracks which they contain is 4 GeV. The loss of efficiency at  $|\eta| = 0$  with the  $b$ -tagging criteria arises from inefficiencies in the pixel vertexing layer, which are assumed here to be 1%; this improves at higher  $|\eta|$ , owing to the presence of larger clusters when the track incidence angle decreases. Beyond  $|\eta| \sim 1$ , the tracking performance deteriorates, mostly because of increased material. As shown in Fig. 15, the fake rate increases near the

Figure 9: Reconstructed inverse transverse momentum multiplied by the charge for high-energy muons ( $\mu^-$ ) (left) and electrons ( $e^-$ ) (right) for  $p_T = 0.5$  TeV (top) and  $p_T = 2$  TeV (bottom) and integrated over a flat distribution in  $\eta$  with  $|\eta| \leq 2.5$ . Those tracks which have been incorrectly reconstructed with a positive charge are indicated by the shaded regions. At 2 TeV, the fraction of electrons (muons) whose charge has been misidentified is 12.8% (13.7%).

Figure 10: Charge misidentification probability for high-energy muons and electrons as a function of  $p_T$  for particles with  $|\eta| \leq 2.5$  (left) and as a function of  $|\eta|$  for  $p_T = 2$  TeV (right).

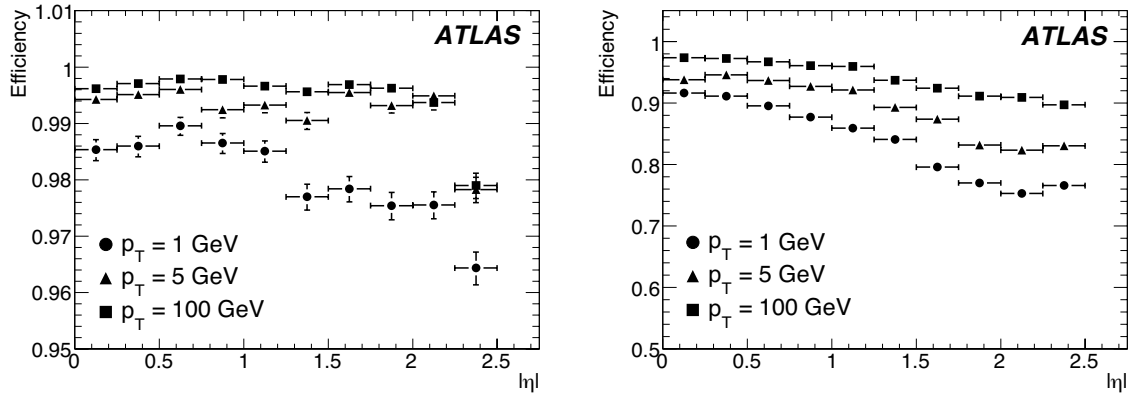

Figure 11: Track reconstruction efficiencies as a function of  $|\eta|$  for muons (left) and pions (right) with  $p_T = 1, 5$  and  $100$  GeV.

Figure 12: Track reconstruction efficiencies as a function of  $|\eta|$  for electrons with  $p_T = 1, 5$  and  $100$  GeV.

Figure 13: Track reconstruction efficiencies as a function of  $|\eta|$  for muons, pions and electrons with  $p_T = 5$  GeV. The inefficiencies for pions and electrons reflect the shape of the amount of material in the inner detector as a function of  $|\eta|$ .

Figure 14: Track reconstruction efficiencies and fake rates as a function of  $|\eta|$ , for charged pions in jets in  $t\bar{t}$  events and for different quality cuts (as described in Section 3.1). “Reconstruction” refers to the basic reconstruction before additional quality cuts.

Figure 15: Track reconstruction efficiencies and fake rates as a function of the distance  $\Delta R$  (defined as  $\Delta R = \sqrt{\Delta\eta^2 + \Delta\phi^2}$ ) of the track to the jet axis, using the standard quality cuts and integrated over  $|\eta| < 2.5$ , for charged pions in jets in  $t\bar{t}$  events.

core of the jet, where the track density is the highest and induces pattern-recognition problems. This effect increases as the jet  $p_T$  increases. Using alternative algorithms, a few percent efficiency can be gained at the cost of doubling the fake rate in the jet core.

The reconstruction described in Section 2 is aimed at tracks with  $p_T > 0.5$  GeV. Multiplicity studies in minimum bias events will be among the first analyses undertaken by ATLAS. In these events, the peak of the track  $p_T$  spectrum is around 0.3 GeV. The reconstruction of these low-momentum tracks will be difficult because of the high curvature of the tracks, increased multiple scattering, and at very low momentum, reduced numbers of hits, since the tracks may fail to reach the outer layers of the inner detector. To complement the track-finding strategy described in Section 2, an additional strategy is employed in which hitherto unused pixel and SCT hits are used. To further aid the reconstruction, the algorithm for the space-point track seeding is modified to use looser internal cuts and the cut on the number of precision hits is reduced to at least five hits. Tracks are accepted with  $p_T > 0.1$  GeV, and in some cases, inefficiencies for  $p_T > 0.5$  GeV are recovered. The resulting track reconstruction efficiency is shown in Fig. 16. The distribution of candidate fake tracks is shown in Fig. 17.

## 4 Vertexing performance

### 4.1 Primary vertices

Vertexing tools constitute important components of the higher-level tracking algorithms. The residuals of the primary vertex reconstruction are shown in Fig. 18, as obtained without using any beam constraint, for  $t\bar{t}$  events and  $H \rightarrow \gamma\gamma$  events with  $m_H = 120$  GeV. The results shown here for  $H \rightarrow \gamma\gamma$  events are based on tracks reconstructed from the underlying event and do not make use of the measurement of the photon direction in the electromagnetic calorimeter. The primary vertex in  $t\bar{t}$  events has always a rather large multiplicity and includes a number of high- $p_T$  tracks, resulting in a narrower and more Gaussian

Figure 16: Track reconstruction efficiencies as a function of  $p_T$  for  $|\eta| < 2.5$  and  $p_T > 0.1$  GeV (left) and as a function of  $|\eta|$  for two different  $p_T$  ranges (right) in minimum bias events (non-diffractive inelastic events).

Figure 17: Rate of candidate fake tracks as a function of  $p_T$  for  $|\eta| < 2.5$  and  $p_T > 0.1$  GeV (left) and as a function of  $|\eta|$  (right) in minimum bias events (non-diffractive inelastic events). The rate of such tracks is a function of the amount of material, indicating that a large fraction of them are secondaries for which the Monte-Carlo truth information is not kept

distribution than for  $H \rightarrow \gamma\gamma$  events. Table 4 shows the resolutions of the primary vertex reconstruction in these  $t\bar{t}$  and  $H \rightarrow \gamma\gamma$  events, without and with a beam constraint in the transverse plane, as well as the efficiencies to reconstruct and select correctly (within  $\pm 300 \mu\text{m}$ ) these primary vertices in the presence of pile-up at a luminosity of  $10^{33} \text{ cm}^{-2}\text{s}^{-1}$ .

Event type	x-y resolution ( $\mu\text{m}$ )	z resolution ( $\mu\text{m}$ )	Reconstruction efficiency (%)	Selection efficiency (%)
$t\bar{t}$ (no BC)	18	41	100	99
$t\bar{t}$ (BC)	11	40	100	99
$H \rightarrow \gamma\gamma$ (no BC)	36	72	96	79
$H \rightarrow \gamma\gamma$ (BC)	14	66	96	79

Table 4: Primary vertex resolutions (RMS), without and with a beam constraint (BC) in the transverse plane, for  $t\bar{t}$  events and  $H \rightarrow \gamma\gamma$  events with  $m_H = 120 \text{ GeV}$  in the absence of pile-up. Also shown, in the presence of pile-up at a luminosity of  $10^{33} \text{ cm}^{-2}\text{s}^{-1}$ , are the efficiencies to reconstruct and then select the hard-scattering vertex within  $\pm 300 \mu\text{m}$  of the true vertex position in  $z$ . The hard-scattering vertex is selected as the primary vertex with the largest  $\Sigma p_T^2$ , summed over all its constituent tracks.

Figure 18: Primary vertex residual along  $x$ , in the transverse plane (left), and along  $z$ , parallel to the beam (right), for events containing top-quark pairs and  $H \rightarrow \gamma\gamma$  decays with  $m_H = 120 \text{ GeV}$ . The results are shown without pile-up and without any beam constraint.

## 4.2 Secondary vertices

The resolution for the reconstruction of the radial position of secondary vertices for  $J/\psi \rightarrow \mu\mu$  decays in events containing  $B$ -hadron decays (mean  $p_T$  of  $15 \text{ GeV}$  for the  $J/\psi$ ) is shown in Fig. 19. While there are some tails in the resolution distributions (left-hand plot), these are small. The corresponding distributions for three-prong hadronic  $\tau$ -decays in  $Z \rightarrow \tau\tau$  events (mean  $p_T$  of  $36 \text{ GeV}$  for the  $\tau$ -lepton) are shown in Fig. 20. Because there are three charged tracks in close proximity, the reconstruction of these decays is more challenging: the vertex resolutions are Gaussian in the central region, but have long tails as can be seen from the points showing 95% coverage in right-hand plot.

Figure 19: Resolution for the reconstruction of the radial position of the secondary vertex for  $J/\psi \rightarrow \mu\mu$  decays in events containing  $B$ -hadron decays for tracks with  $|\eta|$  around 0 (left) and as a function of the pseudorapidity of the  $J/\psi$  (right). The  $J/\psi$  have an average transverse momentum of 15 GeV.

Figure 20: Resolution for the reconstruction of the radial position of the secondary vertex for three-prong hadronic  $\tau$ -decays in  $Z \rightarrow \tau\tau$  events for tracks with  $|\eta|$  around 0 (left) and as a function of the pseudorapidity of the  $\tau$  (right). In the right-hand plot, the circles with bars correspond to Gaussian fits, as illustrated in the left-hand plot; the points showing 68.3% (95%) coverage show the width of the integrated distribution containing 68.3% (95%) of the measurements (corresponding to  $1\sigma$  ( $2\sigma$ ) for a Gaussian distribution). The  $\tau$ -leptons have an average transverse momentum of 36 GeV.

Finally, Fig. 21 shows the resolution as a function of decay radius for the reconstruction of the radial position of secondary vertices for  $K_s^0$  decays (mean  $p_T$  of 6 GeV) in events containing  $B$ -hadron decays. The resolution in each radial slice is determined from a Gaussian fit to the core of the distribution. It can be seen that there are significant tails: just before the barrel layers, the resolution for decays in the barrel region is good, giving rise to the core; while that from the end-caps is variable, depending on the actual position of the decay, giving rise to a broader distribution. The tails can be reduced and the resolutions improved somewhat by tighter cuts on track quality and the reconstructed invariant mass, if desirable. The effect of crossing the three successive pixel layers is clearly visible as well as the degraded resolution for decays beyond the last pixel layer. Figure 22 shows the resolution as a function of decay radius for the reconstruction of the invariant mass of the charged-pion pair for the same  $K_s^0 \rightarrow \pi^+ \pi^-$  decays. Figure 23 shows the efficiency to reconstruct the  $K_s^0$  decays. The reconstruction requires 3D information provided by the silicon detectors, and hence the efficiency falls to zero once the decay is beyond the penultimate SCT layers.

## 5 Particle identification, reconstruction of electrons and photon conversions

The reconstruction of electrons and of photon conversions is a particular challenge for the inner detector. The fraction of energy lost by electrons traversing the inner detector is shown in Fig. 24. In the energy range over which the inner detector will measure electrons, the fraction has little dependence on the actual electron energy. Electrons lose on average between 20 to 50% of their energy (depending on  $|\eta|$ ) by the time they have left the SCT, as illustrated in Fig. 25. The probability for photons to convert is fairly independent of their energies for  $p_T > 1$  GeV. A histogram of the location of photon conversions in  $|\eta| < 0.8$  is shown in Fig. 26 - the radial structure of the detector is clearly visible. Between 10 to 50% of photons have converted into an electron-positron pair before leaving the SCT, as illustrated in Fig. 27.

The TRT plays a central role in electron identification, cross-checking and complementing the electromagnetic calorimeter, especially at energies below 25 GeV [2]. In addition, the TRT contributes to the reconstruction and identification of electron track segments from photon conversions down to 1 GeV and of electrons which have radiated a large fraction of their energy in the silicon layers.

### 5.1 Electron reconstruction

In the absence of bremsstrahlung, the distribution  $p_{true}/p_{recon}$  should be Gaussian; but in the presence of bremsstrahlung, this is far from true, as can be seen for the end-cap in Fig. 28 (left-hand plot). By fitting electron tracks in such a way as to allow for bremsstrahlung, it is possible to improve the reconstructed track parameters, as shown in Figs. 28 and 29 for two examples of bremsstrahlung recovery algorithms. These algorithms rely exclusively on the inner detector information and therefore provide significant improvements only for electron energies below  $\sim 25$  GeV. The dynamic noise adjustment (DNA) method extrapolates track segments to the next silicon detector layer. If there is a significant  $\chi^2$  contribution, compatible with a hard bremsstrahlung, the energy loss is estimated and an additional noise term is included in the Kalman filter [9]. The Gaussian-sum filter (GSF) is a non-linear generalisation of the Kalman filter, which takes into account non-Gaussian noise by modelling it as a weighted sum of Gaussian components and therefore acts as a weighted sum of Kalman filters operating in parallel [10]. With real data, to improve the fitted track parameters for electrons without deteriorating the fits for non-electrons, it is necessary to assess whether a track is likely to correspond to an electron or not. This can be done to some extent by the algorithms themselves by looking at the fits; additional information can be obtained from the transition radiation in the TRT (see 5.2) and the electromagnetic calorimeter. Ultimately, since information is lost during the bremsstrahlung, there is an unavoidable degradation of

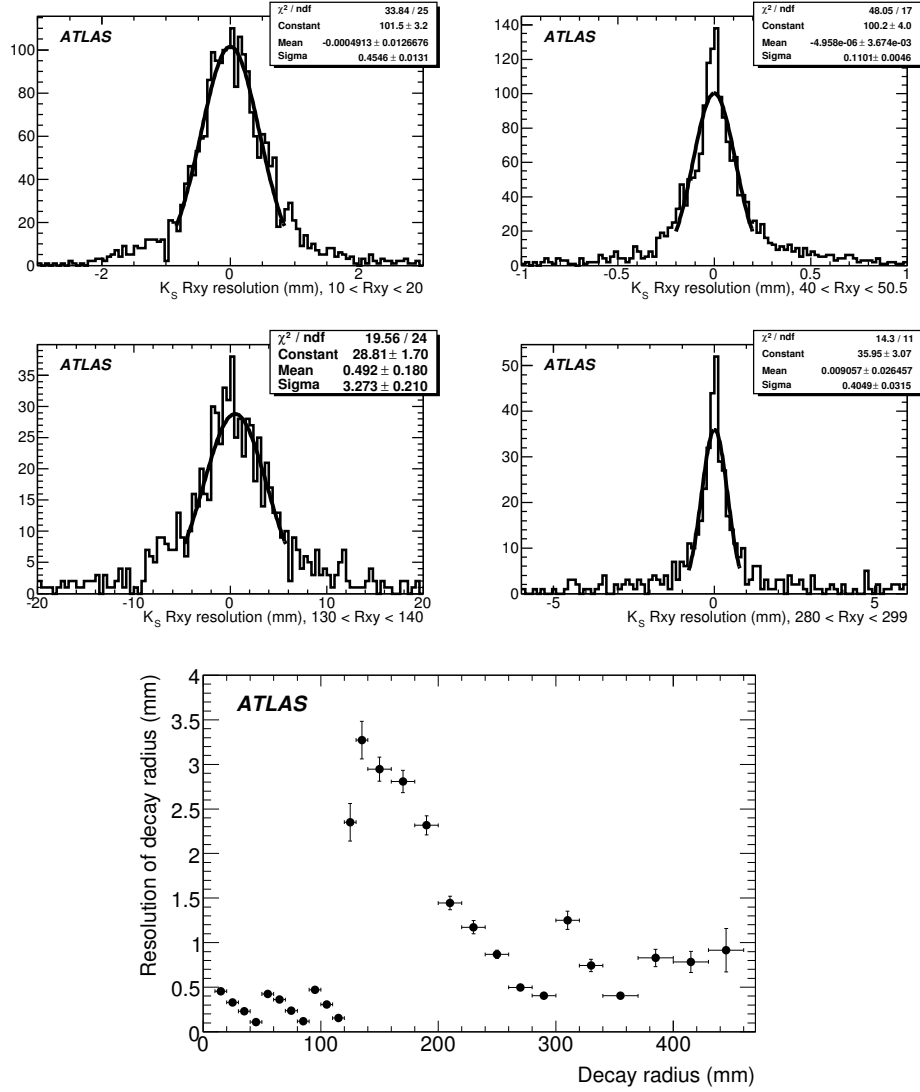

Figure 21: Resolution for the reconstructed radial position of the secondary vertex for  $K_s^0 \rightarrow \pi^+\pi^-$  decays in events containing  $B$ -hadron decays in various radial intervals (upper) and as a function of the  $K_s^0$  decay radius (lower). The resolutions are best for decays just in front of the detector layers. The barrel pixel layers are at: 51, 89 and 123 mm; the first two SCT layers are at 299 and 371 mm.

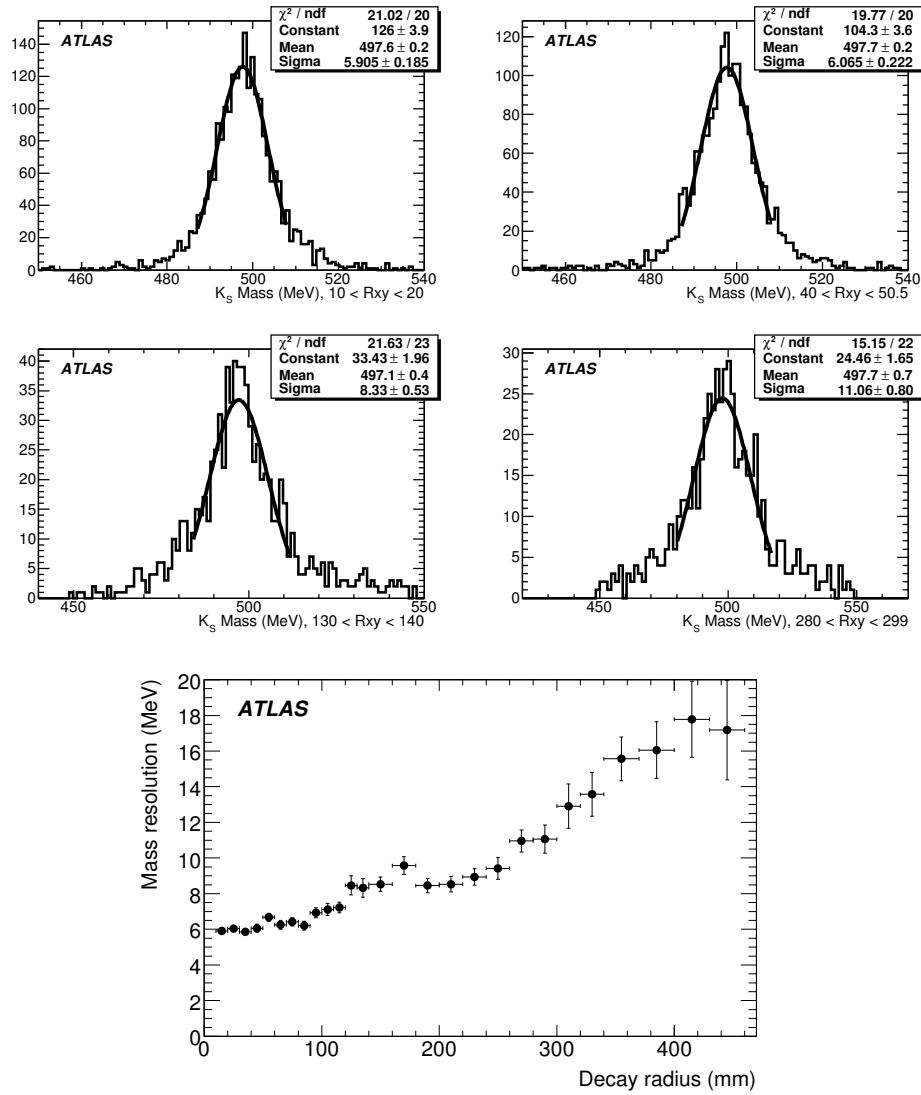

Figure 22: Resolution for the reconstruction of the invariant mass of the charged-pion pair for  $K_S^0 \rightarrow \pi^+ \pi^-$  decays in events containing  $B$ -hadron decays in various radial intervals (upper) and as a function of the  $K_S^0$  decay radius (lower).

Figure 23: Efficiency to reconstruct charged-pion pairs for  $K_s^0 \rightarrow \pi^+\pi^-$  decays in events containing  $B$ -hadron decays as a function of the  $K_s^0$  decay radius (left) and as a function of the  $|\eta|$  of the  $K_s^0$  (right).

Figure 24: Probability distribution as a function of the fraction of energy lost by electrons with  $p_T = 10$  GeV and 25 GeV (integrated over a flat distribution in  $\eta$  with  $|\eta| \leq 2.5$ ) traversing the complete inner detector.

Figure 25: Fraction of energy lost on average by electrons with  $p_T = 25$  GeV as a function of  $|\eta|$ , when exiting the pixel, the SCT and the inner detector tracking volumes. For  $|\eta| > 2.2$ , there is no TRT material, hence the SCT and TRT lines merge.

Figure 26: Radial position of photon conversions in the barrel region ( $|\eta| < 0.8$ ) deduced from Monte-Carlo truth information (arbitrary normalisation).

Figure 28: Probability distributions for the ratio of the true to reconstructed momentum (left) and its reciprocal (right) for electrons with  $p_T = 25$  GeV and  $|\eta| > 1.5$ . The results are shown as probabilities per bin for the default Kalman fitter and for two bremsstrahlung recovery algorithms (see text).

the electron measurement. The algorithms serve to reduce the bias of the track fits caused by the increased track curvature. Only by adding additional information, such as the position of the cluster in the electromagnetic calorimeter [2], is it possible to make a real improvement on the measured momentum.

By allowing for changes in the curvature of the track, the bremsstrahlung recovery algorithms “follow” the tracks better and correctly associate more of the hits, leading to improvements in the reconstruction efficiencies, as can be seen in Fig. 30. GSF has 2-3% greater efficiency than the default reconstruction, since it does not flag hits as outliers, hence a track is less likely to fail the quality cuts on the numbers of hits.

Figure 31 shows the improvements from bremsstrahlung recovery for the reconstructed  $J/\psi \rightarrow ee$  mass. Integrating over the complete pseudorapidity acceptance of the ID, and without using any bremsstrahlung recovery, only 42% of events are reconstructed within  $\pm 500$  MeV of the nominal  $J/\psi$  mass, whereas with the use of the bremsstrahlung recovery, this fraction increases to 53% and 56% for DNA and GSF respectively, and the bias of the peak position is reduced. In the inner detector alone, the  $J/\psi$  signal in the end-caps is more or less completely lost because of the effects of the increased material compared to that in the barrel. The poor performance in the end-caps arises from the significant fraction of energy lost by electrons (O(30)% by the time they have left the pixels) as well as the change in track

Figure 29: Probability distributions for the ratio of the true to reconstructed momentum for electrons with  $p_T = 25$  GeV and  $|\eta| < 0.8$  (left) and  $p_T = 10$  GeV and  $|\eta| > 1.5$  (right). The results are shown as probabilities per bin for the default Kalman fitter and for two bremsstrahlung recovery algorithms (see text).

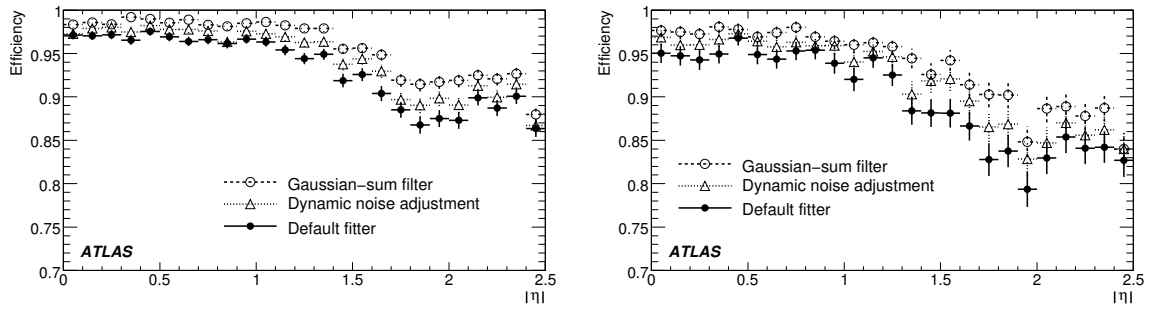

Figure 30: Efficiencies to reconstruct electrons as a function of  $|\eta|$  for electrons with  $p_T = 25$  GeV (left) and  $p_T = 10$  GeV (right). The results are shown for the default Kalman fitter and for two bremsstrahlung recovery algorithms (see text).

Figure 31: Probability for the reconstructed invariant mass of electron pairs from  $J/\psi \rightarrow ee$  decays in events with  $B_d^0 \rightarrow J/\psi(ee)K_s^0$ . Distributions are shown for both electrons with  $|\eta| < 0.8$  (left) and  $|\eta| > 1.5$  (right). The results are shown for the default Kalman fitter and for two bremsstrahlung recovery algorithms (see text). The true  $J/\psi$  mass is shown by the vertical line.

direction. These distributions should be contrasted with those for the muonic decays of the  $J/\psi$  in Fig. 8.

To conclude, the material of the inner detector causes a significant amount of bremsstrahlung for electrons, biasing their fitted parameters. This can be partially compensated within the inner detector using the so-called bremsstrahlung recovery procedures, DNA and GSF. These algorithms should be applied to tracks in a way so as to improve electrons and not degrade pions or muons. DNA runs in a time comparable with other simple fitters, while GSF, albeit producing better results, is a factor of twenty slower than DNA. Exactly how these algorithms are used will depend on individual physics analyses.

## 5.2 Electron identification

While the end-cap TRT (discrete radiator foils) is relatively easy to simulate, the barrel TRT (matrix of fibres) is harder and the best indication of the expected performance comes from the test beam (CTB), where a complete barrel TRT module was tested. Using pion, electron and muon samples in the energy range between 2 and 350 GeV, the barrel TRT response has been measured in the CTB in terms of the high-threshold hit probability, as shown in Fig. 32. The measured performance has been used to parametrise the response in the TRT barrel. The transition-radiation X-rays contribute significantly to the high-threshold hits for electron energies above 2 GeV and saturation sets in for electron energies above 10 GeV. Figure 33 shows the resulting pion identification efficiency (probability of pions being misidentified as electrons) for an electron efficiency of 90%, achieved by performing a likelihood evaluation based on the high-threshold probability for electrons and pions for each straw. Figure 33 also shows the effect of including time-over-threshold information, which improves the pion rejection by about a factor of two when combined with the high-threshold hit information. At low energies, the pion rejection (the inverse of the pion efficiency plotted in Fig. 33) improves with energy as the electrons emit more transition radiation. The performance is optimal at energies of  $\sim 5$  GeV, and pion-rejection factors above 50 are achieved in the energy range of 2–20 GeV. At very high energies, the pions become relativistic and therefore produce more  $\delta$ -rays and eventually emit transition radiation, which explains why the rejection slowly decreases for energies above 10 GeV.

The electron-identification performance expected for the TRT in ATLAS, including the time-over-threshold information, is shown as a function of  $|\eta|$  in Fig. 35 in the form of the pion identification efficiency expected for an electron efficiency of 90% or 95%. The shape observed is closely correlated to the number of TRT straws crossed by the track (see Fig. 34), which decreases from approximately 35 to a minimum of 20 in the transition region between the barrel and end-cap TRT,  $0.8 < |\eta| < 1.1$ , and which

Figure 32: Average probability of a high-threshold hit in the barrel TRT as a function of the Lorentz  $\gamma$ -factor for electrons (open squares), muons (full triangles) and pions (open circles) in the energy range 2–350 GeV, as measured in the combined test-beam (CTB).

Figure 33: Pion efficiency shown as a function of the pion energy for 90% electron efficiency, using high-threshold hits (open circles), time-over-threshold (open triangles) and their combination (full squares), as measured in the combined test-beam.

Figure 34: Number of hits on a track as a function of  $|\eta|$  for a track crossing the TRT.

Figure 35: Pion efficiency expected from simulation as a function of  $|\eta|$  for an efficiency of 90% or 95% for electrons with  $p_T = 25$  GeV.

also decreases rapidly at the edge of the TRT fiducial acceptance for  $|\eta| > 1.8$ . Because of its more efficient and regular foil radiator, the performance in the end-cap TRT is better than in the barrel TRT where it consists of radiating fibres [2].

### 5.3 Conversion reconstruction

Figure 36 shows the efficiency for reconstructing conversions of photons with  $p_T = 20$  GeV and  $|\eta| < 2.1$  as a function of the conversion radius and pseudorapidity, using the standard tracking algorithm combined with the back-tracking algorithm described in Section 2. At radii above 50 cm, the efficiency for reconstructing single tracks drops and that for reconstructing the pair drops even faster because the two tracks are merged. If both tracks from the photon conversion are reconstructed successfully, vertexing tools can be used to reconstruct the photon conversion with high efficiency up to radii of 50 cm. The overall conversion-identification efficiency can be greatly increased at large radii by flagging single tracks as

photon conversions under certain conditions. (The identification is distinct from the reconstruction, since with a single electron, the photon conversion cannot be reconstructed.) Only tracks which have no hits in the vertexing layer, which are not associated to any fitted primary or secondary vertex, and which pass a loose electron identification cut requiring more than 9% high-threshold hits on the TRT segment of the track are retained. The resulting overall efficiency for identifying photon conversions is almost uniform over all radii below 80 cm, as shown in Fig. 37.

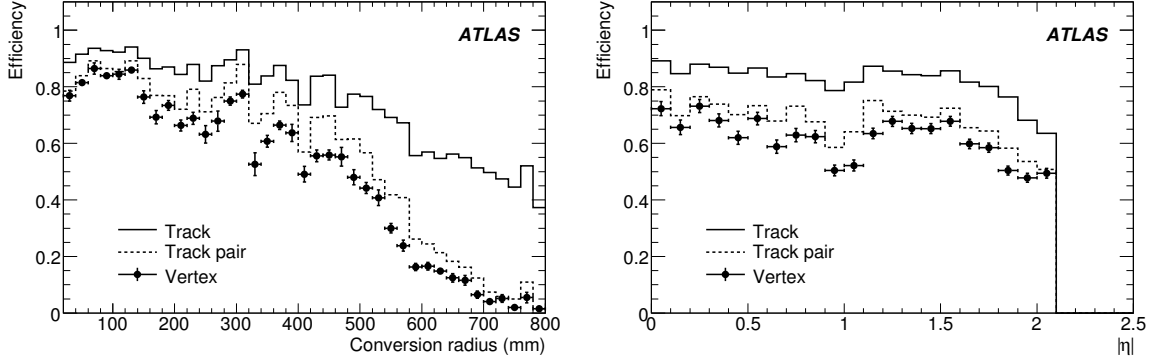

Figure 36: Efficiency to reconstruct conversions of photons with  $p_T = 20$  GeV and  $|\eta| < 2.1$ , as a function of the conversion radius (left) and pseudorapidity (right). Shown are the efficiencies to reconstruct single tracks from conversions, the pair of tracks from the conversion and the conversion vertex.

Figure 37: Efficiency to identify conversions of photons with  $p_T = 20$  GeV and  $|\eta| < 2.1$ , as a function of the conversion radius (left) and pseudorapidity (right). The overall efficiency is a combination of the efficiency to reconstruct the conversion vertex, as shown also in Fig. 36, and of that to identify single-track conversions (see text).

## 6 Conclusions

This paper documents the expected performance for the ATLAS inner detector, focusing on the low-luminosity running at the start-up of the LHC. Most of the performance specifications set out in [1] have been met – it is only at larger values of  $|\eta|$ , where there are significant amounts of material, that the track-finding efficiencies are less than the targets.

The reconstruction of muons, electrons and pions has been studied in detail as a function of transverse momentum and pseudorapidity. For high- $p_T$  muons in the barrel region, the resolution for  $1/p_T$  is expected to be  $0.34 \text{ TeV}^{-1}$  and the resolution for the transverse impact parameter  $10 \mu\text{m}$ . The charge of muons and electrons will be measured in the inner detector over the complete acceptance up to 1 TeV with misidentification probabilities on average of no more than a few percent. In the barrel region, muons with  $p_T \geq 1 \text{ GeV}$  can be identified with efficiencies in excess of 98%. For high- $p_T$  muons, this rises to  $\geq 99.5\%$  across the whole acceptance. Electrons and pions suffer from material effects; for tracks around 5 GeV, they are reconstructed with efficiencies between 70 and 95%. The inner detector is able to reconstruct pions down to 0.2 GeV with efficiencies around 50%. Fake rates are low; even in the core of moderate-energy jets ( $O(50) \text{ GeV } E_T$ ), rates are less than 1%.

Algorithms have been developed to reconstruct primary and secondary vertices, as well as  $K_s^0$  (and other  $V^0$ s) decays and conversions. In the case of  $t\bar{t}$  events, primary vertices can be identified with 99% efficiency in the presence of low-luminosity pile-up.  $K_s^0$  decays can be reconstructed up to a radius of 400 mm, while conversions can be identified by reconstructing pairs of tracks or tagging single electrons in the TRT with 80% efficiency all the way up to a radius of 800 mm.

Electrons suffer from bremsstrahlung caused by the significant material in the inner detector. Algorithms have been developed to improve the reconstruction of electrons, reducing the bias on the measured momentum. While reasonable electron reconstruction is possible in the inner detector barrel, it is quite difficult in the end-caps because of the increased amount of bremsstrahlung – here, the use of the electromagnetic calorimeter will be essential. Electrons can be identified by their transition radiation in the TRT. For an electron efficiency of 90% at  $p_T = 25 \text{ GeV}$ , the pion misidentification probability is of the order of a few percent over most of the acceptance, and the pion rejection will be optimal around 5 GeV.

After many years of preparing the ATLAS inner detector software and having tested it on simulated and test-beam data, we are ready to reconstruct and analyse data from collisions. We now look forward to the first data from the LHC.

# Calibration and Performance of the Electromagnetic Calorimeter

## Abstract

This note describes the calibration of electromagnetic clusters, as implemented in current releases of the ATLAS reconstruction program. A series of corrections are applied to calibrate both the energy and position measurements; these corrections are derived from Monte-Carlo simulations and validated using test-beam data. The possibility of obtaining inter-calibration energy corrections from  $Z \rightarrow ee$  data is also discussed.

## 1 Introduction

In order to realise the full physics potential of the LHC, the ATLAS electromagnetic calorimeter must be able to identify efficiently electrons and photons within a large energy range (5 GeV to 5 TeV), and to measure their energies with a linearity better than 0.5%. The  $W$  boson mass measurement, not considered here, will require better precision.

The procedure to measure the energy of an incident electron or photon in the ATLAS electromagnetic (EM) calorimeter has been described in Ref. [1]. Each step of the energy reconstruction has been validated by a series of beam tests over many years, both using only the calorimeter [2, 3] and also combined with representative components from all detector sub-systems. This has allowed considerable refinement of the calorimeter simulation. This simulation is then used to model the behaviour of the full detector.

One of the key ingredients for the description of the detector performance is the amount and position of the upstream material. The understanding of the ATLAS detector geometry has also made progress over the years; an overview of the present knowledge of the detector and its expected performance can be found in [4]. The amount of material in front of the calorimeter for the as-built detector is significantly larger than was initially estimated; this leads to larger energy losses for electrons and to a larger fraction of photons converting (see Figs. 1 and 2).

The standard ATLAS coordinate system is used: the beam direction defines the  $z$ -axis, and the  $x$ - $y$  plane is transverse to the beam direction. The azimuthal angle  $\phi$  is measured around the beam axis and the polar angle  $\theta$  is the angle from the beam axis. The pseudorapidity is defined as  $\eta \equiv -\ln(\tan(\theta/2))$ .

### 1.1 Electron and photon candidates

The “sliding window” algorithm [5] is used to find and reconstruct electromagnetic clusters. This forms rectangular clusters with a fixed size, positioned so as to maximise the amount of energy within the cluster. An alternate algorithm is available which forms clusters based on connecting neighbouring cells until the cell energy falls below a threshold; this is not used by the default electron and photon reconstruction. The optimal cluster size depends on the particle type being reconstructed and the calorimeter region: electrons need larger clusters than photons due to their larger interaction probability in the upstream material and also due to the fact that they bend in the magnetic field, radiating soft photons along a range in  $\phi$ . Several collections of clusters are therefore built by the reconstruction software, corresponding to different window sizes. These clusters are the starting point of the calibration and selection of electron and photon candidates.

One of the recent improvements in the calibration procedure is that electron and photon candidates are treated separately. For each of the reconstructed clusters, the reconstruction tries to find a matching track within a  $\Delta\eta \times \Delta\phi$  window of  $0.05 \times 0.10$  with momentum  $p$  compatible with the cluster energy  $E$

Figure 1: Average energy loss vs.  $|\eta|$  for  $E = 100$  GeV electrons before the presampler/strips (crosses/open circles), and reconstructed energies before/after (solid/open boxes) corrections.

Figure 2: Fraction of photons converting at a radius of below 80 cm (115 cm) in open (full) circles, as a function of  $|\eta|$  [4].

( $E/p < 10$  [6, 7]). If one is found, the reconstruction checks for presence of an associated conversion. An electron candidate is created if a matched track is found and no conversion is flagged. Otherwise, the candidate is classified as a photon.

This early classification allows applying different corrections to electron and photon candidates. It is the starting point of a more refined identification based largely on shower shapes, described in companion notes [6, 7]. Four levels of electron quality are defined (loose, medium, tight, and tight without isolation). The available photon selection corresponds to the tight electron selection (excluding tracking requirements). The medium and tight selections are used in some parts of the calibration analysis described in this note. But the corrections derived are then applied to all electron and photon candidates.

## 1.2 Calorimeter granularity

The electromagnetic calorimeter (Fig. 3) was designed to be projective in  $\eta$ , and covers the pseudorapidity range  $|\eta| < 3.2$ . Precision measurements are however restricted to  $|\eta| < 2.5$ ; regions forward of this are outside of the scope of this note. The calorimeter is installed in three cryostats: one containing the barrel part ( $|\eta| < 1.475$ ), and two which each contain the two parts of the end-cap ( $1.375 < |\eta| < 3.2$ ). Its accordion structure provides complete  $\phi$  symmetry without azimuthal cracks. The total thickness of the calorimeter is greater than 22 radiation lengths ( $X_0$ ) in the barrel and greater than  $24X_0$  in the end-caps. It is segmented in depth into three longitudinal sections called layers, numbered from 1 to 3 outwards from the beam axis. These layers are often called “front” (or “strips”), “middle,” and “back.” The  $\eta$  granularity of the calorimeter for the front and middle layers is shown in Table 1. The  $\phi$  size of cells is 0.025 in layer 2 and 0.1 in layer 1. Layer 3 has a granularity of  $\Delta\eta \times \Delta\phi = 0.050 \times 0.025$ . For  $|\eta| < 1.8$ , a presampler detector is used to correct for the energy lost by electrons and photons upstream of the calorimeter. All these regions must be treated separately in deriving the individual corrections.

The effect of the choice of cluster size on electron and photon energy reconstruction has been studied in Refs. [1] and [8]. These results are still the baseline of the present software. For electrons, the energy in the barrel electromagnetic calorimeter is collected over an area corresponding to  $3 \times 7$  cells in the middle layer, i.e.  $\Delta\eta \times \Delta\phi = 0.075 \times 0.175$ . For unconverted photons, the area is limited to  $3 \times 5$  cells in the middle layer, whereas converted photons are treated like electrons. The cluster width in  $\eta$  increases with increasing  $|\eta|$ ; therefore, an area of  $5 \times 5$  cells in the middle layer is used for both electrons and photons in the end-cap calorimeter.

Figure 3: Sketch of the accordion structure of the EM calorimeter [8].

	$ \eta $ range	Cell $\eta$ size	
		Layer 1	Layer 2
Barrel	0–1.4	0.025/8	0.025
	1.4–1.475	0.025	0.075
end-cap	1.375–1.425	0.05	0.05
	1.425–1.5	0.025	0.025
	1.5–1.8	0.025/8	0.025
	1.8–2.0	0.025/6	0.025
	2.0–2.4	0.025/4	0.025
	2.4–2.5	0.025	0.025

Table 1: Calorimeter  $\eta$  granularity in layers 1 and 2.

### 1.3 Geometries and data sets

The present knowledge of the detector geometry, resulting from the detector survey, is described in [4] (Sec. 9). But even before the final survey, it was known that the inner detector services located in the crack region would be wider than originally expected, and that the end-cap electromagnetic calorimeter would be shifted by about 4 cm, compared to the nominal (and pointing) geometry described in Ref. [1]. This is taken into account in the simulation, and is treated as a misalignment in the cell calibration procedure described below.

High statistics samples of single electrons and photons, processed with the full detector simulation based on GEANT 4.7 [9], were used to derive and study the corrections. Two detector geometries are available. The first is the “ideal geometry,” which contains the best knowledge of the dead material, but which has no misalignments except for the 4 cm shift of the end-caps. The data sets based on this geometry are used to derive the corrections and for most of the performance studies. The second available geometry is a distorted one, in which extra material is added between the tracking detectors and the calorimeters, and in which misalignments are introduced. For example, the amount of material in the inner detector has increased in some regions by up to 7% of a radiation length for positive  $\phi$ , and the density of material in the gap between the barrel and end-cap cryostats has increased by a factor of 1.7. The distorted data-sets using this geometry are used to estimate systematic uncertainties and to check the sensitivity of the methods to additional material. In addition to these single-particle data sets,  $Z \rightarrow ee$  decays are also available.

The standard calorimeter reconstruction for simulated data includes the effects of possible cell-level miscalibrations by smearing the measured energy of each cell (by about 0.7%), therefore increasing the constant term of the energy resolution. (The fractional energy resolution is conventionally parametrised as  $\sigma(E)/E = a/E \oplus b/\sqrt{E} \oplus c$ , where  $a$  is the noise term,  $b$  is the sampling term and  $c$  is the constant term.) Unless otherwise stated, the results in this note do not include this additional smearing, and therefore correspond to assuming a perfect cell-level calibration.

### 1.4 Energy and position reconstruction

The calibration of the LAr calorimeter is factorised into a channel-by-channel calibration of the electronics readout and an overall energy scale determination.

The first step, often called “electronics calibration”, converts the raw signal extracted from each cell (in ADC counts) into a deposited energy. The method used for this step, which is beyond the scope of this note, was described in Ref. [1]. It was refined and validated when final barrel and end-cap modules were studied in test beams [2, 3]. In the past two years, the experience gained and the algorithm developed

were integrated into the standard ATLAS calibration software [10].

The second step deals with clusters. The energies deposited in the cells of each individual layer of a cluster are summed, and an energy-weighted cluster position is calculated for each layer. There are several important effects which must then be understood:

- Due to the accordion geometry, the amount of absorber material crossed by incident particles varies as a function of  $\phi$ . This produces a  $\phi$  modulation of the reconstructed energy.
- The shower is not fully contained in the  $\eta$  window chosen for clusters, and the cells have a finite granularity. This introduces a modulation in the energy and a bias in the measured position (“S-shape”) which depend on the particle impact point within a cell.
- A perfectly projective particle, coming from the origin of the coordinate system, intersects the calorimeter at the same  $\eta$  position in all layers. The luminous region, however, extends significantly in  $z$ ; a particle from a vertex away from the origin intersects the calorimeter at slightly different  $\eta$  positions in each layer. Properly combining these  $\eta$  measurements requires an accurate parametrisation of the shower depth within each layer.

An early study of these corrections, using both simulation and test beam data, can be found in [11]. The present prediction of these effects and their dependencies on the impact point and energy of the incident particle are described in detail in this note.

The measured energy and position of EM clusters are corrected as described below (see Fig. 4). The required scale of the correction is illustrated by the upper points in Fig. 1, which shows the reconstructed energies of  $E = 100$  GeV electrons before and after calibration. It is about 10% over most of the calorimeter, but is larger in the transition region between cryostats.

Figure 4: Cluster correction steps.

- To start with, the energies in the cluster cells are summed, and an energy weighted  $(\eta, \phi)$  position is calculated for each calorimeter layer. Before applying the cluster corrections, the energy resolution has a constant term of about 0.65% (quoted for photons at  $|\eta| = 0.3$ ).
- As the first step, corrections are applied to the cluster position, measured in each layer. These are described in Sec. 2. The position measurements from the first two layers are then combined to define the shower impact point in the calorimeter, which can then be used for energy reconstruction.
- The next step is to combine the energies deposited in each layer. Two separate procedures have been developed to do this which are described in Secs. 3.1 and 5. In the first one, per-layer energy coefficients, called longitudinal weights, are adjusted to optimise at the same time the energy resolution and the linearity of the response. In the second one, the simulation is used to correct for different types of energy loss one by one, by correlating each of them with measured observables. The corrections are calculated separately for electrons and photons, and determined as a function of  $|\eta|$ . This reduces the local constant term to about 0.61%.
- The third step, described in Sec. 3.2, uses the shower impact point to correct the total energy for modulations in  $\eta$  and  $\phi$ . This reduces the local constant term to about 0.43%.

In spite of the skill and care put into the detector construction, calibration, and operation, some local or “medium range” inhomogeneities in the calorimeter response have to be expected: localised high-voltage or temperature effects or unexpected additional dead material must be detected and corrected for using data. It is planned to use  $Z \rightarrow ee$  decays to measure and correct for such effects and to help fix the absolute energy scale. The method developed and the precision expected are described in Sec. 6.

## 2 Cluster position measurement

The position of a cluster is measured in  $\eta$  and  $\phi$ . The positions are first calculated independently for each calorimeter layer as the energy-weighted barycenters of all cluster cells in the layer. (The barrel and end-cap are also treated separately at this stage.) Secondly, the individual layer measurements are corrected for known systematic biases. Finally, the position measurements from layers 1 and 2 are combined to produce the overall cluster position. The position corrections are derived using single-particle electron and photon data samples. Each sample is mono-energetic, and the available samples span the range 5–1000 GeV.

The  $\eta$  positions that are calculated at this stage are “detector”- $\eta$ , corresponding to the angle that would be made by a particle originating from the origin of the detector coordinate system. In order to properly compare the calculated detector- $\eta$  positions with the  $\eta$  of a generated incident particle, which will in general have its production vertex offset in  $z$  from the detector origin, one must assume a depth for each calorimeter layer. Here, “depth” refers to the radial distance from the beam axis for the barrel calorimeter, and to the distance from the  $x-y$  plane passing through the origin for the end-cap calorimeter. The depths used are those which optimise the  $\eta$ -position resolution; they are shown in Fig. 5.

Figure 5: Calorimeter depths versus  $|\eta|$  for layers 1 and 2 and for 100 GeV photons. The points show the derived optimal depths, and the curves are piecewise polynomial fits to the points. For layer 2 of the barrel, a single curve yielded an adequate fit across  $|\eta| = 0.8$ ; this may be revisited in future versions. From 100 GeV photons.

### 2.1 $\eta$ position correction (S-shape)

The cluster  $\eta$  position is first calculated in each layer as the energy-weighted barycenter of the cluster cells in that layer. (In layer 1, only the three strips around the cluster center are used, regardless of the specified cluster size.) Due to the finite granularity of the readout cells, these measurements are biased towards the centers of the cells. For examples, see Fig. 6. This figure plots the difference in  $\eta$  between the incident particle and the reconstructed cluster ( $\Delta\eta = \eta_{\text{true}} - \eta_{\text{reco}}$ ) as a function of  $\nu$ , the relative  $\eta$

offset of the cluster within the cell, which varies from  $-1/2 \dots 1/2$  across the cell. (The sign of  $\Delta\eta$  is inverted for negative  $\eta$ , and in plots it is usually shown as a fraction of the cell  $\eta$  width.) The general functional form shown in this figure is often referred to as “S-shape”.

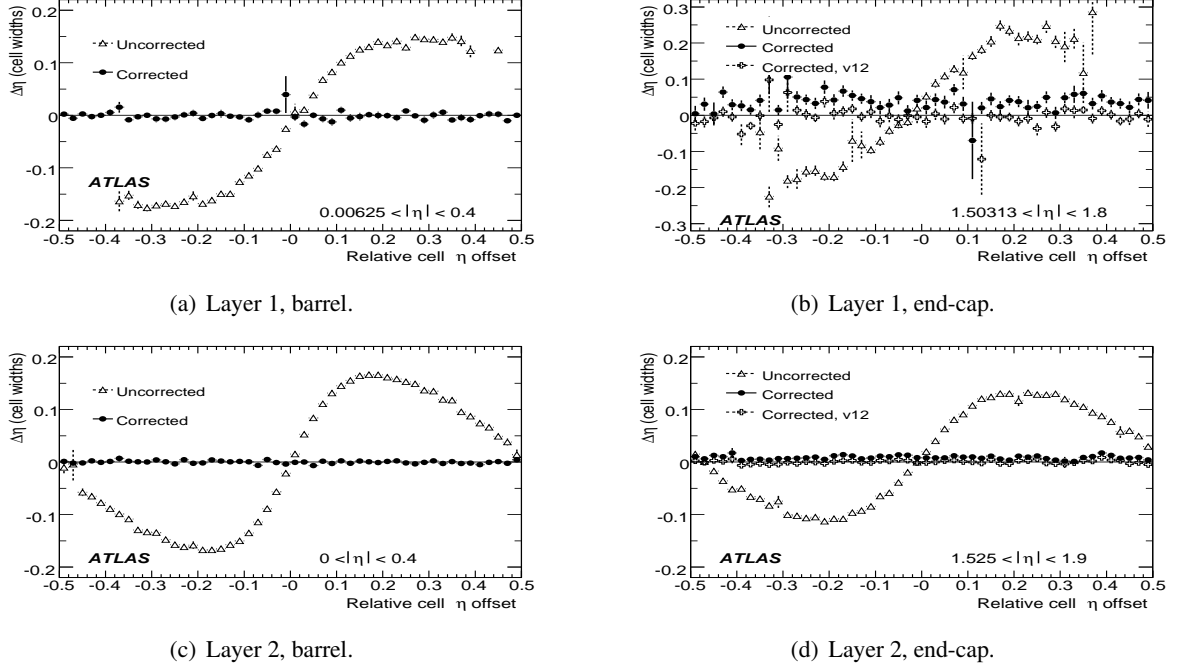

Figure 6:  $\Delta\eta$  versus  $v$  before and after correction for different regions and for 100 GeV electrons. Note the small systematic offset in the end-cap due to a change in the end-cap geometry since the corrections were derived. For comparison, the “v12” points show results reconstructed using the same geometry as that used to derive the corrections.

Figure 6 shows the correction averaged over an  $|\eta|$  range. The actual correction, however, varies continuously over  $\eta$ , due to changes in the detector geometry (the corrections change to a much greater extent near discontinuities in the calorimeter). For example, the calorimeter cells are not perfectly projective (as the inner and outer cell faces are parallel to the beam-line, rather than being perpendicular to a line from the detector origin); this induces a bias away from the center of the calorimeter. The correction will also depend on the cluster energy, as that affects the average shower depth.

To derive the correction, the calorimeter is divided in  $\eta$  into regions based on where the behaviour of the correction changes discontinuously. Within each region, an empirical function is constructed to describe the correction, and an unbinned fit is performed to simulated data for a particular cluster size, type, and energy.

The function used for the empirical fit is of the form

$$f(v) = A \tan^{-1} Bv + Cv + D|v| + E, \quad (1)$$

where  $-1/2 \leq v \leq 1/2$  across a cell (for the actual fit, the parameters are redefined to reduce correlations). To turn this into a function of  $\eta$ , the fit parameters are written as polynomials (usually of second or third degree) in  $|\eta|$ :

$$A = \sum_i a_i |\eta|^i, \quad (2)$$

and similarly for the other parameters. The fit parameters are then the coefficients  $a_i$ ,  $b_i$ , etc.

One feature to note about this function is that, in general,  $f(-1/2) \neq f(1/2)$ , so that it will be discontinuous crossing a cell boundary. For layer 1, this is usually acceptable, since reconstructed cluster positions cluster well away from the cell boundary (Fig. 7(a)). However, in layer 2, the distribution of reconstructed cluster positions remains populated across the cluster boundary (Fig. 7(b)). Therefore, for layer 2, the function is modified so that  $f(-1/2) = f(1/2)$ .

Figure 7:  $\Delta\eta$  versus  $|\eta|$  in layers 1 and 2 of the barrel, along with the empirical fit function.

In some cases, there is still a significant periodic residual after fitting to this form; in such cases, an additional general trigonometric term is added to the fit:

$$f'(v) = f(v) + \alpha \cos(\beta\pi v + \gamma). \quad (3)$$

Finally, a few regions near the calorimeter edges do not exhibit the S-shape form; a general polynomial is used as the empirical function there.

The correction is evaluated separately for each cluster size and type (electrons, photons). The difference in the correction between electrons and photons is a few percent, and there is about a 10% difference between  $5 \times 5$  and  $3 \times N$  clusters.

The correction also depends on energy; over the range 25–1000 GeV, the required correction varies by  $\sim 20\%$ . To apply the correction for a given cluster, the correction is first tabulated for each of the energies for which simulated data samples were available. The final correction is then found by doing a cubic polynomial interpolation within this table. Note a subtlety here: the energies at which the corrections are tabulated are the true cluster energies. However, when the correction is applied, only the reconstructed cluster energy is known. Since the position corrections are done before the energy corrections, the reconstructed cluster energy will be systematically lower than the true energy. If this were used for the interpolation, this would bias the position measurements. So, for the purpose of this interpolation, a crude energy correction is performed by scaling the reconstructed cluster energy by the ratio of the true to reconstructed energy observed in a 100 GeV sample, parametrised as a function of  $|\eta|$ . This energy correction is used only for the energy interpolation of the position corrections.

Plots of  $\Delta\eta$  before and after corrections for several regions are shown in Fig. 6. Note that since the present corrections were derived, the simulated detector geometry was changed slightly in the end-cap, in order to match more closely the as-built detector. This results in a small systematic offset of  $O(10^{-4})$  in these regions.

The  $\eta$  position resolution for photons versus  $|\eta|$  is shown for the two main calorimeter layers (strips and middle) in Fig. 8. The resolution is fairly uniform as function of  $|\eta|$  and is  $2.5\text{--}3.5 \times 10^{-4}$  for the strips (which have a size of 0.003 in  $\eta$  in the barrel electromagnetic calorimeter) and  $5\text{--}6 \times 10^{-4}$  for the middle-layer cells (which have a size of 0.025 in  $\eta$ ). The regions with worse resolution correspond to the

barrel/end-cap transition region and, for the strips, to the region with  $|\eta| > 2$ , where the strip granularity of the end-cap calorimeter becomes progressively much coarser.

Figure 8: Expected  $\eta$  position resolution versus  $|\eta|$  for  $E = 100$  GeV photons for the two main layers of the barrel and end-cap EM calorimeters [4].

Figure 9: Profile plot of  $\Delta\phi$  versus  $|\eta|$  before (triangles) and after (circles) correction. For 100 GeV electrons.

## 2.2 $\phi$ position correction

The measurement of the cluster  $\phi$  position must also be corrected. These corrections are applied only in calorimeter layer 2 (the  $\phi$  granularity is best in this layer). As opposed to the  $\eta$  direction, the accordion geometry results in more energy sharing between cells in the  $\phi$  direction, which washes out the S-shape in this direction. There is, however, a small bias in the  $\phi$  measurement which depends on the average shower depth with respect to the accordion structure (and thus on  $|\eta|$ ). A profile plot of  $\Delta\phi = \phi_{\text{true}} - \phi_{\text{reco}}$  before the correction is shown in Fig. 9. (The sign of the offset is flipped for  $\eta < 0$ , as the two halves of the calorimeter are identical under a rotation.) The discontinuity at  $|\eta| = 0.8$ , where the absorber thickness and the middle layer depth change, is clearly visible.

Figure 10: Expected  $\phi$  position resolution as a function of  $|\eta|$  for electrons and photons with an energy of 100 GeV.

Figure 11: Resolution of  $\eta$  position measurement from layers 1 and 2 combined for 100 GeV photons.

The correction derived here is symmetric in  $\phi$ . In the real detector, the absorbers sag slightly due to gravity, causing a  $\phi$ -dependent modulation in the  $\phi$  offset with a maximum value of about 0.5 mrad [8]. This has not been included in the present simulations, and it is therefore not taken into account in this correction. Studies have shown, however, that the extra smearing of the position measurement from this effect has a negligible contribution to the widths of the invariant mass distributions of  $e^+e^-$  pairs. (These studies were performed by generating decays of massive particles using a toy Monte Carlo, smearing the decay products with energy and angular resolutions roughly appropriate to ATLAS, and comparing the

widths of the resulting invariant mass distributions before and after shifting the  $\phi$  positions by  $A \cos \phi$ . No significant broadening was observed for  $A < 50$  mrad.) The contribution of this effect to the constant term of the energy resolution has not been studied quantitatively, but should also be small.

To produce a correction, the data are binned in  $\eta$ . The result for one sample is shown in Fig. 9. This function is interpolated in  $\eta$ ; it is then also interpolated in energy as for the  $\eta$  position correction.

The  $\phi$  position resolution versus  $|\eta|$  is shown for calorimeter layer 2 in Fig. 10. Electron clusters, which get smeared in the  $\phi$  direction as they radiate while propagating through the magnetic field, have a worse  $\phi$  position resolution than do photon clusters. A discontinuous step is seen in the resolution at  $|\eta| = 0.8$ , where the absorber thickness changes, and the resolution is worst in the transition region between the cryostats.

### 2.3 Position measurement combination

The individual layer  $\eta$  and  $\phi$  measurements are combined to produce the overall  $\eta$  and  $\phi$  for a cluster. For  $\phi$ , only layer 2 is used, so the combination is trivial except in the overlap region, where the energy-weighted average of the barrel and end-cap  $\phi$  measurements is used. For  $\eta$ , both layer 1 and layer 2 are averaged. However, layer 1 is weighted three times as much as layer 2 to roughly take into account the better resolution in layer 1. This prescription, which does not use the actual position resolutions and does not account for correlations, is known to be suboptimal and will be improved in future software versions.

Note that the  $\eta$  combination implicitly assumes that the incoming particle is projective. If its production vertex is shifted from the origin, then the combined  $\eta$  will be biased. This is illustrated in Fig. 11, which shows the resolution of the combined cluster  $\eta$  measurement. Here, the measured cluster  $\eta$  is compared to the  $\eta$  position of the calorimeter intersected by the true particle track at a depth corresponding to the cluster barycenter. This is shown both for all clusters and for clusters with the  $z$  position of the production vertex within 5 mm of the detector center.

### 2.4 Shower direction

At high luminosity, the inner detector cannot accurately determine the interaction vertex due to the large number of additional interactions. This is an issue for the reconstruction of a  $H \rightarrow \gamma\gamma$  signal. For this analysis, achieving the best possible resolution on the invariant mass of the photon pair is crucial for separating the signal peak from the continuum background. If the  $z$ -position of the interaction vertex is unknown, then there will be a large uncertainty in the polar angle of the photons and thus in the pair invariant mass. We can, however, recover information about the incidence angle of the photons by comparing the impact points that are reconstructed in the first and second layers of the EM calorimeter. To do this, we need to know the photon  $\eta$  position and the shower barycenter in each of the two layers (Fig. 5). We can then draw a straight line between these two ( $\eta$ , depth) points; extending this line to the beam axis gives an estimate of the position of the interaction vertex.

Here, this method is applied to single photons with energies compatible with photons from  $H \rightarrow \gamma\gamma$  decays. For  $m_H = 120$  GeV, these photons are predominantly in the range 50 – 100 GeV. Figure 12 shows the resolutions of the photon angle and the interaction vertex measurements as functions of  $|\eta|$ . Figure 13 shows the same resolution as a function of the photon energy, for  $|\eta| < 0.5$ .

## 3 Cluster energy measurement

Most of the energy of an electromagnetically interacting particle is deposited in the sensitive volume of the calorimeter, including the lead absorbers and the liquid-argon gaps. A small fraction is deposited in

Figure 12: Angular and vertex resolution as functions of  $|\eta|$  (Gaussian fits), multiplied by  $\sqrt{E}$ .Figure 13: Angular and vertex resolution as functions of  $E$  (Gaussian fits), for  $|\eta| < 0.5$ .

non-instrumented material in the inner detector, the cryostats, the solenoid, and the cables between the presampler and the first EM calorimeter layer. Energy also escapes from the back of the calorimeter.

The cluster energy is calculated as a linearly weighted sum of the energy in each of the three calorimeter layers plus the presampler. The factors applied to the four energies are called longitudinal weights and their purpose is to correct for the energy losses, providing optimum linearity and resolution.

The ATLAS longitudinal weighting method was first described in Ref. [8]. However, recent ATLAS test beam analyses [2, 3, 12] provided simple extensions of the technique. They also allowed validating this method with real data.

The first section below describes the weighting correction that is performed in current versions of the reconstruction, called the 4-weight method. This is followed by a description of the corrections for  $\eta$ - and  $\phi$ -dependent modulations in the energy. A more advanced energy-dependent calibration scheme, called the calibration hit method, is described separately in Section 5.

### 3.1 4-weight method

The weighting method described in this section is a modification of that described in Ref. [8] and is currently the default in ATLAS reconstruction. The weights used are functions only of  $|\eta|$ ; no energy dependencies are used. The method could be readily extended to include  $\phi$ - and energy-dependent weights in order to minimise residual non-linearities. The reconstructed energy is given by

$$E_{\text{reco}} = A(B + W_{\text{ps}}E_{\text{ps}} + E_1 + E_2 + W_3E_3), \quad (4)$$

where  $E_{\text{ps}}$  and  $E_{1...3}$  are the cluster energies in the presampler and the three layers of the calorimeter (including sampling fractions). The offset term  $B$  corrects for upstream energy losses for which the corresponding electron has not reached the presampler (PS). In the limiting case of no energy in the

PS, this offset corresponds to the energy an electron loses before it undergoes a hard bremsstrahlung for which the resulting photon passes through the PS without converting (i.e., no energy recorded in the PS). The parameters  $A$ ,  $B$ ,  $W_{\text{ps}}$ , and  $W_3$  are calculated by a  $\chi^2$  minimisation of  $(E_{\text{true}} - E_{\text{reco}})^2 / \sigma(E_{\text{true}})^2$  using Monte Carlo single particle samples, where  $\sigma(E_{\text{true}})$  is a parametrisation of the expected energy resolution. This minimisation is done for separate  $|\eta|$  bins, defined by the  $\Delta\eta = 0.025$  granularity of the second layer of the calorimeter. Equal-sized samples with energies between 10 and 200 GeV are combined for the fits (the linearity of low energy points could be improved by using more events at those energies.) The fits are done separately for each cluster size and particle type (electron and photon).

A special parametrisation is applied in the gap region between the barrel and end-cap calorimeters ( $1.447 < |\eta| < 1.55$ ), within which the parametrisation of Eq. (4) is not adequate. Moreover, this region is instrumented with scintillator tiles that can be used to recover some of the energy lost in the gap. The parametrisation used in the crack is

$$E_{\text{reco}} = A(B + E_b + E_e + W_{\text{scint}}E_{\text{scint}}), \quad (5)$$

where  $E_b$  and  $E_e$  are the energies the cluster deposits in the barrel and end-cap calorimeters, respectively.  $E_{\text{scint}}$  is the scintillator energy, and  $W_{\text{scint}}$  the weight applied to it. This parametrisation is found to perform significantly better than that used in [1].

The longitudinal weights in Eq. (4) were extracted for electrons and photons and are shown as a function of  $|\eta|$  in Fig. 14. In Fig. 14(a) one can see that the overall scale  $A$  for electrons (solid) is larger than that for photons. The reason is due to the fact that photons travel on average  $9/7X_0$  before they start losing energy. This effect is close to 1% in the middle of the barrel and increases with the increase of upstream material. The offset term  $B$  is shown in Fig. 14(b); photons have a very small offset, as expected. (Future versions of the correction will use larger statistics to reduce the scatter observed in the fit results.) The PS weight  $W_{\text{ps}}$  shown in Fig. 14(c) is the usual factor applied to preshower/presampler energy responses to correct for upstream losses. Finally, in Fig. 14(d),  $W_3$  is a weight applied to the last calorimeter layer to correct for energy leakage behind the calorimeter.

Detailed studies have revealed that the physical meaning attributed to these weights is only approximate. For example, the weights compensate for losses after the PS via the minimisation procedure. In addition, the weights have a non-negligible energy dependence. However, this energy dependence does not result in large non-linearities because the weights adjust their values to compensate. These effects are more evident at low energies  $E < 15$  GeV, and with large amounts of upstream material. A more rigorous treatment of the longitudinal weighting is presented in Sec. 5.

The performance of this method is shown in Sec. 4

### 3.2 Cluster energy modulation corrections

As the  $\phi$  impact position of a particle shifts across the accordion structure of the absorbers, the amount of passive absorber material it encounters and thus the ratio  $R \equiv E_{\text{reco}}/E_{\text{true}}$  varies slightly, with a periodicity equal to that of the absorber spacing. This effect is small, with a maximum value of about a half-percent. Further, at lower energies, the  $\phi$  position resolution becomes comparable to the absorber spacing; this contributes to washing out the effect at these energies. The reconstructed energy is corrected for this.

To derive the correction, the calorimeter is binned in  $|\eta|$ . The binning used is not uniform, but is chosen so as to segregate regions of the calorimeter with non-uniform  $R$ . Within each  $|\eta|$  bin,  $R$  is plotted versus the  $\phi$  offset of the cluster relative to the absorber. These plots are divided into  $\phi$  bins, each bin is fit to a Gaussian, and the means of the fits are plotted. The resulting plot is then normalised to unity and fit to a two-term Fourier series:

$$f(\phi) = 1 + A[\alpha \cos(N\phi + C) + (1 - \alpha) \cos(2N\phi + D)], \quad (6)$$

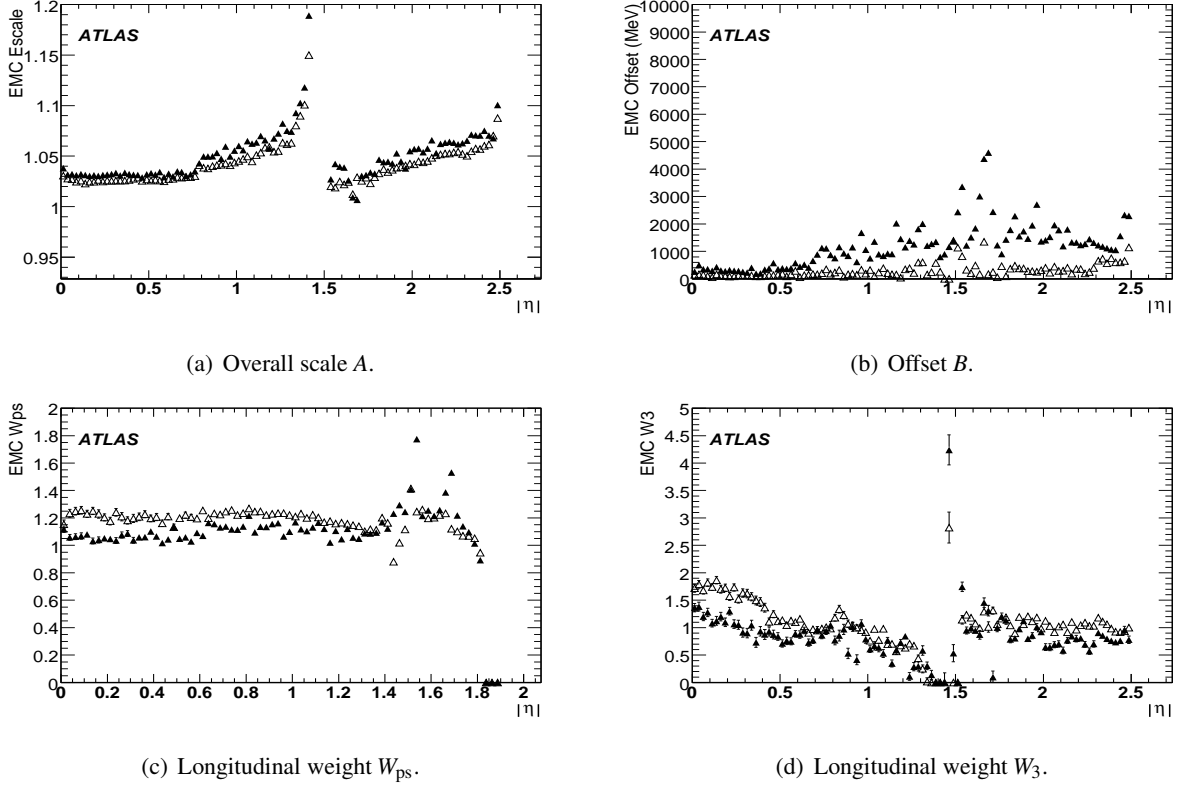

Figure 14: Fitted longitudinal weights for electrons (solid) and photons (open) as functions of  $|\eta|$ .

for fit parameters  $A$ ,  $\alpha$ ,  $C$ , and  $D$ . Parameter  $\alpha$  is restricted to the range 0–1.  $N$  is the total number of absorbers in  $2\pi$  (1024 in the barrel and 768 in the end-cap/end-cap). An example of such a fit is shown in Fig. 15.

Fits are performed separately for each energy, cluster size, and particle type. To apply the correction, it is calculated for each  $\eta$  and energy bin. It is then interpolated both in  $\eta$  and in energy. This correction reduces the constant term in the energy resolution (for photons at  $|\eta| = 0.3$ ) from 0.61% to 0.50%.

Energy modulations are also observed along the  $\eta$  direction. The energy of a cluster is defined as the energy within a rectangular window of fixed size in  $\eta \times \phi$ . The window can only shift by an integral number of cells; however, the impact point of a particle may be anywhere within a cell. Thus, on average, a larger fraction of the hits cluster energy will be contained in the window when the particle hits at the center of a cell than if it hits near an edge. The size of this effect is a few tenths of a percent, and is larger for smaller cluster sizes. The modulation can be fit well with a quadratic; see Fig. 16. Note that this modulation is very small,  $< 0.1\%$ , in the  $\phi$  direction, due to increased energy sharing between the cells; this modulation is not presently corrected. (A larger modulation was seen in the test beam [13], which used  $3 \times 3$  clusters.)

The plots to fit are prepared in a similar manner as for the  $\phi$  modulations, except that the  $x$ -axis is taken to be the  $\eta$  offset within a cell. The plots from all bins where the detector is mostly uniform are then combined into a single plot; that is, the  $|\eta|$  ranges 0.05–0.75, 0.85–1.30, and 1.70–2.50. The resulting plot is then scaled so as to average to unity and fit to a quadratic. The correction is performed separately for each energy, cluster size, and particle type. The final correction is then determined by interpolating in energy. An example fit is shown in Fig. 16. Applying this correction further reduces the constant term to 0.43%. A major contribution to the remaining constant term is from the  $\phi$ -dependency of the inner detector material distribution. (The present weighting correction is averaged over  $\phi$ .)

Figure 15: Energy modulation in  $\phi$  for 200 GeV  $3 \times 7$  electrons with  $0.2 < |\eta| < 0.4$ , along with the modulation fit.

Figure 16: Energy modulation in  $\eta$  for 200 GeV  $3 \times 7$  electrons, along with the modulation fit [4].

## 4 Energy calibration performance

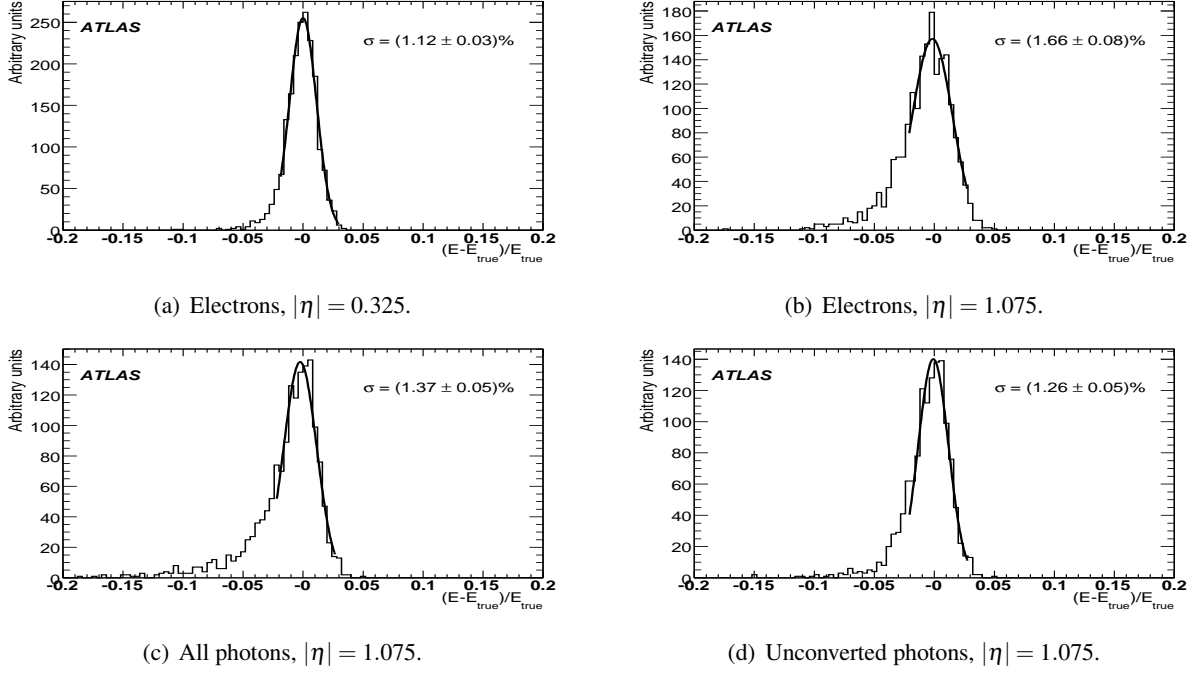

This section shows the performance of the calibration chain used in the current version of the ATLAS reconstruction software used for all of the electron and photon reconstruction and identification studies reported here and elsewhere.

### 4.1 Single electrons and photons

In Fig. 17, the energy response, plotted as the difference between measured and true energy divided by the true energy, is shown for electrons with an energy of 100 GeV for two illustrative  $\eta$ -positions in the barrel electromagnetic calorimeter. The central value of the energy is reconstructed with excellent precision ( $\sim 3 \times 10^{-4}$ ) if one assumes perfect knowledge of the material in front of the calorimeter. Both the Gaussian core and the non-Gaussian component of the tail of the energy distribution are significantly worse at the point with larger  $|\eta|$  due to the larger amount of material in front of the calorimeter. The resolution and non-Gaussian tails are better for photons than for electrons, but are somewhat worse for all photons than for photons that do not convert before leaving the volume of the inner detector.

The linearity (relative difference between the fitted mean energy and the true energy) and resolution are shown in Fig. 18 for electrons and photons. The expected performance is very similar for electrons and photons, with a somewhat larger degradation at larger values of  $|\eta|$  in the case of electrons, as expected from the impact of upstream material. For electrons, the linearity is shown for  $|\eta| = 0.3$  (barrel) and  $|\eta| = 2.0$  (end-cap). The deterioration of the performance seen in the end-cap is attributed to the absence of a presampler ( $|\eta| > 1.8$ ) and the relatively limited statistics of the simulated samples. The resolution shown in Fig. 18(b) is given for three  $|\eta|$  points:  $|\eta| = 0.3$  (inner barrel),  $|\eta| = 1.1$  (outer barrel), and  $|\eta| = 2.0$  (end-cap). The resolution drop at larger  $|\eta|$  is attributed to the significant increase of upstream material in front of the calorimeter with respect to the small  $|\eta|$  region. The extra material causes increased early showering upstream of the calorimeter, which affects the lateral shower shape in the calorimeter. Since Eq. (4) absorbs the corrections for lateral losses into the overall scale constant  $A$ , an increase in lateral-loss fluctuations will result in a deterioration of the resolution. The fits in Fig. 18(b) give a sampling term of  $(10.17 \pm 0.33)\%$  at small  $|\eta|$ , and  $(14.5 \pm 1.0)\%$  in the end-cap.

In Fig. 19, the energy resolution for electrons and photons is shown as a function of  $|\eta|$ . The photon resolution is better than the electron resolution in regions with more material in front of the calorimeter. The extracted constant term of the resolution is shown for photons in Fig. 20 after the weight and modulation corrections. This figure also shows the constant term observed when the standard simulation of cell-level miscalibrations is enabled in the reconstruction program. In Fig. 21, the linearity and resolution

Figure 17: Difference between measured and true energy normalised to true energy at  $E = 100$  GeV.

as a function of  $|\eta|$  is shown for a range of energies for single photons.

#### 4.2 Mass resolution obtained in $H \rightarrow 4e$ and $H \rightarrow \gamma\gamma$ final states

Figure 22 shows the reconstructed distribution, after calibration, of the invariant mass of the electrons in  $H \rightarrow 4e$  decays, with  $m_H = 130$  GeV. (Loose electron selection applied, as defined in [6].) A global constant term of 0.7% has been included in the electromagnetic calorimeter resolution for the two plots in this subsection. The central value of the reconstructed invariant mass is correct to  $\sim 1$  GeV, corresponding to a precision of 0.7%, and the expected Gaussian resolution is  $\sim 1.5\%$ . The non-Gaussian tails in the distribution amount to 20% of events lying further than  $2\sigma$  away from the peak. They are mostly due to bremsstrahlung, particularly in the innermost layers of the inner detector, but also to radiative decays and to electrons poorly measured in the barrel/end-cap transition region of the electromagnetic calorimeter.

Figure 23 shows the reconstructed photon pair invariant mass for  $H \rightarrow \gamma\gamma$  decays with  $m_H = 120$  GeV (tight photon selection applied and barrel/end-cap transition region excluded). The photon directions are derived from a combination of the direction measurement in the electromagnetic calorimeter described above (see Section 2.4) with the primary vertex information from the inner detector. The central value of the reconstructed invariant mass is correct to  $\sim 0.2$  GeV, corresponding to a precision of 0.2%, and the expected resolution is  $\sim 1.2\%$ . Most of the non-Gaussian tails at low values of the reconstructed photon pair mass are seen to be due to photons which convert in the inner detector. The shift in the means comes from the fact that the corrections to-date do not distinguish between converted and unconverted photons.

#### 4.3 Study of systematic effects using $H \rightarrow 4e$

The energy linearity for electrons in  $H \rightarrow 4e$  is shown in Fig. 24(a) for samples based on the ideal (full triangles) and distorted (circles) geometries. The departure from linearity for the distorted geometry is attributed to the presence of extra material in front of the calorimeter. The corresponding resolution is shown in Fig. 24(b) for the distorted geometry.

(a) Electron energy linearity.

(b) Electron energy resolution.

(c) Photon energy linearity.

(d) Photon energy resolution.

Figure 18: Energy linearity (left) and resolution (right) for electrons (top) and photons (bottom).

Figure 19: Energy resolution for electrons and photons as a function of  $|\eta|$ .Figure 20: Extracted constant term of the energy resolution for photons, as a function of  $|\eta|$ , after weight and modulation corrections. Also shown with cell-level miscalibrations enabled.

The uniformity in  $\phi$  and  $\eta$  observed in this sample is shown in Fig. 25. The non-uniformities seen at higher  $|\eta|$  and at positive  $\phi$  are due to simulated extra material in these regions. In the  $\phi$ -uniformity plot (Fig. 25(a)) a residual modulation is observed. This is most likely due to an artefact in the simulation. The longitudinal weights used in the reconstruction depend only on  $\eta$ , and are averaged over  $\phi$ . Adding a dependency on  $\phi$  as well would make the energy scale along  $\phi$  more uniform and also improve the mass resolution of  $Z \rightarrow ee$ .

## 5 Energy correction using calibration hits

This section describes an alternate method for calculating the total energy from the energies in the individual calorimeter layers and the presampler. It is a development of ideas introduced in [14, 15] to

(a) Energy linearity.

(b) Energy resolution.

Figure 21: Energy linearity and resolution for photons ( $5 \times 5$  clusters).Figure 22:  $M(eeee)$  from Higgs boson decays with  $m_H = 130$  GeV (energy from calorimeter only, with no Z boson mass constraint).Figure 23:  $M(\gamma\gamma)$  from Higgs boson decays with  $m_H = 120$  GeV. The shaded plot corresponds to at least one photon converting at  $r < 80$  cm.

analyse test beam data and is described in some detail in [16]. Special simulations are used in which the energy deposited by a particle is recorded in all detector materials, not just the active ones. Through these simulations, the energy depositions in the inactive material can be correlated with the measured quantities. For example, the energy lost in the material in front of the calorimeter (inner detector, cryostat, etc.) can be estimated from the energy deposited in the presampler. The result is a method which provides a modular way to reconstruct the energies of electrons and photons by decoupling all the different corrections. This approach eases comparisons between electrons and photons, and might be particularly useful in the initial stages of the experiment.

The cluster energy is decomposed into three pieces, which will be treated separately below:

$$E = E_{\text{cal}} + E_{\text{front}} + E_{\text{back}}, \quad (7)$$

where  $E_{\text{cal}}$  is the energy deposited in the electromagnetic calorimeter,  $E_{\text{front}}$  is the energy deposited in the presampler and in the inactive material in front of the calorimeter, and  $E_{\text{back}}$  is the energy that leaks out the rear of the EM calorimeter.

This analysis uses simulated single-particle, mono-energetic electron and photon samples, with energies ranging from 25 to 500 GeV.

(a) Energy linearity.

(b) Energy resolution.

Figure 25: Electron energy uniformity in  $\eta$  and  $\phi$ , integrated over other kinematic variables, for the ideal (full triangles) and distorted (circles) geometries.

### 5.1 Reconstruction of the energy deposited in the calorimeter

The energy deposited by a particle in the EM calorimeter,  $E_{\text{cal}}$ , is estimated as

$$E_{\text{cal}} = C_{\text{cal}}(X, \eta)(1 + f_{\text{out}}(X, \eta))E_{\text{cl}}, \quad (8)$$

where

- $E_{\text{cl}} = \sum_{i=1}^3 E_i$ , and  $E_{1\dots3}$  are the energies deposited in each of the three calorimeter layers in a given cluster. In the following,  $E_{\text{ps}}$  will denote the energy deposited in the presampler. The energies  $E_i$  available at this stage of the reconstruction are the energies deposited in the liquid-argon ionisation medium divided by a region-dependent sampling fraction.
- $X$  is the the longitudinal barycentre or shower depth, defined by

$$X = \frac{\sum_{i=1}^3 E_i X_i + E_{\text{ps}} X_{\text{ps}}}{\sum_{i=1}^3 E_i + E_{\text{ps}}}, \quad (9)$$

where  $E_i$  is as above and  $X_i$  is the longitudinal depth, expressed in radiation lengths, of compartment  $i$ , computed from the centre of the detector. The  $X_i$ , which are computed using a geantino<sup>1</sup> scan, are functions of  $\eta$ .

- $\eta$  is the cluster barycentre, corrected for the S-shape effect (see Sec. 2.1).
- $f_{\text{out}}$  is the fraction of the energy deposited outside the cluster.
- $C_{\text{cal}}(X, \eta)$  is the calibration factor for the energy in the EM calorimeter.

The calibration factor  $C_{\text{cal}}$  is defined as the average ratio between the true energy deposited in the EM calorimeter (both absorbers and ionisation medium) and the reconstructed cluster energy  $E_{\text{cl}}$ . It is within a few percent of unity, and takes into account effects such as the dependence of the sampling fraction on  $\eta$  and on the longitudinal profile of the shower. Once the correction factor  $C_{\text{cal}}$  is expressed as a function of  $X$  it is fairly energy independent. The correction factor averaged over all energies is shown in Fig. 26(a). Its dependence on  $X$  is parametrised with a second order polynomial. The fit is performed excluding the bins with less than 0.5% of the total statistics. This criterion is also applied to all the fits performed in the following.

Due to the presence of the magnetic field and bremsstrahlung radiation, the fraction of energy deposited in the calorimeter outside of the cluster is energy dependent. Since only single electrons and photons with no noise or underlying event are simulated, this fraction is easily calculated. The profile of the out-of-cluster energy is asymmetric with the tail on the high side. However the most probable value, obtained with a Gaussian fit around the maximum of the distribution ( $-2\sigma$ ,  $+1.5\sigma$ ), is energy independent when plotted as a function of  $X$ . The most probable value of the fraction of energy deposited outside the cluster averaged over all energies is shown in Fig. 26(b) for electrons and photons and the two  $|\eta|$  values. Electrons and photons behave similarly in the central region but differently in the forward region. This is due to the large difference in the amount of material present in front of the calorimeter ( $\sim 2.5X_0$  at  $|\eta| = 0.3$  and  $\sim 7X_0$  at  $|\eta| = 1.65$ ) combined with the presence of bremsstrahlung and the magnetic field.

---

<sup>1</sup>A “geantino” is an imaginary non-interacting particle used in the simulation. The properties of the material crossed by the particle are recorded.

(a)  $C_{\text{cal}}$  vs.  $X$ .

(b) Fraction of out-of-cluster energy.

Figure 26: Correction factor  $C_{\text{cal}}$  and fraction of out-of-cluster energy as a function of the shower depth  $X$ , averaged over all energies, at two representative  $|\eta|$  points. The dashed lines show the results of the parametrisation.

## 5.2 Energy deposited in front of the calorimeter

The energy lost in the material in front of the calorimeter (inner detector, cryostat, coil, and material between the presampler and strips) is parametrised as a function of the energy lost in the active material of the presampler ( $E_{\text{ps}}$ ):

$$E_{\text{front}} = a(E_{\text{cal}}, \eta) + b(E_{\text{cal}}, \eta)E_{\text{ps}} + c(E_{\text{cal}}, \eta)E_{\text{ps}}^2. \quad (10)$$

An example of this relation is shown in Fig. 27. All coefficients are parametrised in terms of the energy deposited by a particle in the calorimeter ( $E_{\text{cal}}$ ) and  $\eta$ . The coefficient  $c$  is used only in the end-cap,  $1.55 < |\eta| < 1.8$ , and is set to zero otherwise. Note explicitly that  $E_{\text{front}}$  includes the energy deposited in the presampler and between the presampler and the strips. An alternate form for  $E_{\text{front}}$ , which depends on the energy in the first calorimeter layer in addition to  $E_{\text{ps}}$ , was also tried. This did not improve the resolution, so the simpler parametrisation above is retained.

Figure 27: Energy lost in front of the EM calorimeter as a function of the energy measured in the presampler at  $|\eta| = 0.3$  for electrons of 100 GeV. The dashed curve shows the parametrisation derived for electrons.

Figure 28: Energy lost in front of the calorimeter as a function of shower depth  $X$ , for electrons of 100 GeV at  $|\eta| = 1.9$ , in a region where the calorimeter is not instrumented with the presampler.

In the region  $1.8 < |\eta| < 3.2$ , not instrumented with the presampler, the energy deposited in front of the calorimeter is parametrised as a function of  $X$  with a second degree polynomial. Figure 28 shows

this correlation for electrons and photons of 100 GeV at  $|\eta| = 1.9$ . The coefficients of this polynomial are parametrised in terms of  $E_{\text{cal}}$ .

### 5.3 Longitudinal leakage correction

The energy deposited by the showers behind the EM calorimeter is computed as a fraction of the energy reconstructed in the calorimeter. This fraction, when parametrised as a function of  $X$ , is fairly energy independent both for electrons and photons. Averaged over the particle energies, it is parametrised by

$$f_{\text{leak}} \equiv E_{\text{back}}/E_{\text{cal}} = f_0^{\text{leak}}(\eta)X + f_1^{\text{leak}}(\eta)e^X. \quad (11)$$

Figure 29 shows the leakage and the result of the fit for  $|\eta| = 0.3$  and 1.65.

Figure 29: Fraction of energy deposited behind the calorimeter, averaged over particle energies, as a function of the shower depth  $X$ . The parametrisation used is superimposed.

### 5.4 Results

The total cluster energy is computed by adding these three contributions. Example distributions of reconstructed energies are shown in Fig. 30. Mean values and standard deviations are found from a fit to a Crystal-Ball function (a Gaussian with a low-side tail of the form  $(1 - x)^{-n}$ ).

The resolution is shown in Fig. 31 as a function of the particle energy for electrons and photons at two  $|\eta|$  values and in Fig. 32 for various photon energies and all  $\eta$  values. The sampling term is shown in Fig. 33 as a function of  $|\eta|$  for electrons and photons.

For electrons, the sampling term increases from 8.7% at low  $|\eta|$  to 21% at  $|\eta| = 1.55$ . This worsening of the energy resolution is related to the increase of the material in front of the calorimeter. This effect is much less relevant for photons, which have a maximum sampling term of 12%. The constant term is in general lower than 0.6% and is related to the energy modulation in a cell (see Sec. 3.2), not corrected at this stage. The linearity, the ratio between the fitted mean value and the true particle energy, is shown in Fig. 34. It is better than 0.5% over the full  $|\eta|$  range and in the energy interval 25–500 GeV.

The results from the calibration hits correction are comparable in terms of resolution and linearity with the longitudinal weights method. However there are a few differences worth mentioning. The coefficients of the longitudinal weights method are averaged over a range of energies, while the parametrisations of the calibration hits method are energy dependent. This means that it should be easier to extend the calibrated energy range for the calibration hits method without compromising energy linearity. Another important difference is that while the coefficients of the longitudinal weights method have no direct

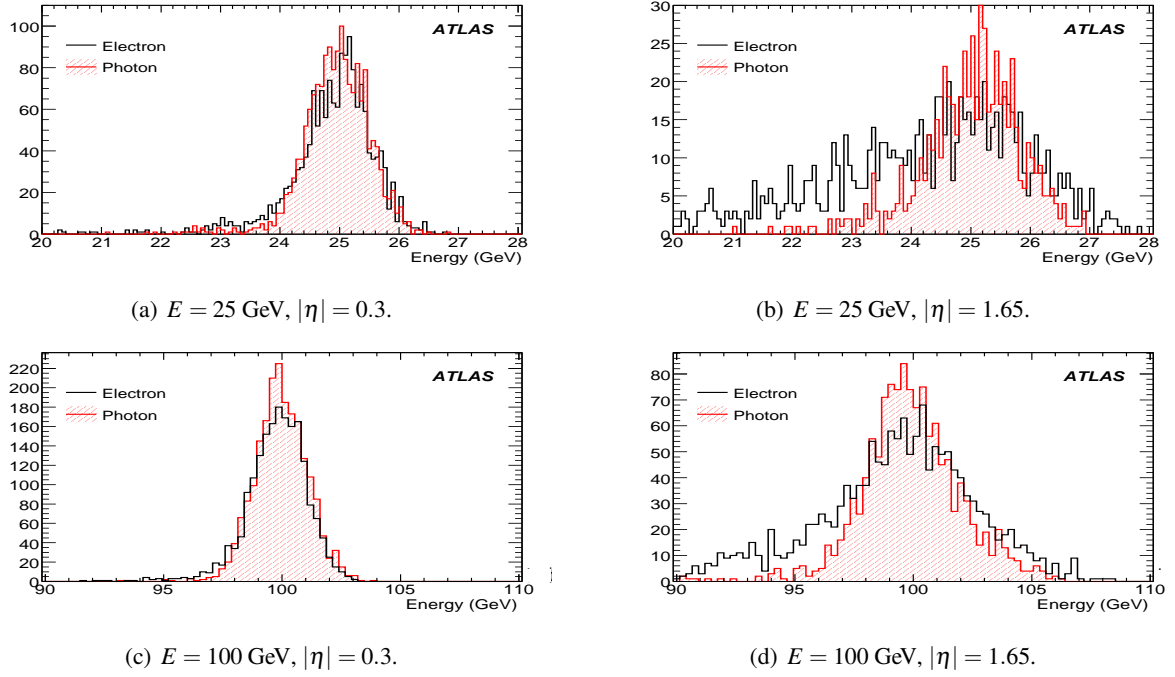

Figure 30: Total reconstructed energy profiles.

Figure 31: Resolution versus particle energy.

Figure 32: Resolution for various photon energies as a function of  $|\eta|$ .Figure 33: Sampling term as a function of  $|\eta|$ .

Figure 34: Linearity for various particle energies as a function of  $|\eta|$ .

physical meaning, the parametrisation of the calibration hits method allows isolating the different components of the calibrated cluster energy: that deposited in the calorimeter, inside and outside of the cluster, and in front and behind of it. The knowledge of these separate contributions, which depend on accurate and detailed simulations of the tracker and the calorimeters, could be particularly useful in the early stages of the experiment, for example to disentangle effects such as a miscalibration of the calorimeter or an imperfect knowledge of the inner detector material. It is also worth noting that the estimate of the energy lost in front of the calorimeter is crucial to obtaining a good resolution and linearity; at low energies and large rapidities, a large fraction of the energy of an electron is deposited in front of the calorimeter. The calculation of missing momentum could also benefit from this separation of effects.

## 6 In-situ calibration with $Z \rightarrow ee$ events

### 6.1 Motivation

In the EM calorimeter, the construction tolerances and the calibration system ensure that the response is locally uniform, with a constant term  $< 0.5\%$  over regions of size  $\Delta\eta \times \Delta\phi = 0.2 \times 0.4$ . This has been shown with test beam data [13]. Electron pairs from  $Z$  boson decays can then be used to intercalibrate the 384 regions of such size within the acceptance of  $|\eta| < 2.4$ . These regions must be intercalibrated to within  $0.5\%$  in order to achieve a desired global constant term of  $< 0.7\%$ . The basic idea of this calibration method is to constrain the di-electron invariant mass distribution to the well-known  $Z$  boson line shape. A second goal of the calibration is to provide the absolute calorimeter electromagnetic energy scale. This must be known to an accuracy of  $\sim 0.1\%$  in order to achieve the ATLAS physics goals<sup>2</sup>.

### 6.2 Description of the method

Long-range non-uniformities can arise for many reasons, including variations in the liquid argon impurities and temperature, amount of upstream material, mechanical deformations, and high voltage (as localised calorimeter defects may necessitate operating a small number of channels below nominal voltage). For a given region  $i$ , we parametrise the long-range non-uniformity modifying the measured electron energy as  $E_i^{\text{reco}} = E_i^{\text{true}}(1 + \alpha_i)$ . Neglecting second-order terms and supposing that the angle between the two electrons is perfectly known, the effect on the di-electron invariant mass is:

$$M_{ij}^{\text{reco}} \simeq M_{ij}^{\text{true}} \left(1 + \frac{\alpha_i + \alpha_j}{2}\right) = M_{ij}^{\text{true}} \left(1 + \frac{\beta_{ij}}{2}\right), \quad (12)$$

where  $\beta_{ij} \equiv \alpha_i + \alpha_j$ .

<sup>2</sup>Except for the  $W$  boson mass measurement, which needs a much better knowledge of the energy scale ( $\sim 0.02\%$ ).

The method to extract the  $\alpha$ 's is fully described in [17] and is done in two steps. First, the  $\beta$ 's are determined, then the  $\alpha$ 's. For a given pair of regions  $(i, j)$ , the coefficient  $\beta_{ij}$  and its associated uncertainty are determined by minimising the following log-likelihood:

$$-\ln L_{\text{tot}} = \sum_{k=1}^{N_{ij}} -\ln L \left( M_k / \left( 1 + \frac{\beta_{ij}}{2} \right), \sigma_{M,k} \right), \quad (13)$$

where  $k$  counts all selected events populating the pair of regions  $(i, j)$ ,  $M_k$  is the di-electron invariant mass of event  $k$ , and  $L(M, \sigma_M)$  quantifies the compatibility of an event with the  $Z$  boson line shape and is described below. Fits with only one event are removed. Once the  $\beta$ 's are determined from the minimisation, the  $\alpha$ 's can be found from the overdetermined linear system given by  $\beta_{ij} \equiv \alpha_i + \alpha_j$ . This is done using a generalised least squares method, and gives an analytic solution.

The  $Z$  boson line shape is modeled with a relativistic Breit-Wigner distribution [18, 19]:

$$\text{BW}(M) \sim \frac{M^2}{(M^2 - M_Z^2)^2 + \Gamma_Z^2 M^4 / M_Z^2}, \quad (14)$$

where  $M_Z$  and  $\Gamma_Z$  are the mass and the width of the  $Z$  boson. They were measured precisely at LEP; the values used are, respectively,  $91.188 \pm 0.002$  GeV and  $2.495 \pm 0.002$  GeV [20]. In proton-proton collisions, the mass spectrum of the  $Z$  boson differs from the Breit-Wigner shape of the partonic process cross section. The probability that a quark and antiquark in the interacting  $pp$  system produce an object of mass  $M$  falls with increasing mass. In order to take this into account, the Breit-Wigner is multiplied by the ad-hoc parametrisation  $\mathcal{L}(M) = 1/M^\beta$ . The parton luminosity parameter  $\beta$  is assumed to be a constant and is determined by fitting the  $Z$  boson mass distribution obtained with events generated with PYTHIA version 6.403 [21]. Figure 35(a) shows the  $Z$  boson mass distribution fitted with a Breit-Wigner with and without the parton luminosity factor. The fitted value of the parameter  $\beta$  is  $1.59 \pm 0.10$ ; this will be used in the following. Since the photon propagator and the interference term between the photon and the  $Z$  boson were not taken into account in the previous parametrisation, the parton luminosity term also accounts for the effects of these two terms.

Figure 35: (a)  $Z$  boson mass distribution for PYTHIA events fitted with a Breit-Wigner distribution with (solid line) and without (dashed line) the parton luminosity factor.  $\chi^2/N_{\text{DOF}}$  is 1.09 and 3.96, respectively. (b) Residual distribution fitted with a Gaussian.

Finally, in order to take into account the finite resolution of the electromagnetic calorimeter, the Breit-Wigner multiplied by the parton luminosity term is convoluted with a Gaussian:

$$L(M, \sigma_M) = \int_{-\infty}^{+\infty} \text{BW}(M-u) \mathcal{L}(M-u) \frac{e^{-u^2/2\sigma_M^2}}{\sqrt{2\pi}\sigma_M} du, \quad (15)$$

where  $\sigma_M$  is the resolution of the measured mass. It is related to the electron energy resolution via

$$\frac{\sigma_M}{M} = \frac{1}{2} \sqrt{\left(\frac{\sigma_{E_1}}{E_1}\right)^2 + \left(\frac{\sigma_{E_2}}{E_2}\right)^2}. \quad (16)$$

At  $|\eta| = 0.3$ , the sampling term of the electron energy resolution is equal to 10.0% and increases with increasing  $|\eta|$ . Technically, the integral is converted to a discrete summation over the convolution parameter  $u$  which takes values between  $-5\sigma_M$  and  $+5\sigma_M$ .

### 6.3 Generator-level tests

The method is first tested on generator-level  $Z \rightarrow ee$  Monte Carlo events. These were generated using PYTHIA 6.403 [21] with  $M_Z = 91.19$  GeV and  $\Gamma_Z = 2.495$  GeV. Events are required to have at least one electron with  $p_T > 10$  GeV and  $|\eta| < 2.7$  and a di-electron invariant mass  $M_{ee} > 60$  GeV. To simulate the detector resolution, generated electron energies are smeared to obtain  $\sigma_E/E = 10\%/\sqrt{E/\text{GeV}}$ .

For each calorimeter region  $i$ , a bias  $\alpha_i$  is generated from a Gaussian distribution with a mean  $\mu_{\text{bias}}$  and width  $\sigma_{\text{bias}}$ . These will be called the “injected”  $\alpha$ ’s,  $\alpha_{\text{inj}}$ .

For the first tests,  $\mu_{\text{bias}}$  is fixed to 0 and  $\sigma_{\text{bias}}$  to 2%. The calibration method explained above is applied to 50,000 events after selection. The residual distribution ( $\alpha_{\text{fit}} - \alpha_{\text{inj}}$ ) is shown in Fig. 35(b). The mean value of the residual distribution corresponds to the energy scale, and its width to the energy resolution. Thus it can be seen that the fitting method gives unbiased estimators of the injected  $\alpha$ ’s.

In the case where  $\mu_{\text{bias}}$  is different from zero, the mean value of the residual distribution will be different from zero. For example, for  $\mu_{\text{bias}} = -3\%$ ,  $\langle \alpha_{\text{fit}} - \alpha_{\text{inj}} \rangle = 0.1\%$ . This is a consequence of neglecting the higher-order terms in the Taylor expansion of Eq. (12). Iterating the procedure twice suffices to recover an unbiased estimate of the  $\alpha$ ’s, as shown in Fig. 36(a).

Figure 36: (a) Mean value of the Gaussian fitting the residual distribution as a function of the number of iterations for different mean values of the injected  $\alpha$ ’s; (b) Constant term as a function of the number of events or as a function of the luminosity.

Figure 35(b) also shows the resulting uniformity. After the fit, the RMS of the distribution has been reduced from 2% to 0.4%. The RMS of the residual distribution is a measure of the expected long-range constant term. Figure 36(b) shows the long-range constant term as a function of the number of reconstructed  $Z \rightarrow ee$  decays or of the integrated luminosity assuming an event selection efficiency of 25%. Therefore, by summing the local constant term of 0.5% with the long-range constant term of 0.4% obtained here, a total constant term of about 0.7% could be achieved with  $\sim 100 \text{ pb}^{-1}$ . These results assume perfect knowledge of the material in front of the electromagnetic calorimeter.

## 6.4 Results with distorted geometry

The previous section showed results based on generator-level Monte Carlo. The results in this section use PYTHIA events with full detector simulation and reconstruction, using a geometry with additional material in front of the electromagnetic calorimeter.

The number of events available is 349,450 corresponding to an integrated luminosity of  $\sim 200 \text{ pb}^{-1}$ . Events with at least two reconstructed electrons are kept. The two leading electrons are required to be of at least medium quality [6], to have  $p_T > 20 \text{ GeV}$  and  $|\eta| < 2.4$ , and to be of opposite sign. Finally, the di-electron invariant mass is required to be within  $80 < M_{ee} < 100 \text{ GeV}$ . The total selection efficiency is 21.5%; the efficiency for finding two electron candidates within  $|\eta| < 2.4$  is 50%.

The calibration method is applied first without injecting any biases ( $\alpha_{\text{inj}} = 0$  for all regions). However, the presence of the misalignments and extra material means that there will be some biases intrinsic to the simulation. These “true” biases can be estimated using generator information:

$$\alpha_{\text{true},i} = \frac{1}{N_i} \sum_k^{N_i} \frac{p_T^{\text{reco},k} - p_T^{\text{gen},k}}{p_T^{\text{gen},k}}, \quad (17)$$

where  $k$  counts over the  $N_i$  electrons falling in region  $i$ , and  $p_T^{\text{reco},k}$  and  $p_T^{\text{gen},k}$  are the reconstructed and true transverse momenta of electron  $k$ . The distribution of  $\alpha_{\text{true}}$  is shown in Fig. 37(a), as is the results of the fit. The low-end tail corresponds to regions located in the gap between the barrel and end-cap cryostats (Fig. 38(a)), where the density of material has been increased by a factor of 1.7. There is fair agreement between the  $\alpha$ ’s extracted using the data-driven method and those estimated from generator information. Figure 37(b) shows the difference between  $\alpha_{\text{fit}}$  and  $\alpha_{\text{true}}$ ; a Gaussian fitted to this distribution has a mean of 0.1% and a width of 0.5%. The distribution of  $\alpha_{\text{fit}}$  as a function of  $\eta$  and  $\phi$  is shown in Fig. 38 for the ideal and distorted geometries. The asymmetry between positive and negative  $\phi$  is due to the effect of the extra material in the inner detector at positive  $\phi$ . The difference between positive and negative  $\phi$  values is about 0.6%.

The same exercise is also done by introducing, on top of the non-uniformities due to extra material, a bias  $\alpha_{\text{inj}}$  generated from a Gaussian distribution with a mean  $\mu_{\text{bias}} = 0$  and width  $\sigma_{\text{bias}} = 2\%$ . Results are shown in Fig. 39. The Gaussian fitted to this distribution also has a mean of 0.1% and a width of 0.5%.

One can conclude that, using  $\sim 87,000$  reconstructed  $Z \rightarrow ee$  events (which corresponds to about  $200 \text{ pb}^{-1}$ ), and with an initial spread of 2% from region to region, the long-range constant term should not be greater than 0.5%.<sup>3</sup> This should give an overall constant term  $\sim 0.7\%$ . The bias on the absolute energy should be small and of the order of 0.2%. If the exercise is repeated with only  $100 \text{ pb}^{-1}$  of data, the Gaussian fitted to the residual distribution also has a mean of 0.2%, but the width is larger, leading to a long-range constant term of 0.8%.

## 7 Estimation of the systematic uncertainty on the energy scale

The absolute energy scale has been obtained using electrons from  $Z \rightarrow ee$  decays. It has been determined on events simulated with the misaligned geometry while the longitudinal weights were found with the ideal geometry. On top of the non-uniformities due to extra material, a bias modeling the calorimeter non-uniformities is introduced and is generated from a Gaussian distribution with a mean  $\mu_{\text{bias}} = 0$  and width  $\sigma_{\text{bias}} = 2\%$ . The resulting bias on the energy scale can be assessed by comparing the fitted  $\alpha$ ’s with those from generator information; the bias is equal to 0.2%. This bias is understood and is due to the fact that the model of the  $Z$  boson line shape doesn’t take into account the effects of bremsstrahlung. Work is ongoing to improve this issue.

<sup>3</sup>Part of the RMS of the residual distribution is also due to uncertainties on the measurement of  $\alpha_{\text{true}}$ .

(a)  $\alpha_{\text{fit}}$  (solid) and  $\alpha_{\text{true}}$  (dashed).(b) Difference between  $\alpha_{\text{fit}}$  and  $\alpha_{\text{true}}$ .Figure 37: Fit results with distorted geometry and  $\alpha_{\text{inj}} = 0$ .(a)  $\alpha_{\text{fit}}$  integrated over  $\phi$  as a function of  $\eta$ .(b)  $\alpha_{\text{fit}}$  integrated over  $\eta$  as a function of  $\phi$ , fitted in two separate regions.Figure 38:  $\alpha_{\text{fit}}$  distributions with  $\alpha_{\text{inj}} = 0$  and with distorted/ideal (full/open circles) geometry.(a)  $\alpha_{\text{fit}}$  (solid) and  $\alpha_{\text{true}} + \alpha_{\text{inj}}$  (dashed).(b) Difference between  $\alpha_{\text{fit}}$  and  $\alpha_{\text{true}} + \alpha_{\text{inj}}$ .

Figure 39: Fit results with distorted geometry and additional injected biases.

The background has been neglected but it has been checked that the contribution from QCD events where the two jets are misidentified as electrons is small. Thus, it should have a negligible effect on the determination on the energy scale.

Electrons from  $Z$  boson decays have a  $p_T$  spectrum with a maximum value around 45 GeV. Care will thus have to be taken to extrapolate the calibration obtained from  $Z \rightarrow ee$  decays to electron energy regions not well populated by these events. Corrections determined with  $Z$  boson decays were applied to single electron samples with different generated transverse momenta (20, 40, 120, and 500 GeV) reconstructed with the misaligned geometry. Figure 40 shows  $\langle\alpha_{\text{true}}\rangle$  after correction as a function of  $p_T$  for four  $|\eta|$  bins. In principle,  $\langle\alpha_{\text{true}}\rangle$  should be equal to zero. This is true for the 40 GeV electron sample at a level of 0.2% except in the bin ( $1.4 < |\eta| < 2.0$ ) containing the crack region. For central electrons ( $|\eta| < 0.6$ ), the dependence versus  $p_T$  is smaller than 0.5%. The effect is worse for non-central electrons. For instance, at  $p_T = 120$  GeV,  $\alpha_{\text{true}}$  after corrections varies from 1 to 1.6 percent. This non-linearity is due to the presence of extra material in front of the calorimeter.

Figure 40:  $\langle\alpha_{\text{true}}\rangle$  after correction as a function of  $p_T$  for four  $\eta$  bins.

To conclude, at the  $Z$  boson energy scale, the estimate of the systematic uncertainty is around 0.2%. At other energy scales, the systematic uncertainty is dominated by effects of extra material. For central electrons, corrections can be extrapolated over the full  $p_T$  spectrum to a level of 0.5%. The linearity is degraded for non-central electrons at a level of 1 or 2 percent except in the crack region where it is worse. These numbers depend on the amount of extra material added to the misaligned geometry compared to the ideal geometry and will likely be different with real data.

The performance presented here corresponds to our current understanding of the determination of the absolute energy scale. Improvements are expected to achieve systematic uncertainties smaller than 0.5%. For instance, including information from the  $E/p$  ratio measured for isolated high- $p_T$  electrons from  $W \rightarrow e\nu$  decays will compliment the direct calibration of the absolute scale with  $Z \rightarrow ee$  events. Photon conversions can also help to determine the amount of material in front of the calorimeter.

## Conclusion

The methods and algorithms described in this note were already mentioned in Ref. [1] many years ago. Over the years, they have reached a higher level of stability and maturity, and have been implemented in the ATLAS reconstruction software. It is believed that, given the constraints of the ATLAS detector, in particular the amount of dead material in front of the calorimeter, the performances described here will not evolve much further.

The real challenge at the beginning of data-taking will be the detection and correction for additional inner detector material or calorimeter inhomogeneities which would not have affected the somewhat smaller-scale detectors used in the test beam. Discrepancies between data and simulation will have to be

understood prior to the use of the methods described above. The in-situ calibration with  $Z \rightarrow ee$  events described in Section 6 will play an important role, and refinements of the method presented here are expected.

# Reconstruction and Identification of Electrons

## Abstract

This note discusses the overall ATLAS detector performance for the reconstruction and identification of high- $p_T$  electrons over a wide range of transverse energies, spanning from 10 GeV to 1000 GeV.

Electrons are reconstructed using information from both the calorimeter and the inner detector. The reference offline performance in terms of efficiencies for electrons from various sources and of rejections against jets is described. In a second part, this note discusses the requirements and prospects for electrons as probes for physics within and beyond the Standard Model: Higgs-boson, supersymmetry and exotic scenarios. In the last part, this note outlines prospects for electron identification with early data, corresponding to an integrated luminosity of  $100 \text{ pb}^{-1}$ , focusing on the use of the signal from  $Z \rightarrow ee$  decays for a data-driven evaluation of the offline performance.

## 1 Introduction

Excellent particle identification capability is required at the LHC for most physics studies. Several channels expected from new physics, for instance some decay modes of the Higgs boson into electrons, have small cross-sections and suffer from large (usually QCD) backgrounds. Therefore powerful and efficient electron identification is needed to observe such signals. Even for standard processes, the signal-to-background ratio is usually less favourable than at past and present hadron colliders. The ratio between the rates of isolated electrons and the rate of QCD jets with  $p_T$  in the range 20-50 GeV is expected to be  $\sim 10^{-5}$  at the LHC, almost two orders of magnitude smaller than at the Tevatron  $p\bar{p}$  collider. Therefore, to achieve comparable performances, the electron identification capability of the LHC detectors must be almost two orders of magnitude better than what has been achieved so far.

Physics channels of prime interest at the LHC are expected to produce electrons with  $p_T$  between a few GeV and 5 TeV. Good electron identification is therefore needed over a broad energy range. In the moderate  $p_T$  region (20 - 50 GeV), a jet-rejection factor exceeding  $10^5$  will be needed to extract a relatively pure inclusive signal from genuine electrons above the residual background from jets faking electrons. The required rejection factor decreases rapidly with increasing  $p_T$  to  $\sim 10^3$  for jets in the TeV region. For multi-lepton final states, such as possible  $H \rightarrow eeee$  in the mass region  $130 < m_H < 180$  GeV, a rejection of  $\sim 3000$  per jet should be sufficient to reduce the fake-electron backgrounds to a level well below that from real electrons. In this case, however, the electrons have a rather soft  $p_T$  spectrum (as low as 5 GeV), resulting in lower reconstruction and identification efficiencies.

Since the publication of the ATLAS physics TDR [1], the ATLAS detector description has been greatly improved, with, in particular, the introduction of a more realistic material description for the inner detector and for the region between the inner detector and the first layer of the electromagnetic calorimeter [2] [3]. This has led to some significant changes in the expected performance. The reconstruction software has also evolved significantly. Each step of the energy reconstruction has been validated by a series of beam tests [4] [5] [6] using prototype modules of the liquid argon electromagnetic calorimeter, and also more recently, combined with prototype modules of the inner detector. At present, two electron reconstruction algorithms have been implemented in the ATLAS offline software, both integrated into one single package and a common event data model.

- The standard one, which is seeded from the electromagnetic (EM) calorimeters, starts from clusters reconstructed in the calorimeters and then builds the identification variables based on information from the inner detector and the EM calorimeters.

- A second algorithm, which is seeded from the inner detector tracks, is optimized for electrons with energies as low as a few GeV, and selects good-quality tracks matching a relatively isolated deposition of energy in the EM calorimeters. The identification variables are then calculated in the same way as for the standard algorithm.

The standard algorithm is the one used to obtain the results presented in this note, while the track-based algorithm is used for low  $p_T$  and non-isolated electrons and is the subject of another note [7].

This note is organised as follows. Section 2 discusses the reconstruction and identification of electrons in the fiducial range of the ATLAS detector ( $|\eta| < 2.5$ ), whereas section 3 describes the identification of electrons in the forward region ( $2.5 < |\eta| < 4.9$ ). Section 4 describes some important performance aspects of electron identification in discovery physics processes. Section 5 discusses the strategies for measuring reconstruction and identification efficiencies using a data-driven approach based on  $Z \rightarrow ee$  events.

## 2 Calorimeter-seeded reconstruction and identification

In the standard reconstruction of electrons, a seed electromagnetic tower with transverse energy above  $\sim 3$  GeV is taken from the EM calorimeter [3] and a matching track is searched for among all reconstructed tracks which do not belong to a photon-conversion pair reconstructed in the inner detector. The track, after extrapolation to the EM calorimeter, is required to match the cluster within a broad  $\Delta\eta \times \Delta\phi$  window of  $0.05 \times 0.10$ . The ratio,  $E/p$ , of the energy of the cluster to the momentum of the track is required to be lower than 10. Approximately 93% of true isolated electrons, with  $E_T > 20$  GeV and  $|\eta| < 2.5$ , are selected as electron candidates. The inefficiency is mainly due to the large amount of material in the inner detector and is therefore  $\eta$ -dependent. As an example, 4% of electron candidates with  $p_T = 40$  GeV fail the cut  $E/p < 10$  and most of the losses are in the end-cap region. Various identification techniques can be applied to the reconstructed electron candidates, combining calorimeter and track quantities and the TRT information to discriminate jets and background electrons from the signal electrons. A simple cut-based identification procedure is described below together with its expected performance. This is followed by a brief overview of the possibilities offered by more advanced methods, such as a likelihood discriminant.

### 2.1 Electron-jet studies

For the purposes of this note, the electron identification efficiency is defined as

$$\varepsilon = \frac{N_e^{\text{Id}}}{N_e^{\text{truth}}},$$

where  $N_e^{\text{Id}}$  is the number of reconstructed and identified candidates and  $N_e^{\text{truth}}$  is the number of true electrons selected using the appropriate kinematic cuts at the generator level. A geometrical matching (within a cone of size  $\Delta R = 0.2$ ) between the reconstructed cluster and the true electron is required in the calculation of  $N_e^{\text{Id}}$ . A classification is applied to define whether a reconstructed electron candidate should be considered as signal or background. This classification is based on the type of the Monte Carlo particle associated to the reconstructed track, as well as that of its non-electron parent particle. As shown in Table 1, candidates are divided into four categories and signal efficiencies are calculated separately for isolated and non-isolated electrons.

For the jet rejection studies, the PYTHIA (version 6.4) [10] event generator has been used to produce the large statistics of jet background samples required to assess both the trigger and offline performance of the electron reconstruction and identification tools described in this note. Two different samples were

generated to cover the  $E_T$  -range of interest for single electrons (10-40 GeV). The first one, referred to as filtered di-jets, contains all hard-scattering QCD processes with  $E_T > 15$  GeV, e.g.  $qg \rightarrow qg$ , including heavy-flavour production, together with other physics processes of interest, such as prompt-photon production and single  $W/Z$  production. The second one, referred to as minimum bias, contains the same processes without any explicit hard-scattering cut-off. A filter was applied at the generator level to simulate the L1 trigger requirements [11], with the goal of increasing in an unbiased way the probability that the selected jets pass the electron identification cuts after GEANT [12] simulation. The summed transverse energy of all stable particles (excluding muons and neutrinos) with  $|\eta| < 2.7$  in a region  $\Delta\phi \times \Delta\eta = 0.12 \times 0.12$  was required to be greater than a chosen  $E_T$  -threshold for an event to be retained. For the filtered di-jet sample, this  $E_T$  -threshold is 17 GeV, while for the minimum-bias sample, it is 6 GeV. The filter retains 8.3% of the di-jet events and 5.7% of the minimum-bias events. The total number of events available for analysis after filtering, simulation and reconstruction, amounts to 8.2 million events for the di-jet sample and to 4.1 million events for the minimum-bias sample.

Category	Type of particle	Type of parent particle
Isolated	Electron	$Z, W, t, \tau$ or $\mu$
Non-isolated	Electron	$J/\psi, b$ -hadron or $c$ -hadron decays
Background electron	Electron	Photon (conversions), $\pi^0/\eta$ Dalitz decays, $u/d/s$ -hadron decays
Non-electron	Charged hadrons, $\mu$	

Table 1: Classification of simulated electron candidates according to their associated parent particle. Muons are included as source because of the potential emission of a Bremsstrahlungs photon.

$E_T > 17$ GeV			$E_T > 8$ GeV	
Isolated	Non-isolated	Background	Non-isolated	Background
$W - 75.0\%$	$b$ -hadrons - 38.7%	$\gamma$ -conv. - 97.8%	$b$ -hadrons - 39.3%	$\gamma$ -conv. - 98.4%
$Z - 20.9\%$	$c$ -hadrons - 60.6%	Dalitz decays - 1.8%	$c$ -hadrons - 59.7%	Dalitz decays - 1.3%
$t - < 0.1\%$	$J/\psi - 0.7\%$	$u/d/s$ -hadrons - 0.4%	$J/\psi - 1.0\%$	$u/d/s$ -hadrons - 0.3%
$\tau - 4.1\%$				

Table 2: Contribution and origin of isolated, non-isolated, and background electron candidates in the two di-jet samples before the identification criteria are applied.

The jet rejections quoted in this note are normalised with respect to the number of particle jets reconstructed using particle four-momenta within a cone size  $\Delta R = 0.4$  and derived from a dedicated un-filtered generated sample of di-jets or minimum-bias events. In the di-jet and minimum-bias samples, the average numbers per generated event of such particle jets with  $E_T$  above 17 and 8 GeV, respectively, and in the range  $|\eta| < 2.47$ , are 0.74 and 0.31, respectively.

After reconstruction of electron candidates and before any of the identification cuts are applied, the signal is completely dominated by non-isolated electrons from  $b$ - and  $c$ -hadron decays. The expected signal-to-background ratios for the filtered di-jet ( $E_T$  above 17 GeV) and minimum-bias ( $E_T$  above 8 GeV) samples are 1:80 and 1:50, respectively. The residual jet background is dominated by charged hadrons. Only a small fraction of the background at this stage consists of electrons from photon conversions or Dalitz decays, namely 6.4% and 9.4%, respectively. Table 2 summarises the relative compositions of the filtered di-jet and minimum-bias samples in terms of the three categories containing electrons described in Table 1.

Type	Description	Variable name
Loose cuts		
Acceptance of the detector	$ \eta  < 2.47$	
Hadronic leakage	Ratio of $E_T$ in the first sampling of the hadronic calorimeter to $E_T$ of the EM cluster	
Second layer of EM calorimeter.	Ratio in $\eta$ of cell energies in $3 \times 7$ versus $7 \times 7$ cells. Ratio in $\phi$ of cell energies in $3 \times 3$ versus $3 \times 7$ cells. Lateral width of the shower.	$R_\eta$ $R_\phi$
Medium cuts (includes loose cuts)		
First layer of EM calorimeter.	Difference between energy associated with the second largest energy deposit and energy associated with the minimal value between the first and second maxima. Second largest energy deposit normalised to the cluster energy. Total shower width. Shower width for three strips around maximum strip. Fraction of energy outside core of three central strips but within seven strips.	$\Delta E_s$  $R_{\max 2}$  $w_{\text{stot}}$ $w_{s3}$ $F_{\text{side}}$
Track quality	Number of hits in the pixel detector (at least one). Number of hits in the pixels and SCT (at least nine). Transverse impact parameter ( $< 1$ mm).	
Tight (isol) (includes medium cuts)		
Isolation	Ratio of transverse energy in a cone $\Delta R < 0.2$ to the total cluster transverse energy.	
Vertexing-layer	Number of hits in the vertexing-layer (at least one).	
Track matching	$\Delta\eta$ between the cluster and the track ( $< 0.005$ ). $\Delta\phi$ between the cluster and the track ( $< 0.02$ ). Ratio of the cluster energy to the track momentum.	$E/p$
TRT	Total number of hits in the TRT. Ratio of the number of high-threshold hits to the total number of hits in the TRT.	
Tight (TRT) (includes tight (isol) except for isolation)		
TRT	Same as TRT cuts above, but with tighter values corresponding to about 90% efficiency for isolated electrons.	

Table 3: Definition of variables used for loose, medium and tight electron identification cuts. The cut values are given explicitly only when they are independent of  $\eta$  and  $p_T$ . For a detailed description of the cut variables used for the loose and medium cuts, refer to sections 2.1.1.1 and 2.1.1.2.

### 2.1.1 Cut-based method description

Standard identification of high- $p_T$  electrons is based on many cuts which can all be applied independently. These cuts have been optimised in up to seven bins in  $\eta$  and up to six bins in  $p_T$ . Three reference sets of cuts have been defined: loose, medium and tight, as summarised in Table 3. This provides flexibility in analysis, for example to improve the signal efficiency for rare processes which are not subject to large backgrounds from fakes.

**2.1.1.1 Loose cuts** This set of cuts performs a simple electron identification based only on limited information from the calorimeters. Cuts are applied on the hadronic leakage and on shower-shape variables, derived from only the middle layer of the EM calorimeter (lateral shower shape and lateral shower width). This set of cuts provides excellent identification efficiency, but low background rejection.

**2.1.1.2 Medium cuts** This set of cuts improves the quality by adding cuts on the strips in the first layer of the EM calorimeter and on the tracking variables:

- Strip-based cuts are effective in the rejection of  $\pi^0 \rightarrow \gamma\gamma$  decays. Since the energy-deposit pattern from  $\pi^0$ 's is often found to have two maxima due to  $\pi^0 \rightarrow \gamma\gamma$  decay, showers are studied in a window  $\Delta\eta \times \Delta\phi = 0.125 \times 0.2$  around the cell with the highest  $E_T$  to look for a second maximum. If more than two maxima are found the second highest maximum is considered. The variables used include  $\Delta E_s = E_{\max 2} - E_{\min}$ , the difference between the energy associated with the second maximum  $E_{\max 2}$  and the energy reconstructed in the strip with the minimal value, found between the first and second maxima,  $E_{\min}$ . Also included are:  $R_{\max 2} = E_{\max 2} / (1 + 9 \times 10^{-3} E_T)$ , where  $E_T$  is the transverse energy of the cluster in the EM calorimeter and the constant value 9 is in units of  $\text{GeV}^{-1}$ ;  $w_{\text{stot}}$ , the shower width over the strips covering 2.5 cells of the second layer (20 strips in the barrel for instance);  $w_{s3}$ , the shower width over three strips around the one with the maximal energy deposit; and  $F_{\text{side}}$ , the fraction of energy deposited outside the shower core of three central strips.
- The tracking variables include the number of hits in the pixels, the number of silicon hits (pixels plus SCT) and the transverse impact parameter.

The medium cuts increase the jet rejection by a factor of 3-4 with respect to the loose cuts, while reducing the identification efficiency by  $\sim 10\%$ .

**2.1.1.3 Tight cuts** This set of cuts makes use of all the particle-identification tools currently available for electrons. In addition to the cuts used in the medium set, cuts are applied on the number of vertexing-layer hits (to reject electrons from conversions), on the number of hits in the TRT, on the ratio of high-threshold hits to the number of hits in the TRT (to reject the dominant background from charged hadrons), on the difference between the cluster and the extrapolated track positions in  $\eta$  and  $\phi$ , and on the ratio of cluster energy to track momentum, as shown in Table 3. Two different final selections are available within this tight category: they are named tight (isol) and tight (TRT) and are optimised differently for isolated and non-isolated electrons. In the case of tight (isol) cuts, an additional energy isolation cut is applied to the cluster, using all cell energies within a cone of  $\Delta R < 0.2$  around the electron candidate. This set of cuts provides, in general, the highest isolated electron identification and the highest rejection against jets. The tight (TRT) cuts do not include the additional explicit energy isolation cut, but instead apply tighter cuts on the TRT information to further remove the background from charged hadrons.

Figures 1 and 2 compare the distributions expected from  $Z \rightarrow ee$  decays and from the filtered di-jet sample for a few examples of the basic discriminating variables described above for electron identification.

## 2.1.2 Performance of cut-based electron identification

The performance of the cut-based electron identification is summarised in Tables 4 and 5. Table 4 shows, for each of the background samples, the composition of each of the three categories of electron candidates containing real electrons, as it evolves from reconstruction (no identification cuts) to loose, medium and tight cuts. In the case of non-isolated electrons, there is a strong reduction of the initially dominant component from  $c$ -hadrons as the identification cuts applied become tighter. In the case of background electrons, there is a significant reduction of the contribution from photon conversions when applying tight cuts, since the vertexing-layer requirement does not much affect electrons from Dalitz decays and  $u/d/s$ -hadrons. As shown in Table 5, the signal from prompt electrons is dominated by non-isolated electrons from heavy flavours, which are usually close in space to hadrons from the jet fragmentation. The

Figure 1: Left: ratio between the transverse energy of the electron candidate and the sum of this transverse energy and that contained in the first layer of the hadronic calorimeter. The distributions are shown for electrons from  $Z \rightarrow ee$  decays (solid line) and for filtered di-jets (dotted line). Right: difference in  $\eta$  between cluster and extrapolated track positions for electrons from  $Z \rightarrow ee$  decays (solid line) and for filtered di-jets (dotted line).

Figure 2: Shower-shape distributions for electrons from  $Z \rightarrow ee$  decays (solid lines) compared to those from filtered di-jets (dotted lines). Shown are the energy ratios  $R_\phi$  (left) and  $R_\eta$  (right) described in Table 3.

resulting overlap between the electron shower and nearby hadronic showers explains the much lower efficiency observed for these electrons than for isolated electrons from  $Z \rightarrow ee$  decays. These non-isolated electrons will nevertheless provide the most abundant initial source of signal electrons and will be used for alignment of the electromagnetic calorimeters and the inner detector, for  $E/p$  calibrations, and more generally to improve the understanding of the material of the inner detector as a radiation/conversion source. For tight cuts and an electron  $E_T$  of  $\sim 20$  GeV, the isolated electrons from  $W$ ,  $Z$  and top-quark decays represent less than 20% of the total prompt electron signal.

For the lower  $E_T$  -threshold of 8 GeV, the expected signal from isolated electrons is negligible. Not surprisingly, the tight (TRT) cuts are more efficient to select non-isolated electrons from heavy-flavour decay, while the tight (isol) cuts are more efficient at selecting isolated electrons. After tight cuts, the signal-to-background ratio is close to 3:1, and depends only weakly on the  $E_T$  - threshold in the 10-40 GeV  $E_T$  -range studied here. The residual background is dominated by charged hadrons, which could be further rejected by stronger cuts (TRT and/or isolation). The initial goal of obtaining a rejection of the order of  $10^5$  against jets has been achieved with an overall efficiency of 64% for isolated electrons with

Isolated										
	$E_T > 17 \text{ GeV}$									
	No cut	Loose		Medium		Tight (TRT)		Tight (isol)		
$W$	75.0	75.1		74.9		73.9		73.6

$u/d/s$ -hadrons	0.4	0.4	1.1	3.5	3.9	0.3	0.5	2.0	9.0	4.6

Table 4: Percentage contribution and origin of isolated, non-isolated and background electrons in the filtered di-jet and minimum-bias samples. The classification is based on the type of the parent particle of the electron.

$E_T \sim 10\text{-}40 \text{ GeV}$ . The efficiency may be improved with further optimisation of the cuts, as discussed below.

Table 6 shows the efficiencies for prompt electrons and the jet rejections in more detail in the case of medium identification cuts, using a fine binning as a function of  $|\eta|$ . The efficiency for prompt electrons is significantly worse in the end-cap region ( $|\eta| > 1.52$ ) with a correspondingly higher background rejection. The overlap region between the barrel and end-cap calorimeters ( $1.37 < |\eta| < 1.52$ ) has both worse efficiency and rejection, as expected because of the large amount of passive material in front of the EM calorimeter. To improve the electron efficiency in the end-cap region, the EM calorimeter cuts in the first layer and the tracking cuts will need to be studied and tuned further.

### 2.1.3 Expected differential rates for inclusive electron signal and background

Figure 3 (left:  $E_T > 17 \text{ GeV}$  and right:  $E_T > 8 \text{ GeV}$ ) show the expected differential cross-sections for electron candidates as a function of  $E_T$ , for an integrated luminosity of  $100 \text{ pb}^{-1}$ . The different histograms correspond to electron candidates before any identification cuts and after the loose, medium, tight (TRT) and tight (isol) cuts. As illustrated in Table 5, these differential rates are dominated by the jet background except when applying the tight cuts.

The expected differential cross-sections after tight (TRT) cuts are shown in Fig. 4, where they are broken down into their three main components, isolated electrons from  $W$ ,  $Z$  and top-quark decays, non-isolated electrons from  $b$ ,  $c$  decay, and the residual jet background. The shapes of the spectra for the non-isolated electrons and residual jet background are very similar, whereas the spectrum from isolated electrons exhibits the expected behaviour for a sample dominated by electrons from  $W$ ,  $Z$  decay. For an integrated luminosity of  $100 \text{ pb}^{-1}$ , Fig. 4 (right) shows that one may expect approximately ten million reconstructed and identified inclusive electrons from  $b$ ,  $c$  decay with  $E_T > 10 \text{ GeV}$ , while Fig. 4 (left) shows that for the same integrated luminosity one may expect 500 000 such electrons with  $E_T > 20 \text{ GeV}$ , with a dominant contribution from  $W$ ,  $Z$  decays for  $E_T > 35 \text{ GeV}$ . These large data samples expected for a modest integrated luminosity are an integral part of the trigger menu strategy for early data, as explained in more detail in [11], and will clearly be extremely useful to certify many aspects of the

Cuts	$E_T > 17 \text{ GeV}$			$E_T > 8 \text{ GeV}$		
	Efficiency (%)		Jet rejection	Efficiency (%)		Jet rejection
	$Z \rightarrow ee$	$b, c \rightarrow e$		Single electrons ( $E_T = 10 \text{ GeV}$ )	$b, c \rightarrow e$	
Loose	$87.96 \pm 0.07$	$50.8 \pm 0.5$	$567 \pm 1$	$75.8 \pm 0.1$	$55.8 \pm 0.7$	$513 \pm 2$
Medium	$77.29 \pm 0.06$	$30.7 \pm 0.5$	$2184 \pm 13$	$64.8 \pm 0.1$	$41.9 \pm 0.7$	$1288 \pm 10$
Tight (TRT.)	$61.66 \pm 0.07$	$22.5 \pm 0.4$	$(8.9 \pm 0.3)10^4$	$46.2 \pm 0.1$	$29.2 \pm 0.6$	$(6.5 \pm 0.3)10^4$
Tight (isol.)	$64.22 \pm 0.07$	$17.3 \pm 0.4$	$(9.8 \pm 0.4)10^4$	$48.5 \pm 0.1$	$28.0 \pm 0.6$	$(5.8 \pm 0.3)10^4$
	Fraction of surviving candidates (%)			Fraction of surviving candidates (%)		
	Isolated	Non-isolated	Jets	Non-isolated		Jets
Medium	1.1	7.4	91.5 (5.5 + 86.0)	9.0		91.0 (5.0 + 86.0)
Tight (TRT)	10.5	63.3	26.2 (8.3 + 17.9)	77.8		22.2 (7.1 + 15.1)
Tight (isol)	13.0	58.3	28.6 (8.7 + 19.9)	75.1		24.9 (6.4 + 18.5)

Table 5: Expected efficiencies for isolated and non-isolated electrons and corresponding jet background rejections for the four standard levels of cuts used for electron identification. The results are shown for the simulated filtered di-jet and minimum-bias samples, corresponding respectively to  $E_T$ -thresholds of 17 GeV (left) and 8 GeV (right). The three bottom rows show the fractions of all surviving candidates which fall into the different categories for the medium cuts and the two sets of tight cuts. The isolated electrons are prompt electrons from  $W$ ,  $Z$  and top-quark decay and the non-isolated electrons are from  $b$ ,  $c$  decay. The residual jet background is split into its two dominant components, electrons from photon conversions and Dalitz decays (first term in brackets) and charged hadrons (second term in brackets). The quoted errors are statistical.

electron identification performance of ATLAS with real data. One example is the understanding of material effects and of inter-calibration between inner detector and EM calorimeter using  $E/p$  for a clean subset of the inclusive electrons with  $E_T > 10 \text{ GeV}$ . This sample will be complementary to the samples of low-mass electron pairs from  $J/\psi$  and  $\Upsilon$  decays, discussed in [7]. A second example is the certification of the isolated electron identification using a clean sample of  $W \rightarrow e\nu$  decays. Clearly, with more statistics, the large samples of  $Z \rightarrow ee$  decays which will be collected will provide the opportunity to refine the understanding of the performance to an extremely high level of accuracy, as discussed in Section 5.

#### 2.1.4 Systematic uncertainties on expected performance

To estimate possible systematic uncertainties related to the cut-based electron identification, two shower shape variables have been studied as a function of the amount of material in front of the EM calorimeter. Figure 5 illustrates the impact of additional material, the effect of which has not been included in the EM cluster corrections which are applied as described in [3], for electrons from  $H \rightarrow eeee$  decays. The results are shown in two  $|\eta|$ -ranges for the nominal material and for the case of additional material accounting in total to  $\sim 0.1 X_0$  and  $\sim 0.2 X_0$  (Fig. 5). It is evident that in regions with significant amounts of material the shower is broader (less energy in the core). These differences reduce the electron efficiency; however, the true systematic error on the efficiency due to such effects will depend on how well the inner-detector material can be measured using data.

Figure 6 shows the fraction of energy in the strip layer outside the three core strips and inside the seven-strip window for the same  $|\eta|$ -ranges. The impact of the additional material is also clearly visible. The estimated change in the electron efficiencies quoted in Table 5 is expected to be less than 2%. It is important to note that the material effects are more pronounced in the strip layer than in the middle layer of the calorimeter. Therefore, one should expect larger uncertainties from this source of systematics for the medium electron cuts than for the loose electron cuts, which rely only on the middle layer of the

$ \eta $	$E_T > 17 \text{ GeV}$			$E_T > 8 \text{ GeV}$

2.35 – 2.47	$67.8 \pm 0.3$	$14 \pm 2$	$4050 \pm 170$	$62.5 \pm 0.6$	$30 \pm 3$	$3980 \pm 250$
0.00 – 2.47	$77.3 \pm 0.06$	$31 \pm 1$	$2184 \pm 13$	$64.8 \pm 0.1$	$42 \pm 1$	$1288 \pm 8$

Table 6: Expected efficiencies for isolated and non-isolated electrons and corresponding jet background rejections for the medium identification cuts as a function of  $|\eta|$ . The results are shown for the simulated filtered di-jet and minimum-bias samples, corresponding respectively to  $E_T$ -thresholds of 17 GeV (left) and 8 GeV (right). The quoted errors are statistical.

Figure 3: Differential cross-sections as a function of  $E_T$  before identification cuts and after loose, medium, tight (TRT) and tight-isol cuts, for an integrated luminosity of  $100 \text{ pb}^{-1}$  and for the simulated filtered di-jet sample with  $E_T$  above 17 GeV (left) and the simulated minimum-bias sample with  $E_T$  above 8 GeV (right).

calorimeter.

Another important source of systematics affects the jet rejections quoted in Table 5: this arises from the exact  $p_T$ -spectrum and mixture of quark and gluon jets, and to a certain extent from heavy flavour jets present in the background under consideration. The numbers quoted in this note are related to the rather low- $p_T$  di-jet background which is relevant for the search for early signals from single electrons. Other background samples relevant to certain physics studies have been shown to display worse rejections, by up to a factor of 3 to 5. This clearly indicates that the fake electron rates will only be better understood with real data.

### 2.1.5 Multivariate techniques

In addition to the standard cut-based electron identification described above, several multivariate techniques have been developed and implemented in the ATLAS software. These include a likelihood discriminant, a discriminant called H-matrix, a boosted decision tree, and a neural network. Table 7 sum-

Figure 4: Differential cross-sections as a function of  $E_T$  after tight (TRT) cuts, shown separately for the expected components from isolated electrons, non-isolated electrons and residual jet background, for an integrated luminosity of  $100 \text{ pb}^{-1}$  and for the simulated filtered di-jet sample with  $E_T$  above 17 GeV (left) and the simulated minimum-bias sample with  $E_T$  above 8 GeV (right).

Figure 5: Energy containment,  $R_\eta$  (Table 3), for  $1.12 < |\eta| < 1.25$  (left) and  $1.62 < |\eta| < 1.75$  (right). The symbols correspond to the nominal description and the histogram to the one with additional material.

marises the gains in efficiency and rejection which may be expected with respect to the cut-based method by using the likelihood discriminant method. The gains appear to be artificially large in the case of the loose and medium cuts, because these cuts do not make use of all the information available in terms of electron identification, since they were designed for robustness and ease of use with initial data. Nevertheless, they indicate how much the electron efficiency may be improved once all the discriminant variables will be understood in the data.

Figure 7 shows the rejection versus efficiency curve obtained using the likelihood discriminant method, compared to the results obtained for the two sets of tight cuts shown in Table 5. The likelihood discriminant method provides a gain in rejection of about 20-40% with respect to the cut-based method for the same efficiency of 61-64%. Alternatively, it provides a gain in efficiency of 5-10% (tight and medium cuts) for the same rejection. Multivariate methods of this type will of course only be used once the detector performance has been understood using the simpler cut-based electron identification criteria.

Figure 6: Energy fraction outside a three-strip core,  $F_{side}$  (Table 3), for  $1.12 < |\eta| < 1.25$  (left) and  $1.62 < |\eta| < 1.75$  (right). The symbols correspond to the nominal description and the histogram to the one with additional material.

Cuts	Cut-based method		Likelihood method	
	Efficiency $\epsilon_e$ (%)	Rejection $R_j$	Efficiency (%) at fixed $R_j$	Rejection at fixed $\epsilon_e$
Loose	$87.97 \pm 0.05$	$567 \pm 1$	$89.11 \pm 0.05$	$2767 \pm 17$
Medium	$77.29 \pm 0.06$	$2184 \pm 7$	$88.26 \pm 0.05$	$(3.77 \pm 0.08) \times 10^4$
Tight (isol)	$64.22 \pm 0.07$	$(9.9 \pm 0.2) \times 10^4$	$67.53 \pm 0.06$	$(1.26 \pm 0.05) \times 10^5$
Tight (TRT)	$61.66 \pm 0.07$	$(8.9 \pm 0.2) \times 10^4$	$68.71 \pm 0.06$	$(1.46 \pm 0.06) \times 10^5$

Table 7: For the loose, medium and tight electron identification cuts, expected electron efficiencies for a fixed jet rejection and jet rejections for a fixed electron efficiency, as obtained from the likelihood discriminant method. The quoted errors are statistical.

## 2.2 Isolation studies

Many physics analyses in ATLAS will be based on final states with isolated leptons from decays of  $W$ - or  $Z$ -bosons. These channels usually have the advantage of small background expectation from processes with similar signature, compared to channels with hadronic final states. Nevertheless, they may also suffer from jet background processes, namely if leptons from semi-leptonic heavy-quark decays mimic the isolated leptons of the signal. Therefore, dedicated tools beyond the lepton identification algorithms are needed in order to suppress such sources of background by factors of up to the order of  $10^3$ . In this section, the performance of a projective likelihood estimator for the separation of isolated electrons from non-isolated electron backgrounds is described. The four variables chosen as input to this isolation likelihood are:

- transverse energy deposited in a small cone of  $\Delta R < 0.2$  around the electron cluster;
- transverse energy deposited in a hollow cone of  $0.2 < \Delta R < 0.4$  around the electron cluster;
- sum of the squares of the transverse momenta of all additional tracks measured in a cone of  $\Delta R < 0.4$  around the electron cluster;
- impact parameter significance of the electron track (with respect to the primary vertex in the transverse plane).

Electrons from  $Z \rightarrow ee$  decays were used as a clean source of isolated electrons. The reconstructed electrons from this sample were required to be matched to a Monte Carlo electron from  $Z$ -boson decay

Figure 7: Jet rejection versus isolated electron efficiency obtained with a likelihood method (full circles) compared to the results from the two sets of tight cuts (open triangle and open square).

Figure 8: Background electron rejections versus signal efficiencies for electrons in  $Z \rightarrow ee$  decays (left) and in  $t\bar{t}$  decays (right), for two illustrative bins in  $|\eta|$  and  $p_T$ .

and to pass the medium identification cuts in order to be considered as signal electrons. Background electrons were selected from a high-statistics  $t\bar{t}$  sample, filtered for a pair of like-sign Monte Carlo electrons, and matched to a Monte Carlo electron from  $b/c$ -decay.

The results of the performance studies of the isolation likelihood are shown in Fig. 8 for two illustrative bins in  $|\eta|$  and  $p_T$ . The best results are achieved for high- $p_T$  electrons measured in the barrel region of the EM calorimeter. As can be seen in Fig. 8 left, for electrons with only little hadronic activity in the final state, such as those from  $Z \rightarrow ee$  and  $H \rightarrow eeee$  decays, the isolation likelihood provides a background rejection of the order of  $10^3$ , for signal electron efficiencies of 80% (barrel) and 50% (end-caps). The difference observed between barrel and end-caps is mostly due to the  $\eta$ -dependence of the medium identification cuts shown in Table 6. For comparison, the efficiency for the selection of signal electrons in  $t\bar{t}$  events is shown in Fig. 8 right: due to the additional hadronic activity in these final states, the efficiency decreases by 5–10% for the same background rejection, when compared to that quoted for  $Z \rightarrow ee$  decays.

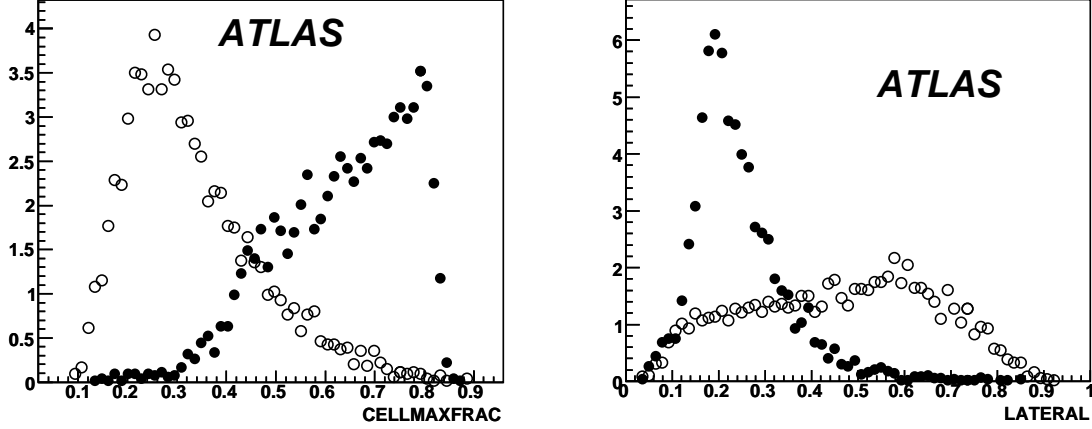

Figure 9: Example of discriminating variables used in the forward region for signal electrons (full circles) and the QCD di-jet background (open circles). Shown in the case of the FCal are the fraction of the total cluster energy deposited in the cell with maximum energy (left) and the relative lateral moment (right).

### 3 Electron identification outside the inner detector acceptance

Electron identification in the forward region ( $|\eta| > 2.5$ ) will be important in many physics analyses, including electroweak measurements and searches for new phenomena. In contrast to the central electrons, forward electron reconstruction can only use information from the calorimeters, since the inner detector covers only  $|\eta| < 2.5$ . Such electrons can therefore only be identified cleanly above the background in specific topologies, such as  $Z \rightarrow ee$  or  $H \rightarrow eeee$  decays.

This section describes the performance of a cut-based method used to identify electrons in the forward region and separate them from the QCD background. The comparison of the performance obtained with a likelihood method is also presented.

Signal electrons are selected from  $Z \rightarrow ee$  decays and background electrons from a high-statistics sample of QCD di-jet events. Three  $|\eta|$ -regions are considered: the first one covers the inner wheel of the electromagnetic end-cap, i.e.  $2.5 < |\eta| < 3.2$  (the HEC is not used), the second one covers the overlap region between the electromagnetic end-cap and the forward calorimeter (FCal), i.e.  $3.2 < |\eta| < 3.4$ , and the last region covers the FCal acceptance, i.e.  $3.4 < |\eta| < 4.9$ . A topological clustering algorithm [13] is used in this analysis and only clusters with  $E_T > 20$  GeV are considered. Two examples of the discriminating variables used in these studies are shown in Fig. 9, namely the fraction of the total cluster energy deposited in the cell with maximum energy and the relative lateral moment. The relative lateral moment is defined as  $\text{lat}_2 / (\text{lat}_2 + \text{lat}_{\text{max}})$ , where the lateral moments  $\text{lat}_2$  and  $\text{lat}_{\text{max}}$  differ in the treatment of the two most energetic cells. Other examples include the first moment of the energy density, the relative longitudinal moment, defined in the same way as the relative lateral moment only with two longitudinal moments, the second moments of the distances of each cell to the shower barycentre and to the shower axis, and the distance of the cluster barycentre from the front face of the calorimeter.

The likelihood discriminant uses the same variables as the cut-based method. Figure 10 shows the performance of the cut-based and likelihood discriminant methods for electrons from  $Z \rightarrow ee$  decay with  $E_T > 20$  GeV. For an electron identification efficiency of 80%, both methods achieve the required goal of  $\sim 1\%$  fake rate from the QCD background. This performance is expected to yield, for example, a clean  $Z \rightarrow ee$  sample with one electron already selected in the central region and one electron in the forward region [14]: the expected background contribution under the Z-boson peak is estimated to be

Figure 10: Expected rejection against QCD jets versus efficiency for signal electrons from  $Z \rightarrow ee$  decay, for the cut-based and likelihood discriminant methods in the inner wheel of the electromagnetic end-cap (left) and in the FCal (right). The rejection power of the likelihood method is expected to increase when additional variables beyond the minimal set shown here are added.

Figure 11: Electron identification efficiency as a function of  $\eta$  (left) and  $E_T$  (right) for electrons with  $E_T > 5$  GeV from  $H \rightarrow eeee$  decays.

below  $\sim 1\%$ .

## 4 Electrons as probes for physics within and beyond the Standard Model

### 4.1 Electrons in Higgs-boson decays

Electrons from the  $H \rightarrow eeee$  decay with  $m_H < 2m_Z$  are an important benchmark for the evaluation of the performance of the electron reconstruction and identification [15]. Here, only electrons with  $|\eta| < 2.5$  and  $E_T > 5$  GeV are considered. The electron efficiency as a function of  $|\eta|$  and  $E_T$  for loose, medium, and tight electron cuts is shown in Fig. 11. The drop in efficiency at low  $E_T$  is mainly due to the loss of discrimination power of the shower-shape cuts at lower transverse energies. A loss of efficiency is also visible in the transition region between the barrel and end-cap calorimeters. The results shown here are in quantitative agreement with those obtained for electrons from  $Z \rightarrow ee$  decay discussed in Section 2.1.2.

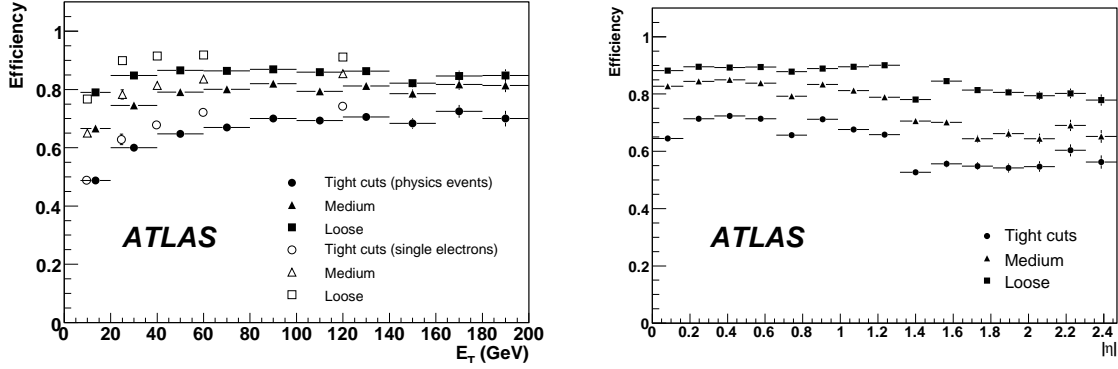

Figure 12: Electron identification efficiency as a function of  $E_T$  (left) and  $|\eta|$  (right). The full symbols correspond to electrons in SUSY events and the open ones to single electrons of fixed  $E_T$ . The efficiencies as a function of  $|\eta|$  are shown only for electrons with  $E_T > 17$  GeV.

#### 4.2 Electrons produced in decays of supersymmetric particles

In many supersymmetry (SUSY) scenarios, the most abundantly produced sparticles are squarks (directly or from a gluino decay), which generally decay into a chargino or neutralino and jets. In turn, charginos and neutralinos are very likely to decay into leptons. One interesting mode for SUSY searches is the tri-lepton signal, in which three isolated leptons are expected in the final state. Such SUSY events would feature high- $p_T$  isolated leptons accompanied by a high multiplicity of high- $E_T$  jets. Hence, it is crucial to efficiently identify electrons in such an environment, while preserving the very high jet rejection presented in Section 2. The electron identification efficiency in SUSY events is calculated using the SU3 ATLAS point [16]. In this scenario, a large number of charginos and neutralinos are produced and numerous leptons are expected in the final state.

Figure 13: Electron identification efficiency as a function of the distance  $\Delta R$  to the closest jet in SUSY events, for electrons with  $E_T > 17$  GeV.

Figure 12 shows the identification efficiency of the loose, medium and tight (isol) cuts as a function of  $E_T$  and  $|\eta|$ . The efficiencies shown as a function of  $E_T$  are compared with efficiencies for single electrons of  $E_T = 10, 25, 40, 60$  and  $120$  GeV. As expected, single electrons display higher efficiencies than those in SUSY events, because of the large hadronic activity in these events. The efficiencies

Figure 14: Electron identification efficiency as a function of  $E_T$  (left) and  $|\eta|$  (right), for electrons from  $Z' \rightarrow e^+e^-$  decays with  $m_{Z'} = 1$  TeV.

obtained for values of  $E_T$  below 20 GeV, are significantly below the plateau values at high  $E_T$ , for which the cuts were initially optimised.

The efficiencies as a function of  $|\eta|$  show the same features as those discussed in Table 6, namely the efficiency in the end-cap region is lower than in the barrel, whereas the jet rejection is significantly higher. Specific drops in efficiency can be seen for  $|\eta| \sim 1.35$ , which corresponds to the barrel/end-cap transition region, and for  $|\eta| \approx 0.8$ , which corresponds to the change in the lead thickness between the two types of electrodes in the barrel EM calorimeter.

Figure 13 shows the electron identification efficiency as a function of the distance  $\Delta R$  to the closest jet in SUSY events. Jets are reconstructed from topological clusters using a  $\Delta R = 0.4$  cone algorithm. For values of  $\Delta R > 0.4$ , the efficiencies are compatible with those expected for single electrons, whereas for values of  $\Delta R < 0.4$ , the efficiencies decrease because of the overlap between the hadronic showers from the jet and the electron shower itself.

Jet $E_T$ -range	140 – 280 GeV		280 – 560 GeV		560 – 1120 GeV	
	Efficiency	Rejection	Efficiency	Rejection	Efficiency	Rejection
Loose cuts	$86.6 \pm 0.2\%$	$825 \pm 35$	$89.6 \pm 0.1\%$	$620 \pm 25$	$91.5 \pm 0.4\%$	$550 \pm 20$
Medium cuts	$80.6 \pm 0.2\%$	$4000 \pm 370$	$84.6 \pm 0.1\%$	$2300 \pm 170$	$86.7 \pm 0.5\%$	$1900 \pm 120$

Table 8: Electron identification efficiencies and QCD di-jet background rejections obtained for loose and medium identification cuts, including a calorimeter isolation cut (see text), and for three different jet  $E_T$  -ranges. The signal electrons are from  $Z' \rightarrow e^+e^-$  decays with  $m_{Z'} = 1$  TeV and are required to have  $E_T > 100$  GeV.

### 4.3 Electrons in exotic events

High-mass di-electron final states are a promising source of early discovery physics, because of the simplicity and robustness of very high- $p_T$  electron reconstruction, identification and resolution. Very high- $p_T$  electrons refer here to those with transverse momentum ranging from 100 GeV up to several TeV. The backgrounds to very high- $p_T$  electron pairs are expected to be small, and, therefore, only loose or medium identification cuts are considered here. Isolated electrons are required to satisfy the calorimeter isolation cut described in Section 2.

Figure 14 shows efficiencies as a function of  $E_T$  and  $|\eta|$  for the loose and medium identification cuts, for electrons from  $Z' \rightarrow e^+e^-$  decays with  $m_{Z'} = 1$  TeV [17]. From these curves, one can note the slow increase in efficiency with  $E_T$  before reaching a plateau in the very high- $E_T$  region. Overall efficiencies of  $\sim 90\%$  and of  $\sim 85\%$  can be achieved for loose and medium electron cuts, respectively, with a uniform behaviour limited to the barrel region, i.e.  $|\eta| < 1.5$ .

The QCD background rejection was studied as a function of the jet transverse energy, as shown in Table 8. Using the medium identification cuts, which correspond to an overall efficiency of  $\sim 85\%$ , a jet rejection factor of several thousand can be achieved for  $E_T > 100$  GeV, which should be sufficient to observe the signal in many exotic scenarios.

## 5 Electrons from $Z \rightarrow ee$ decays in early data

The experimental uncertainty on the electron identification efficiency is expected to be the source of one of the main systematic errors in many measurements, and in particular in cross-section determinations. In addition, a reliable monitoring of the electron identification efficiency is important in the commissioning phase of the detector and software. The previous sections have shown detailed estimates of the expected electron identification efficiency based on simulated samples. This section focuses on the measurement of electron reconstruction and identification efficiencies using a data-driven approach based on  $Z \rightarrow ee$  events.

The tag-and-probe method [18] is used in this analysis. It consists of tagging a clean sample of events using one electron, and then measuring the efficiency of interest using the second electron from the  $Z$ -boson decay. Although more difficult because of trigger-threshold issues and of more severe background conditions, the same approach could be applied to  $J/\psi$  and  $\Upsilon$  resonances, thus covering the lower end of the  $p_T$  spectrum [7].

### 5.1 Tag-and-probe method

The tag condition typically requires an electron identified with tight cuts. Both electrons are also required to be above a  $p_T$  threshold consistent with the trigger used. The invariant mass of the lepton pair is then used to identify the number of tagged events,  $N_1$  (containing  $Z \rightarrow ee$  decays), and a sub-sample  $N_2$ , where the second pre-selected electron further passes a given set of identification cuts. The efficiency for a given signature is given by the ratio between  $N_2$  and  $N_1$ .

To account for background, the lepton-pair invariant mass spectrum is fitted around the  $Z$  mass peak using a Gaussian distribution convoluted with a Breit-Wigner plus an exponential function. The dominant background arises from QCD and is estimated using a procedure explained in [18]; its contribution is small in general and its impact on the measurement is therefore very limited.

The probe electron is checked against the selection as an electron candidate (to which only the pre-selection cuts are applied), and as a loose, medium or tight electron. To monitor in detail the efficiency dependence, the results are presented in bins of  $\eta$  and  $p_T$ , at the expense of an increased statistical error in each bin.

A quantitative comparison between the efficiency computed with this tag-and-probe method ( $\epsilon_{TP}$ ) and the efficiency obtained from the Monte Carlo truth ( $\epsilon_{MC}$ ) is used to validate the tag-and-probe method.

### 5.2 Electron reconstruction efficiency

The reconstruction and identification of electrons is based on seed-clusters in the electromagnetic calorimeter matched to tracks, as explained in Section 2. The tag electron is a reconstructed electron selected using

Figure 15: Efficiency of the electron pre-selection as a function of  $|\eta|$  (left) and  $E_T$  (right) for  $Z \rightarrow ee$  decays, using the tag-and-probe method and the Monte Carlo truth information.

tight (isol) cuts and also required to pass the trigger EM13i/e15i [11]. The tag electron is also required to be outside the barrel/end-cap transition region ( $1.37 < |\eta| < 1.52$ ). The probe electron is pre-selected by identifying a cluster in the opposite hemisphere, such that the azimuthal difference between tag and probe electrons is  $\Delta\phi > 3/4\pi$ . Both tag and probe electrons are required to have  $E_T > 15$  GeV. The invariant mass of the lepton pair is required to be between 80 and 100 GeV. Figure 15 compares  $\varepsilon_{TP}$  and  $\varepsilon_{MC}$  as a function of  $|\eta|$  and  $E_T$ . Table 9 summarises the results obtained for this first step in the reconstruction and identification of the probe electron.

$E_T$ -range (GeV)	15 – 25		25 – 40		40 – 70	
$ \eta $ -range	$\varepsilon_{TP}$	$\Delta\varepsilon_{TP/MC}$	$\varepsilon_{TP}$	$\Delta\varepsilon_{TP/MC}$	$\varepsilon_{TP}$	$\Delta\varepsilon_{TP/MC}$
0 – 0.80	$96.1 \pm 0.4$	$2.0 \pm 0.4$	$96.2 \pm 0.2$	$0.1 \pm 0.2$	$99.0 \pm 0.1$	$2.0 \pm 0.1$
0.80 – 1.37	$94.9 \pm 0.6$	$1.5 \pm 0.6$	$96.0 \pm 0.2$	$1.6 \pm 0.2$	$95.1 \pm 0.2$	$-0.5 \pm 0.2$
1.52 – 1.80	$89.0 \pm 1.2$	$3.6 \pm 1.2$	$88.8 \pm 0.6$	$1.3 \pm 0.6$	$91.9 \pm 0.6$	$1.7 \pm 0.6$
1.80 – 2.40	$83.0 \pm 1.0$	$0.6 \pm 1.0$	$83.2 \pm 0.6$	$0.8 \pm 0.6$	$84.9 \pm 0.6$	$1.1 \pm 0.6$

Table 9: Efficiency of the electron pre-selection,  $\varepsilon_{TP}$ , in percent as obtained from the tag-and-probe method, for different ranges of electron  $E_T$  and  $|\eta|$ . The errors quoted for  $\varepsilon_{TP}$  are statistical and correspond to an integrated luminosity of  $100 \text{ pb}^{-1}$ . Also shown is the difference,  $\Delta\varepsilon_{TP/MC}$ , between this estimate of the pre-selection efficiency and that obtained using the matching to the Monte Carlo electron.

### 5.3 Electron identification efficiency.

In this section, the electron identification efficiency is presented with respect to the reconstructed electrons discussed in Section 5.2. The QCD background was not considered here, since it is less than a few percent below the Z-boson mass peak. The reconstructed probe electron was checked against loose, medium and tight selection cuts. Table 10 summarises the results obtained for this second step in the reconstruction and identification of the probe electron. Figure 16 shows as a function of  $\eta$  and  $p_T$  the comparison between  $\varepsilon_{TP}$  and  $\varepsilon_{MC}$ , for the medium cuts. The losses at high  $\eta$  are due to the material in the inner detector, as discussed in Section 2.

Figure 16: Efficiency of the medium electron identification cuts relative to the pre-selection cuts as a function of  $|\eta|$  (left) and  $E_T$  (right) for  $Z \rightarrow ee$  decays, using the tag-and-probe method and the Monte Carlo truth information.

#### 5.4 Statistical and systematic uncertainties

A number of uncertainties may affect these tag-and-probe measurements once the accumulated data will provide high enough statistics to perform similar measurements to those quoted above:

- Differences between  $\epsilon_{TP}$  and  $\epsilon_{MC}$   
The relative difference  $\Delta\epsilon_{TP/MC}$  in regions (in  $p_T$  and  $|\eta|$ ), where the efficiency is flat, is less than 0.5%, assuming that the statistical error on  $\epsilon_{MC}$  is negligible.  $\Delta\epsilon_{TP/MC}$  marginally depends on the definition of a true electron and the systematic uncertainty related to this is estimated to be  $< 0.1\%$ , when varying the cut on the separation in  $\eta/\phi$  space ( $\Delta R$ ) between the reconstructed electron candidate and the true electron.
- Statistical uncertainty.  
The size of the available  $Z$ -boson sample is a source of systematic error. With an integrated luminosity of  $100 \text{ pb}^{-1}$ , the error is expected to be in the range 1-2% for  $p_T > 25 \text{ GeV}$ , and  $\sim 4\%$  in the low- $p_T$  bin.
- Selection criteria  
Another source of systematic error comes from varying the selection criteria. For instance, uncertainties introduced by varying the cut on the  $Z$ -boson mass or requiring an isolation criterion for the probe electron were evaluated. The magnitude of the uncertainty introduced is smaller than 0.5% for  $p_T > 40 \text{ GeV}$ . At low  $p_T$ , this uncertainty is estimated to be in the 1-2% range.
- QCD background contribution  
Adding the expected contribution from the QCD background to the signal does not degrade the results, except for  $1.52 < |\eta| < 1.8$ , a region which is close to the barrel/end-cap transition region and also where the efficiency is not uniform. The contribution from the uncertainties on the residual QCD background is expected to be negligible.

## 6 Conclusion

Excellent electron identification will clearly play an important role at the LHC, since high- $p_T$  leptons will be powerful probes for physics within and beyond the Standard Model. Based on this motivation,

<i>Loose</i> $ \eta  \backslash p_T$	15 – 25		25 – 40		40 – 70

Table 10: Loose, medium and tight electron identification efficiencies relative to the pre-selection efficiencies for different bins in  $E_T$  and  $|\eta|$ . The first error is statistical and corresponds to an integrated luminosity of  $100 \text{ pb}^{-1}$ . The second error is the difference obtained between  $\epsilon_{TP}$  and  $\epsilon_{MC}$ .

various algorithms and tools have been developed to efficiently reconstruct and identify electrons and separate them from the huge backgrounds from hadronic jets.

Presently, two reconstruction algorithms have been implemented in the ATLAS offline software, both integrated into one single package and a common event model. The first one relies on calorimeter seeds for reconstructing electrons, whereas the second algorithm relies on track-based seeds, is optimised for electrons with lower energies, and relies less on isolation.

The calorimeter based algorithm starts from the reconstructed cluster in the electromagnetic calorimeter, then builds identification variables based on information from the calorimeter and the inner detector. The rejection power with respect to QCD jets comes almost entirely from the identification procedure. Depending on the electron transverse energy and the analysis requirements, rejection factors of 500 to 100 000 can be achieved, for efficiencies of 88% to 64%, using a simple cut-based selection. More refined identification procedures combining calorimeter and track quantities using multivariate techniques provide a gain in rejection of about 20 – 40% with respect to the cut-based method, for the same efficiency of 61 – 64%. Alternatively, they provide a gain of 5 – 10% in efficiency, for the same jet rejection (tight and medium cuts).

Electrons in the forward region can also be identified and separated from the background. A simple cut-based method, exploring the energy depositions in the inner wheel of the electromagnetic end-cap calorimeter and in the forward calorimeter as well as the shower-shape distributions, shows that  $\sim 99\%$  of the QCD background can be rejected, for an electron identification efficiency of  $\sim 80\%$ . This performance should be sufficient to select cleanly, for example,  $Z \rightarrow ee$  decays with one electron in the forward region.

Studies of the strategies for measuring efficiencies and fake rates in early data show that the tag-and-

probe method is a good tool to estimate the electron identification efficiency and to control the reliability of the Monte Carlo simulation. With  $100 \text{ pb}^{-1}$ , the method is limited by the statistics of the Z sample, whereas its systematic uncertainty is of the order of 1 to 2 %.

The work presented here primarily addresses the description and performance of the offline reconstruction and identification of electrons. However, it also gives an overview of the possible path towards physics discoveries with electrons in Higgs, SUSY, and exotic scenarios.

# Reconstruction and Identification of Photons

## Abstract

This note presents the description and performance of photon identification methods in ATLAS. The reconstruction of an electromagnetic object begins in the calorimeter, and the inner detector information determines whether the object is a photon - either converted or unconverted - or an electron. Three photon identification methods are presented: a simple cut-based method, a Log-likelihood-ratio-based method and a covariance-matrix-based method. The shower shape variables based on calorimeter information and track information used in all three methods are described. The efficiencies for single photons and for photons from the benchmark  $H \rightarrow \gamma\gamma$  signal events, as well as the rejection of the background from jet samples, are presented. The performance of the cut-based method on high- $p_T$  photons from a graviton decay process  $G \rightarrow \gamma\gamma$  is also discussed.

## 1 Introduction

Isolated photons with large transverse momentum,  $p_T$ , in the final state are distinguishing signatures for many physics analyses envisaged at the LHC. The Higgs particle has been sought over several decades in many high-energy experiments, including those currently running at the Tevatron. It is understood that if the Standard Model Higgs particle exists, and unitarity is not violated, its mass is within the reach of LHC. As described in detail in other parts of this work [1], while the expected cross-section times branching ratio of the Higgs particle decaying into the two photon final state is relatively small, given its distinct signature, isolated high- $p_T$  photons may play a significant role in discovering the Higgs particle in the low mass region. In addition, very high- $p_T$  photons are also signatures of more exotic particles, such as the graviton predicted in Ref. [2], which is expected to have mass larger than 500 GeV. These photons appear as a single, isolated objects with most of their energy deposit in the electromagnetic compartment of the calorimeter. Thus the primary source for background to these photons, namely fake photons, result from jets that fluctuate highly electromagnetic which contain a high fraction of photons from neutral hadron decays, such as  $\pi^0 \rightarrow \gamma\gamma$ .

Since the ATLAS electromagnetic calorimeter [3] is highly segmented with a three-fold granularity in depth and with an  $\eta \times \phi$  granularity in the barrel of  $0.003 \times 0.1$ ,  $0.025 \times 0.025$ , and  $0.05 \times 0.025$ , respectively, in the front, middle and rear compartments assisted by a pre-sampler in front of the calorimeter, photon identification methods in ATLAS should be much more powerful than those used in past experiments. The experiment also employs elaborate trigger systems that select electrons and photons efficiently, as described in detail in Ref. [4].

This paper presents three ATLAS photon identification methods and their performance for single, isolated photons as well as for photons from physics processes.

## 2 Data samples

The  $H \rightarrow \gamma\gamma$  ( $m_H = 120$  GeV) process is used as the primary signal benchmark sample for medium  $p_T$  photons and with the pile-up that corresponds to the instantaneous luminosity  $10^{33} \text{ cm}^{-2}\text{s}^{-1}$ . Rejection studies were conducted using a pre-filtered jet sample (described in details in Ref. [5]), containing all relevant hard-scattering QCD processes with  $p_T > 15$  GeV. A filter is applied at the generator level, requiring the summed transverse energy of all stable particles (excluding muons and neutrinos) in a region of  $\Delta\phi \times \Delta\eta = 0.12 \times 0.12$  to be above 17 GeV. A total number of 3 million events were used

in rejection studies. Two additional samples with  $150 \text{ GeV} < p_T < 280 \text{ GeV}$  (Jet5) and  $280 < p_T < 400 \text{ GeV}$  (Jet6) were also employed for high- $p_T$  photon rejection studies. Finally, an additional 300,000 event  $\gamma$ +jet sample has been used for rejection and fake rate studies.

In addition to these signal and background samples, the three identification methods described in this paper were developed using single photon samples - events with no activity except the photon - with full detector simulation in the energy range  $10 - 1000 \text{ GeV}$  with flat pseudorapidity distributions over  $|\eta| < 2.5$ . For high- $p_T$  photons, graviton samples with masses of 0.5 and 1.0 TeV were employed.

All the samples used in this note were generated using PYTHIA and its fragmentation scheme and were passed through the full detector simulation. Some of the simulations were done with the nominal geometry and material distribution (“ideal”) and others with additional material added (“distorted”).

In order to maintain the consistency between different studies, the following requirements and definitions are used for efficiencies and rejections.

- Truth match: the reconstructed photons must lie within a cone of radius  $\Delta R = \sqrt{\Delta\eta^2 + \Delta\phi^2} < 0.2$  of the true photons in the simulation.
- The reconstructed photons must be within the fiducial volume, pseudorapidity  $0 < |\eta| < 1.37$  or  $1.52 < |\eta| < 2.47$  to avoid the overlap between the barrel and end-cap calorimeters.

Using the base samples that satisfy the above requirements, the efficiency is defined as follows:

$$\varepsilon = \frac{N_{\gamma}^{reco}}{N_{\gamma}^{truth}} \quad (1)$$

where  $N_{\gamma}^{truth}$  is the number of true photons in the simulation that satisfy all the requirements above with the true  $E_T$  greater than either 25 GeV or 40 GeV and  $N_{\gamma}^{reco}$  is the number of reconstructed photons that satisfy all the requirements with the true  $E_T$  greater than either 25 GeV or 40 GeV and that pass the threshold for one of the three methods.

Similarly, the rejection from the pre-filtered jet sample is computed as follows:

$$R = \frac{N_{jet}}{N_{fake\gamma}} \frac{N_1}{N_2} \frac{1}{\varepsilon_{\gamma-filter}} \quad (2)$$

where  $N_{jet}$  is the total number of jets reconstructed in the normalisation sample (same generation as the reconstructed sample but without the filter requirements) using particle four-momenta from the generator hadron level within a cone size  $\Delta R = 0.4$ , and  $N_2 (= 400,000)$  is the number of events used in this normalisation sample. The values for  $N_{jet}/N_2$  in the fiducial volume of  $|\eta| < 1.37$  or  $1.52 < |\eta| < 2.37$  are 0.226 for jets with  $E_T > 25 \text{ GeV}$  and 0.042 for jets with  $E_T > 40 \text{ GeV}$ .  $N_{fake\gamma}$  is the number of fake photons in the reconstructed (filtered) sample with the candidates that matched to true photons from the hard scatter or from quark bremsstrahlung removed, and  $N_1 (= 3,095,900)$  is the number of events analyzed from this sample. Finally,  $\varepsilon_{\gamma-filter} (= 0.082)$  is the efficiency of the generator level filter applied to the jet sample.

### 3 Photon identification methods

As discussed in previous sections, three photon identification methods have been developed and are available at present in ATLAS: a simple cut-based identification method, a Log-likelihood-ratio-based identification method (LLR) and the covariance-matrix-based identification method (H-matrix). A partial description of the basic electromagnetic object reconstruction and a detailed presentation of their calibration can be found in Ref. [6].

### 3.1 Characteristic variables and cut-based photon identification

In order to separate real photons from fake photons resulting from jets, several discriminating variables are defined using the information both from the calorimeters and the inner tracking system. Cuts on these variables are developed to maintain high photon efficiency even in the presence of pile-up resulting from the overlapping minimum bias events due to high instantaneous luminosity at the LHC. The discriminating variables used in this study are the same as in previous studies [7–11]. Calorimeter information is used to select events containing a high- $E_T$  electromagnetic shower. The fine-grained first compartment allows to reject showers from photons from  $\pi^0$  decays. Track isolation is used to improve the rejection. Only electromagnetic clusters with  $E_T > 20$  GeV are used in this study.

#### 3.1.1 Variables using calorimeter information

In the electromagnetic calorimeter, photons are narrow objects, well contained in the electromagnetic calorimeter, while fake photons induced from jets tend to have a broader profile and can deposit a substantial fraction of their energy in the hadronic calorimeter. Hence, longitudinal and transverse shower-shape variables can be used to reject jets.

- **Hadronic leakage :** The hadronic leakage is defined as the ratio of the transverse energy in the first layer of the hadronic calorimeter in a window  $\Delta\eta \times \Delta\phi = 0.24 \times 0.24$  to the transverse energy of the cluster in order to avoid boundary effects that could result from using readout cells. Real photons are purely an electromagnetic object, therefore they deposit their energy primarily in the electromagnetic compartment of the calorimeter. Fake photons induced from jets contain hadrons that would penetrate deeper into the calorimeter depositing sizable energy beyond the electromagnetic calorimeter.
- **Variables using the second compartment of the ECAL :** Electromagnetic showers deposit most of their energy in the second layer of the electromagnetic calorimeter. For this reason several variables that measure the shape of the shower are available as follows:
  - The real photons deposit most of their energy in a  $\Delta\eta \times \Delta\phi = 3 \times 7$  window (in units of middle cells). The lateral shower-shape variables,  $R_\eta$  and  $R_\phi$ , are given by the ratio of the energy reconstructed in  $3 \times 7$  middle cells to the energy in  $7 \times 7$  cells and the ratio of the energy reconstructed in  $3 \times 3$  cells to the energy in  $3 \times 7$  cells, respectively. Due to the effect of the magnetic field increasing the width of the converted photon contributions in the  $\phi$  direction,  $R_\phi$  is less discriminating than  $R_\eta$ .
  - The lateral width in  $\eta$  is calculated in a window of  $3 \times 5$  cells using the energy weighted sum over all cells.  $w_2 = \sqrt{\frac{\sum(E_c \times \eta_c^2)}{\sum E_c} - \left[\frac{\sum(E_c \times \eta_c)}{\sum E_c}\right]^2}$ , where  $E_c$  is the energy deposit in each cell, and  $\eta_c$  is the actual  $\eta$  position of the cell represented by the center of the cell in  $\eta$  direction. Therefore,  $w_2$  is given in units of  $\eta$ . A correction is applied as a function of the impact point within the cell to reduce the bias from the finite cell size.
- **Variables using the first compartment of the ECAL :** Cuts applied on the variables in the hadronic calorimeter and the second layer of the electromagnetic calorimeter reject jets which contain high-energy hadrons and resulting broad showers. Jets containing single or multiple neutral hadrons such as  $\eta$  and  $\pi^0$ , provide the main contribution which can fake photons. The readout of the first layer of the calorimeter uses strips and provides very fine granularity in pseudorapidity. Thus, the information from this layer can be used to identify substructures in the showers and distinguish isolated photons from the hard scatter and photons from  $\pi^0$  decays efficiently. The lateral

shower shape in the strips is exploited for  $|\eta| < 2.35$  where the strip granularity is sufficiently fine, as long as a 0.5% or larger fraction of the total energy is reconstructed in this layer.

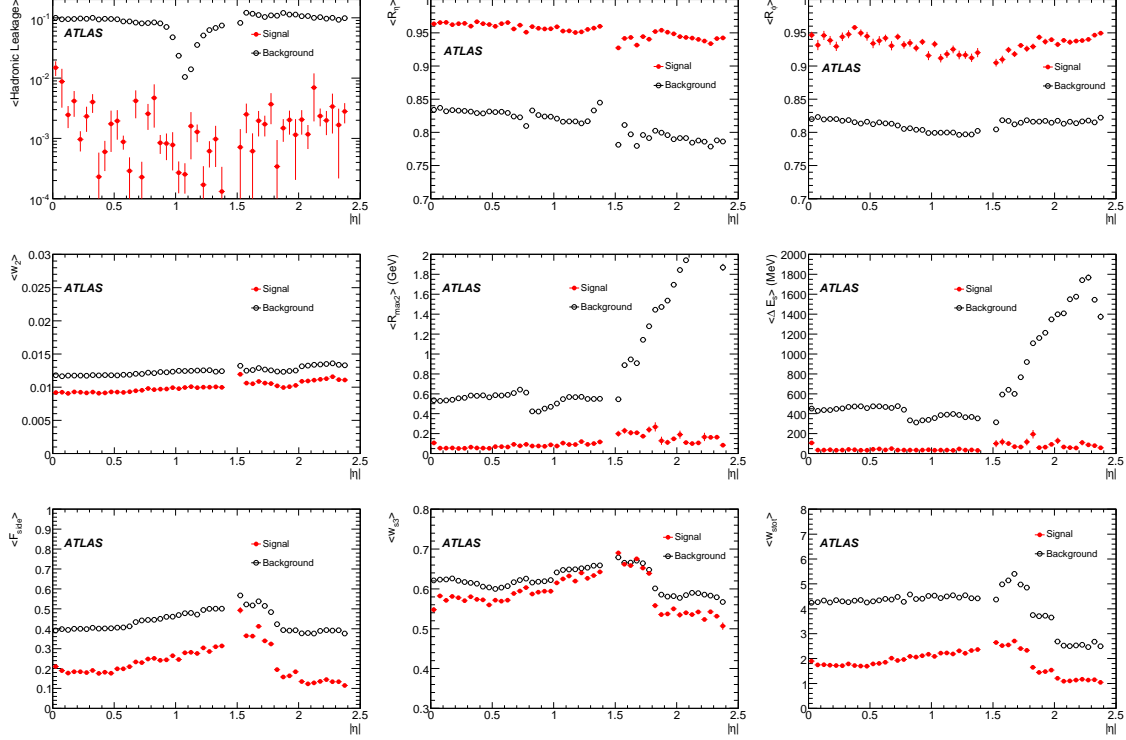

Figure 1: Distributions of the mean of each calorimetric discriminating variable as a function of the pseudorapidity  $|\eta|$  for true and fake photons (before cuts) with  $20 < E_T < 30$  GeV. The samples have been simulated with the geometry under the realistic alignment scenario and additional material.

- Since the energy-deposit pattern from  $\pi^0$ 's is often found to have two maxima due to  $\pi^0 \rightarrow \gamma\gamma$  decay, showers are studied in a window  $\Delta\eta \times \Delta\phi = 0.125 \times 0.2$  around the cell with the highest  $E_T$  to look for a second maximum. If more than two maxima are found the second highest maximum is considered. The following two variables are constructed using the information from the identified second maximum:
  - $\Delta E_s = E_{\max 2} - E_{\min}$ , the difference between the energy associated with the second maximum  $E_{\max 2}$  and the energy reconstructed in the strip with the minimum value, found in between the first and second maxima,  $E_{\min}$ .
  - $R_{\max 2} = E_{\max 2} / (1 + 9 \times 10^{-3} E_T / \text{GeV})$ , where  $E_T$  is the transverse energy of the cluster in the electromagnetic calorimeter. The value of the second maximal energy deposit is corrected as a function of the transverse energy of the cluster to minimise its sensitivity to fluctuations [9, 10].
- $F_{\text{side}} = [E(\pm 3) - E(\pm 1)] / E(\pm 1)$ , the fraction of the energy deposited outside the shower core of three central strips. The variable  $E(\pm n)$  is the energy deposited in  $\pm n$  strips around the strip with the highest energy.
- $w_{s3} = \sqrt{\sum E_i \times (i - i_{\max})^2 / \sum E_i}$ , the shower width over the three strips around the one with the maximal energy deposit. The index  $i$  is the strip identification number,  $i_{\max}$  the identi-

fication number of the most energetic strip, and  $E_i$  is the energy deposit in strip  $i$ .  $w_{s3}$  is expressed in units of strip cells and corrected for impact point dependence [9].

- $w_{stot}$ , the shower width over the strips that cover 2.5 cells of the second layer (20 strips in the barrel for instance). It is expressed in units of strip cells.

Figure 1 shows the average values of the calorimeter-based discriminating variables as a function of the absolute value of pseudorapidity. Features in the plots can be explained by: upstream material thickness which increases with pseudorapidity in the barrel; physical cell-size changes in the end-cap to maintain a constant granularity in  $\eta$ - $\phi$ ; and the change in the granularity of the first layer in the end-cap. In particular, the rise of  $R_{max2}$  and of  $\Delta E_s$  for  $|\eta| > 1.5$  stems from a combination of effects from the variation of the quantity of the upstream material and changes in the strip-cell sizes in the end-cap calorimeters. The dip in the hadronic leakage variable near  $|\eta| = 1.1$  corresponds to a smaller coverage by the first hadronic layer in this region.

Figure 2: Normalised distributions of the discriminating variable for  $|\eta| < 0.7$  for true and fake photons (before cuts) with  $20 < E_T < 30$  GeV. The samples have been simulated with the geometry under the realistic alignment scenario.

The cut values are tuned separately in six pseudorapidity intervals in  $|\eta| < 2.37$  to reflect the pseudorapidity dependence of these variables. The subdivision is motivated by the varying granularity and material in front of the electromagnetic calorimeter. The quantities calculated using the first compartment can be used only in the regions  $|\eta| < 1.37$  and  $1.52 < |\eta| < 2.37$  since there are no strips in the crack region or beyond  $|\eta| > 2.40$ . In addition, up to eight different bins in transverse energy are also used for the cut value adjustment. Figure 2 shows the distributions of the variables in the first  $\eta$  bin and in one energy bin. The dashed vertical lines represent the cut values in this bin. The variables are shown for all reconstructed electromagnetic objects before cuts.

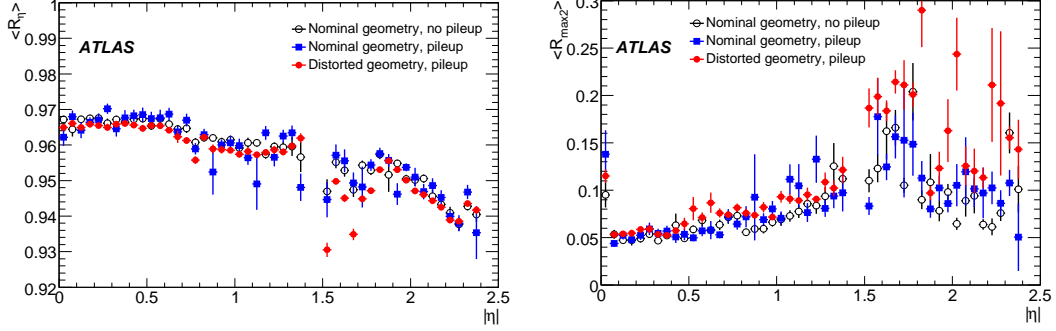

Figure 3: Effect of pile-up and distorted material on mean values of two shower-shape variables for photons from  $H \rightarrow \gamma\gamma$  decays:  $R_\eta$  (left) and energy of the second maximum in the first layer (right).

Figure 3 shows the impact of pile-up and additional material before the calorimeter on the shower-shapes for photons from Higgs decays. The impact of the large amount of additional material in the transition region,  $1.5 < |\eta| < 1.8$ , in the realistic alignment geometry can clearly be seen for two shower-shape variables. While pile-up at a luminosity of  $10^{33} \text{ cm}^{-2}\text{s}^{-1}$  does not change the average shower shape significantly as can be seen for the two variables in Figure 3, it is observed that it does increase RMS of the distributions.

At present, the same cuts are applied for converted and unconverted photons. Studies of the  $\gamma\text{-}\pi^0$  separation, however, have shown that if conversions can be identified efficiently, different cuts can be applied for converted and unconverted photons [12], which could improve rejection by 10-20% while maintaining the same overall photon identification efficiency.

The cuts have been chosen comparing the photons from  $H \rightarrow \gamma\gamma$  decays to fake candidates in inclusive jet samples. For this optimisation, samples generated with realistic alignment geometry and pile-up have been used. Some improvement in the performances should be possible at higher  $E_T$  for further refinement and optimisation in some of the variables, such as hadronic leakage. The rejection presented in this paper has been estimated on a sample statistically independent from the one used to tune the cuts.

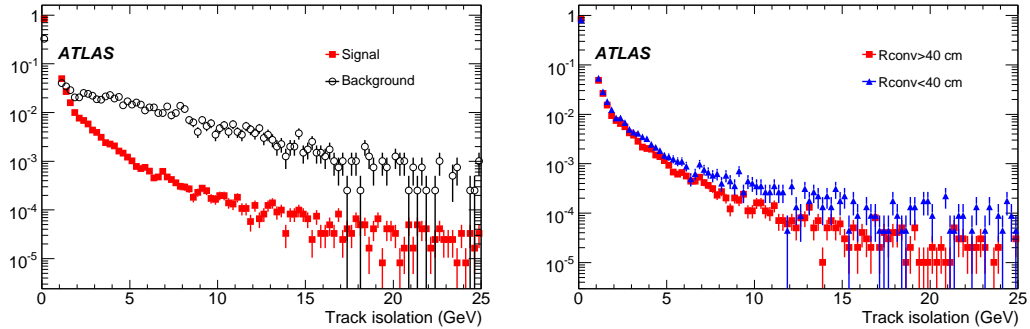

Figure 4: Normalised distribution of the track-isolation variable for events passing the calorimeter selection criteria. Left: comparison of true and fake photons. Right: comparison of early conversions (true conversion radius less than 40 cm) and late conversions (true conversion radius above 40 cm) for photons from  $H \rightarrow \gamma\gamma$  decays.

### 3.1.2 Track isolation

After the calorimeter cuts, the contamination of the inclusive signal from charged hadrons is greatly reduced. The remaining background is dominated by low track multiplicity jets containing high- $p_T$   $\pi^0$  mesons. In order to further remove fake photons from these jets, the track-isolation variable is defined as the sum of the  $p_T$  of all tracks with  $p_T$  above 1 GeV within  $\Delta R < 0.3$ , where  $\Delta R$  is the  $\eta - \phi$  distance between the track position at the vertex and the cluster centroid. Track  $p_T > 1$  GeV is imposed to minimise the effect of pile-up and underlying events.

Since the tracks from photon conversions should not be included in computing this variable, some additional selections are applied to tracks within  $\Delta R < 0.1$  of the cluster centroid. The impact parameter with respect to the beam line must be less than 0.1 mm. The track  $p_T$  must not exceed 15 GeV to remove tracks from very asymmetric conversions, must not be part of a reconstructed conversion vertex and must have a hit in the innermost pixel layer.

The plot on the left in Fig. 4 shows the distribution of the track-isolation variable for true and fake-photon candidates, after the calorimeter shower-shape cuts. An additional rejection of factor 1.5 to 2 is possible for a relatively small efficiency loss. The plot on the right in this figure shows the track-isolation variable for early converted and late converted photons. The difference between the two distributions is rather small, showing that the tracks from conversions have been efficiently removed. At present, a 4 GeV upper cut on the track-isolation variable is applied for this method.

## 3.2 Log-likelihood-ratio-based photon identification

In the Log-likelihood-ratio (LLR)-based method, the distribution of each of the shower-shape variables is normalised to unity to obtain the probability density functions (PDF). The shower-shape variables are pseudorapidity-dependent, so they are separated in four regions of  $|\eta|$  and three bins in  $p_T$  for this method. The PDF's are obtained using 1.6 million  $\gamma$ +jet events which provided slightly over 100,000 events in each bin. Since the statistics for the PDF computation is somewhat low in some kinematic phase-space regions, further improvement can be obtained by using tools to smooth the PDF's to compensate for the low statistics [13]. Once the PDF's are established, the Log-likelihood-ratio parameter is defined as:

$$LLR = \sum_{i=1}^n \ln(L_{si}/L_{bi}), \quad (3)$$

where  $L_{si}$  and  $L_{bi}$  are PDF's of the  $i^{th}$  shower-shape variable for the photon and the jet, respectively.

The shower-shape variables used for the LLR method were the same as those used for the cut-based method described previously. Track isolation was also included as a discriminating variable in Equation 3. Figure 5 shows the LLR parameter distribution for photons and for jets. The LLR cut can be tuned over  $\eta$  and  $p_T$  to obtain an optimal separation between photons and jets.

## 3.3 Covariance-matrix-based photon identification

The shower-shape variables associated with a photon shower in the calorimeter are correlated. The covariance matrix (H-matrix) technique takes advantage of these correlations. The technique was employed successfully in the DØ experiment at the Tevatron and was used to identify electrons [14].

The ten photon shower-shape variables used in the ATLAS H-matrix method are as follows:

- Five longitudinal shower-shape variables: fraction of energy deposited in pre-sampler layer; fractions of energy deposited in sampling layers 1, 2 and 3 separately; and the hadronic leakage, the energy leakage into the first layer of the hadronic calorimeter.

Figure 5: Expected Log-likelihood ratio (LLR) cut-parameter distributions for photons (solid histogram) and for jets (dashed histogram).

Figure 6: The distributions of H-matrix  $\chi^2$  for photons from the  $H \rightarrow \gamma\gamma$  sample (solid histogram) and for jets from the inclusive jet samples (dashed histogram).

- Five transverse shower-shape variables: the ratio of the energy in  $3 \times 3$  cells to the energy in  $7 \times 7$  in the second sampling layer of the electromagnetic calorimeter;  $w_{rms3}$ , the corrected width in 3 strips in sampling layer 1;  $w_2$ , the corrected width in a  $3 \times 5$  window in sampling layer 2; the energy outside of the shower core;  $R_\phi$ , the ratio of energy in a  $3 \times 3$  to a  $3 \times 7$  window around the cluster centroid.

Using the above variables, a covariance matrix,  $M$ , is constructed as follows:

$$M_{ij} = \frac{1}{N} \sum_{n=1}^N (y_i^{(n)} - \bar{y}_i)(y_j^{(n)} - \bar{y}_j), \quad (4)$$

where indices  $i$  and  $j$  run over the ten variables,  $N$  is the total number of photons used in the training sample,  $y_j^n$  is the  $j^{th}$  variable for the  $n^{th}$  photon candidate, and  $\bar{y}_j$  is the mean value of  $y_j$  variable for the

control sample electrons/photons. These matrix elements are constructed for each  $\eta$  bin and parametrised for energy dependences. The photon likeness of an object is then measured by the value of the  $\chi^2$ , defined as follows:

$$\chi^2 = \sum_{i,j=1}^{dim} (y_i^{(m)} - \bar{y}_i) H_{ij} (y_j^{(m)} - \bar{y}_j) \quad (5)$$

where  $H \equiv M^{-1}$ , the inverse of the covariance matrix, and the indices  $i$  and  $j$  run from 1 to the total number of variables (ten) which is the same as the dimension of the matrix,  $dim$ .

The mean value of the  $\chi^2$  is close to the number of dimensions for a photon shower. The shapes of the distributions of the selected shower-shape variables depend on the  $\eta$  and the energy of the incident photon. These effects are taken into account in the construction of the H-matrix using single photon samples of energies 10 – 1000 GeV generated flat in  $|\eta|$  and parametrising each of the covariance terms in the matrix  $M$  of Eq. 4 as a function of the photon energy. The parametrisation as a function of photon energy is obtained in each of the 12  $\eta$  bins. The discrimination power of the H-matrix between real photons and jets is well illustrated in Fig. 6, where the  $\chi^2$  distribution of the H-matrix for the jet sample is contrasted to that obtained from photons from  $H \rightarrow \gamma\gamma$  decays.

Since the H-matrix implementation at this time does not include the same variables as the other two methods, its performance is currently not directly comparable. Consequently, the performance is not reported here, although the method is described for completeness.

Figure 7: Efficiency of the calorimeter cuts as a function of pseudorapidity (left) and transverse energy (right) of the photons for the distorted geometry.

Efficiency	$\varepsilon$ (calorimeter cuts)	$\varepsilon$ (track-isolation cut)
Nominal geometry no pile-up	$(87.6 \pm 0.2)\%$	$(99.0 \pm 0.1)\%$
Nominal geometry with pile-up	$(86.6 \pm 0.5)\%$	$(98.0 \pm 0.2)\%$
Distorted geometry with pile-up	$(83.6 \pm 0.2)\%$	$(98.1 \pm 0.1)\%$

## 4 Photon identification performance for medium- $p_T$ photons

This section describes the performance (efficiencies and rejections) of the cut-based method and the Log-likelihood ratio method on medium- $p_T$  photons, in particular the photons from  $H \rightarrow \gamma\gamma$  decays and the jet background samples described in Section 2.

#### 4.1 Performance of the cut-based method

In the performance studies presented in this section, all reconstructed electromagnetic objects, including both electron and photon candidates are considered. The efficiency as defined in Section 2 includes both the reconstruction efficiency and the efficiency of the identification cuts.

Figure 7 shows the efficiency of the calorimeter cuts for photons with  $E_T > 25$  GeV from  $H \rightarrow \gamma\gamma$  decay as a function of pseudorapidity (left) and transverse energy (right) for events in the presence of the pile-up expected at a luminosity of  $10^{33} \text{ cm}^{-2}\text{s}^{-1}$ . The optimisation of the cuts for the  $H \rightarrow \gamma\gamma$  signal has led to an efficiency which is uniform for  $E_T > 40$  GeV, but which decreases substantially below 40 GeV because of the much larger fake backgrounds from jets expected at these lower transverse energies. The average efficiencies of the calorimeter and track-isolation cuts are summarised in Table 1.

	All	Quark jets	Gluon jets
$N(\text{jet})/N(\text{generated events})$	0.23	0.056	0.177
Before isolation cut			
$N(\text{fake})/N(\text{filtered events})$	$(5.43 \pm 0.13) \cdot 10^{-4}$	$(3.87 \pm 0.11) \cdot 10^{-4}$	$(1.44 \pm 0.07) \cdot 10^{-4}$
Rejection	$5070 \pm 120$	$1770 \pm 50$	$15000 \pm 700$
After isolation cut			
$N(\text{fake})/N(\text{filtered events})$	$(3.38 \pm 0.10) \cdot 10^{-4}$	$(2.47 \pm 0.08) \cdot 10^{-4}$	$(0.78 \pm 0.49) \cdot 10^{-4}$
Rejection	$8160 \pm 250$	$2760 \pm 100$	$27500 \pm 2000$

Table 2: Rejection (Equation 2) measured in the inclusive jet sample for  $E_T > 25$  GeV

	All	Quark jets	Gluon jets
$N(\text{jet})/N(\text{generated events})$	0.042	0.011	0.034
Before isolation cut			
$N(\text{fake})/N(\text{filtered events})$	$(1.16 \pm 0.06) \cdot 10^{-4}$	$(8.3 \pm 0.5) \cdot 10^{-5}$	$(2.8 \pm 0.3) \cdot 10^{-5}$
Rejection	$4400 \pm 230$	$1610 \pm 100$	$15000 \pm 1600$
After isolation cut			
$N(\text{fake})/N(\text{filtered events})$	$(6.4 \pm 0.4) \cdot 10^{-5}$	$(4.6 \pm 0.5) \cdot 10^{-5}$	$(1.5 \pm 0.2) \cdot 10^{-5}$
Rejection	$7800 \pm 540$	$2900 \pm 240$	$28000 \pm 4000$

Table 3: Rejection (Equation 2) measured in the inclusive jet sample for  $E_T > 40$  GeV

The rejection from the pre-filtered jet sample is computed using Equation 2. The rejection is computed separately for all jets, for quark-initiated jets and for gluon-initiated jets. The quark or gluon initiation is defined using the type of the highest  $E_T$  parton from the PYTHIA record inside the cone  $\Delta R = 0.4$  around the reconstructed jet object. The rejection values are summarised in Table 2 for the three categories of jets. A small fraction ( $\approx 1\text{-}2\%$ ) of jet objects are not classified, so the sum of quarks and gluons is slightly smaller than the total. A cut  $E_T > 25$  GeV is applied to both reconstructed photons and jets. Table 3 shows the same computation, but for  $E_T > 40$  GeV.

Figure 8 shows the fake rate, defined as the inverse of the rejection, as a function of pseudorapidity for all jets with  $E_T$  greater than 25 GeV. There is a slight increase of fake rate as a function of pseudorapidity due to the increase in material in front of the calorimeter, which imposes somewhat looser cuts to preserve a constant efficiency. Some additional increase near  $|\eta| = 1.1$  is also visible probably coming from the reduced energy in the first layer of the hadronic calorimeter as pointed out previously. This effect, however, gives a less than 10% increase in the overall fake rate.

Figure 8: Fake-photon rate as a function of pseudorapidity in the filtered jet sample

Figure 9:  $E_T$  spectra from the inclusive jet sample, for the generated jets (solid squares for full simulation and solid triangles for uncorrected jets from parametrised fast simulation) and the fake-photon candidates before (inverted solid triangles) and after (open circles) the track-isolation cut. The normalisation is that predicted by PYTHIA.

Figure 9 shows the  $E_T$  distribution of the jets and of the fake photon candidates before and after the track-isolation cut. This figure also shows that the rejection at 25 GeV is  $\approx 30\%$  lower if the normalisation is based on the uncorrected parametrised jets from the fast simulation, as was done in Ref. [11].

Figure 10 shows the  $\pi^0$  content of the fake-photon candidates at three different cut levels; all reconstructed electromagnetic objects, after the cut on the hadronic leakage and the second layer shower-shape variables (Had+S2) and after all the cuts (Had+S1+S2). A fake photon is defined as coming from a  $\pi^0$  if the energy of the leading  $\pi^0$  in the cone of 0.2 around the cluster centroid is more than 80% of the reconstructed cluster energy. The figure shows already after the second layer shower-shape cuts, the dominant background contribution comes from  $\pi^0$  as expected. After all cuts, the fraction of  $\pi^0$  is  $\approx 70\%$  of the remaining fake-photon candidates.

Figure 11 shows the rejection of the cuts on the first layer variables for candidates from single  $\pi^0$ 's passing the cuts on the hadronic leakage and the second layer shower-shape variables. As expected, the

Figure 10:  $E_T$  distribution of fake-photon candidates in jets after different level of cuts. The contribution from "single"  $\pi^0$  is also shown

Figure 11: Rejection of the strip-layer cuts against fake photons coming from "single"  $\pi^0$  in the jet sample as a function of the transverse energy, for three different pseudorapidity regions.

rejection power against these isolated  $\pi^0$ 's decreases with energy, as the opening angle between the two photons from  $\pi^0$  decays become smaller. The rejection is also better in the central part in the barrel as there is less material than in the higher  $\eta$  part of the barrel, and also opening angle is larger than in the end-cap for the same  $p_T$ . As a cross-check, Fig. 12 shows the efficiency of the calorimeter cuts for single photons and single  $\pi^0$  of  $E_T = 40$  GeV, as a function of pseudorapidity. Again, the rejection is slightly higher than 3 in the central part of the barrel calorimeter and is in reasonable agreement with findings from previous studies [15].

The rejections measured in these studies have to be taken with care as they rely strongly on the modelling of the fragmentation tail in PYTHIA and the details of the simulation of the detector response. A discussion of the first effect can be found in Ref. [8] from which one would expect an uncertainty of 50 – 100%, and where the uncertainty is larger for gluon initiated jets. In addition, a recent investigation on the differences in fragmentation algorithms in PYTHIA and HERWIG shows appreciable differences in  $\pi^0$  production rates. Some differences in rejection are anticipated if the momentum distributions of the  $\pi^0$ 's from the two fragmentation algorithms differ.

## 4.2 Performance of the Log-likelihood-ratio method

The efficiency for the Log-likelihood-ratio (LLR) method is computed for individual photons from the  $H \rightarrow \gamma\gamma$  events generated with the nominal geometry. Figure 13 shows the photon efficiency as a function

Figure 12: Efficiency of calorimeter cuts versus pseudorapidity for 40 GeV  $E_T$  single photons and  $\pi^0$  (distorted geometry without pile-up).

of  $p_T$  (left) and  $\eta$  (right) for LLR cut values set at 8, 9 and 10. The overall efficiencies for LLR cuts at 8, 9 and 10 are summarised in Table 4. Jet rejection (left) and photon identification efficiency (right) are shown in Fig. 14 as a function of LLR cut parameter values for three different jet  $p_T$  ranges which correspond to the three mean jet  $p_T$  values indicated.

LLR cut	$E_T > 25$ GeV			$E_T > 40$ GeV		
	$LLR > 8$	$LLR > 9$	$LLR > 10$	$LLR > 8$	$LLR > 9$	$LLR > 10$
Efficiency(%)	$87.6 \pm 0.3$	$84.3 \pm 0.2$	$80.0 \pm 0.2$	$86.4 \pm 0.3$	$83.2 \pm 0.2$	$79.0 \pm 0.2$
Rej.( $\gamma$ +jet)	$1660 \pm 170$	$2190 \pm 260$	$2930 \pm 390$	$1690 \pm 140$	$2170 \pm 210$	$2650 \pm 280$
Rej. (di-jet)	$6820 \pm 440$	$8930 \pm 650$	$12430 \pm 1070$	$6780 \pm 1000$	$7800 \pm 1230$	$11550 \pm 2220$

Table 4: Overall photon efficiencies and jet rejections for different Log-likelihood ratio (LLR) cut values.

Figure 13 shows the  $p_T$ -dependence of the photon efficiency. A looser cut on low- $p_T$  photons seems to be beneficial in order to retain a flat photon efficiency as a function of  $p_T$ . Furthermore, it might also be useful to parametrise the LLR cut values as a function of photon  $p_T$  for further optimisation. The jet rejection is also  $p_T$ -dependent as shown in the plot on the left in Fig. 14. A harder cut on LLR for varying jet  $p_T$  can help to keep the rejection constant as a function of  $p_T$ .

The rejection for jets from  $\gamma$ +jet and di-jet samples are shown in the fourth and fifth rows in Table 4. The cuts on the photon and jet  $p_T$  are 25 GeV and 40 GeV, respectively. The rejection against jets from the di-jet samples is significantly higher than that from the  $\gamma$ +jet samples. This is largely due to the fact that the jets in  $\gamma$ +jet events are dominated by quark-initiated jets while those in di-jet events are enriched with gluon-initiated jets.

## 5 Photon identification performance for high- $p_T$ photons

Searches for particles of very high mass decaying to photons, such as the Randall-Sundrum graviton,  $G$ , decaying via  $G \rightarrow \gamma\gamma$  [2], require excellent detector and particle identification performance in a kinematic region very different from the benchmark  $H \rightarrow \gamma\gamma$  process. The  $p_T$ -dependent effect caused by

Figure 13: Photon efficiency as a function of  $p_T$  and  $\eta$  for different Log-likelihood ratio (LLR) cuts. The photons are from  $H \rightarrow \gamma\gamma$  decays simulated with the nominal geometry.

Figure 14: Jet rejection (left) and photon efficiency (right) as a function of Log-likelihood ratio (LLR) cut-parameter values.

differences in kinematics can complicate high-mass graviton searches because they modify the shape of background distributions as a function of the two-photon invariant mass,  $m_{\gamma\gamma}$ .

The performance of the cut-based identification method for high- $p_T$  photons has been investigated. Studies of the shower characteristics of the photons in the  $H \rightarrow \gamma\gamma$  and  $G \rightarrow \gamma\gamma$  ( $m_G = 500$  GeV) processes found only minor differences in most of the shower-shape variables. In the absence of the track-isolation cut, the photon efficiency as a function of  $p_T$  in both the barrel and end-cap calorimeters is approximately constant above  $p_T = 50$  GeV. The barrel and end-cap photon electromagnetic reconstruction efficiencies, before applying any identification or isolation cuts, are found to be within 10% of one another for photons from graviton decays. After applying photon identification but no isolation requirements, the efficiencies are  $0.829 \pm 0.004$  in the barrel and  $0.639 \pm 0.010$  in the end-cap calorimeters for  $p_T^\gamma > 100$  GeV and  $m_G > 500$  GeV.

An isolation variable based on the calorimeter energy in a cone of size  $\Delta R = 0.45$  around the cluster centroid was studied. The cut on the calorimeter isolation was observed to produce roughly constant efficiency as a function of  $p_T$ . A linearly  $p_T$ -dependent selection cut was determined for barrel and

Figure 15: Photon efficiency in the 500 GeV graviton sample as a function of  $p_T$  for barrel (left) and end-cap (right) calorimeters.

Figure 16: Fake-photon rejection as a function of  $p_T$  of the reconstructed photon object for high- $p_T$  binned di-jet samples in the barrel (left) and end-cap (right) calorimeters.

end-cap photons independently. The efficiencies of these  $p_T$ -dependent cuts for barrel and end-cap calorimeters are shown in Fig. 15 for photons from 500 GeV graviton decays. As can be seen in the figures, these  $p_T$ -dependent isolation cuts show about a 0.1% reduction in efficiency for photons over the entire  $p_T$ -range.

The Jet5 and Jet6 high- $p_T$  jet samples discussed in Section 2 were used for rejection studies. Figure 16 shows the  $p_T$  dependence of jet rejection with and without the calorimeter energy isolation cuts. It can be seen that while the efficiency loss is small, employing the isolation cut increases rejection across the full  $p_T$  range. In particular, the region below  $p_T = 500$  GeV shows a factor 5 – 10 increase in rejection. Table 5 provides the measured rejections in the barrel and end-cap calorimeters using these two di-jet samples.

## 6 Comparison of the photon identification methods

Figure 17 shows the rejection and efficiency curves for two of the three currently available photon identification methods - the cut-based method and the Log Likelihood Ratio method - for  $\gamma$ +jet generated in specific photon momentum bins and the benchmark  $H \rightarrow \gamma\gamma$  samples. Similarly, Fig. 18 shows the rejection and efficiency curves for these methods for di-jet and  $H \rightarrow \gamma\gamma$  samples. Tables 6 and 7 provide

numerical comparisons of fake-photon rejections for the two methods, for similar photon identification efficiencies and for the  $\gamma$ +jet and di-jet samples, respectively.

The  $\gamma$ +jet events, with jets dominated by quark-initiated jets, are the source of the largest background to the  $H \rightarrow \gamma\gamma$  process. It is apparent from Figs. 17 and 18 that the methods demonstrate significantly reduced rejections for jets from the  $\gamma$ +jet samples than for those from di-jet samples whose jets are predominantly from gluons. As discussed in previous sections, this difference in rejection can be attributed to the fragmentation differences between the quark and gluon-initiated jets.

Finally, Figs. 17 and 18 also illustrate that, for equal efficiencies, the Log-likelihood ratio method and the cut-based method perform comparably in rejecting jets.

Figure 17: Jet rejection vs photon efficiency for binned  $\gamma$ +jet and  $H \rightarrow \gamma\gamma$  benchmark samples for  $p_T^\gamma, p_T^{jet} > 25$  GeV(left) and  $p_T^\gamma, p_T^{jet} > 40$  GeV(right).

Figure 18: Jet rejection vs photon efficiency of the two methods for filtered di-jet and  $H \rightarrow \gamma\gamma$  benchmark samples for  $p_T^\gamma, p_T^{jet} > 25$  GeV (left) and  $p_T^\gamma, p_T^{jet} > 40$  GeV (right).

## 7 Conclusions

This note presents the three photon identification methods developed in ATLAS, the cut-based method, the Log-likelihood ratio (LLR)-based method and the covariance-matrix-based method (H-matrix). The efficiencies and fake-photon rejections of the first two methods have been measured using fully simulated  $H \rightarrow \gamma\gamma$  ( $m_H = 120$  GeV),  $\gamma$ +jet and filtered electromagnetic di-jet samples. The cut-based and LLR

methods show similar rejection factors at equal efficiencies. The strength of the continuous methods such as the LLR and H-matrix is the ability to vary the cuts on LLR or  $\chi^2$  values to optimise for specific physics analyses. The performance of the cut-based method for very high- $p_T$  photons from Randall-Sundrum graviton samples has also been studied and, while the cut selection was optimised at low- $p_T$  compared to the signal in the graviton sample, the efficiency remains high. While the currently available photon identification methods perform very well in rejecting background, with high efficiency in retaining photons, it is of critical importance to study the performance of the methods with beam-collision data.

Region	Rejection( $\times 10^3$ )	Rejection( $\times 10^3$ )
Barrel	$1.54 \pm 0.05$	$3.85 \pm 0.03$
End-cap	$0.64 \pm 0.03$	$1.14 \pm 0.08$
Total	$1.25 \pm 0.03$	$2.78 \pm 0.08$

# Reconstruction of Photon Conversions

## Abstract

The reconstruction of photon conversions in the ATLAS detector is important for improving both the efficiency and the accuracy of the detection of particle decays with photon final states, including  $H \rightarrow \gamma\gamma$ . In this note, the performance of the reconstruction of photon conversions for simulated events of different types is described, using both standard inside-out tracking and the more recently implemented outside-in tracking.

## 1 Introduction

Reconstruction of photon conversions in the ATLAS detector is important for a variety of physics measurements involving electromagnetic decay products. In particular, the efficiency of detection of particles with high-mass di-photon final states, such as the Higgs boson or a heavy graviton, is greatly enhanced by efficient conversion reconstruction. Conversion reconstruction will also be used for detector-related studies: mapping the locations of the conversion vertices provides a precise localisation of the material in the ATLAS inner detector.

As photons may convert at any point in the tracker in the presence of material, the ability to reconstruct conversions will depend strongly on the type of tracking algorithm used. Due to the structure of the ATLAS tracker, photons which convert within 300 mm of the beam axis may be reconstructed with a high efficiency with standard (inside-out) Si-seeded tracking, while photons which convert further from the beam pipe may only be reconstructed using (outside-in) tracks, which begin with TRT seeds with or without associated Si hits. Track reconstruction will be discussed in Section 2, while the reconstruction of conversion vertices will be discussed in Section 3, and the overall reconstruction of conversions will be discussed in Section 4. Applications of photon conversion reconstruction in the case of neutral pion decays and low- $p_T$  photons as well as the application of conversion reconstruction to the case of high- $p_T$  physics measurements (such as  $H \rightarrow \gamma\gamma$ ), will be found in Section 5. A summary and concluding remarks are found in Section 6.

### 1.1 Theory

The ATLAS detector is designed to measure, among other things, the energies and momenta of photons produced in high-energy proton-proton collisions. The photons which are relevant to physics measurements will have energies in excess of 1 GeV. These photons must pass through the ATLAS tracker before depositing their energy in the Liquid Argon Calorimeter. At photon energies above 1 GeV, the interaction of the photons with the tracker will be completely dominated by  $e^+e^-$  pair production in the presence of material, otherwise known as photon conversion. All other interactions between the photons and the tracker material, such as Compton or Rayleigh scattering, will have cross-sections which are orders of magnitude below that for the photon conversion, and may thus be safely ignored. The leading-order Feynman diagrams for photon conversions in the presence of material are shown in Figure 1. The presence of the material is required in order for the conversion to satisfy both energy and momentum conservation.

The cross-section for the conversion of photons in the presence of material is both well understood theoretically and thoroughly measured. Work on calculating this cross-section began almost immediately after the discovery of the positron by Anderson in 1932 [1]. Bethe and Heitler first gave a relativistic treatment of photon conversion in 1934 [2] in which the screening of the nuclear Coulomb field was taken into account. A detailed review of the theory regarding photon conversion and the calculation of

Figure 1: Leading-order Feynman diagrams for photon conversions.

the conversion cross-section for a variety of materials was given by Tsai in 1974 [3]. A more modern treatment of the topic of conversions, including corrections to the Bethe-Heitler formula for photon energies above 5 TeV was given by Klein in 2006 [4].

For photon energies used in this study (1 GeV and above) the cross-section for the conversion process is almost completely independent of the energy of the incident photon, and may be given by the following equation [3]:

$$\sigma = \frac{7A}{9X_0N_A}. \quad (1)$$

In this expression  $A$  is the atomic mass of the target given in g/mol, and  $N_A = 6.022 \times 10^{23}$  is Avogadro's number.  $X_0$  is known as the radiation length of the material through which the photon passes, which for elements heavier than helium may be approximated from the atomic mass  $A$  and the atomic number  $Z$  by the following relation [5]:

$$X_0 = \frac{716.4 \text{ g cm}^{-2} A}{Z(Z+1)\ln(287\sqrt{Z})}. \quad (2)$$

This radiation length is defined such that it is 7/9 of the mean free path for photon conversion. Plots showing the total radiation length traversed by photons in the tracker before reaching the calorimeter may be found in the next section.

The differential cross-section for photon conversions of energies of 1 GeV and above in terms of the quantity  $x = (E_{\text{electron}}/E_{\text{photon}})$  is [4]:

$$\frac{d\sigma}{dx} = \frac{A}{X_0N_A} \left(1 - \frac{4}{3}x(1-x)\right). \quad (3)$$

This cross-section is symmetric in  $x$  and  $1-x$ , the electron and positron energies, and it implies that the momentum of the photon is not simply shared equally between the electron and the positron. Some fraction of the photon conversions will be highly asymmetric, and either the electron or the positron may be produced with a very low energy. If this energy falls below the threshold required to produce a reconstructable track in the ATLAS tracker, then the converted photon will be seen to have only one track, and will be difficult to distinguish from a single electron or positron. This problem is more serious at lower photon energies, as the proportion of conversions which are asymmetric enough to cause the loss

Figure 2: Material in the inner detector as a function of  $|\eta|$ .

of one of the two tracks increases as the photon energy decreases. The difficulties involved in identifying these highly asymmetric single-track conversions will be discussed in a later section.

## 1.2 Experimental setup

In this section a very brief description of the ATLAS tracker and electromagnetic calorimeter is included. These are the two sub-systems necessary for the studies relevant to this note. A detailed description of the ATLAS detector can be found in the ATLAS detector paper [6] and references therein.

The ATLAS tracker consists of several co-axial layers immersed in a 2T solenoidal magnetic field. In the so-called barrel region, the innermost of these is a pixel detector consisting of three highly segmented cylindrical layers surrounded by four stereo-pair silicon microstrip (SCT) layers. In addition to the cylindrical layers forming the barrel, both the pixel and the SCT also have end-caps consisting of disk shaped segments used for tracking particles with large pseudorapidities ( $|\eta| > 1.5$ ). The outermost portion of the tracker consists of the Transition Radiation Tracker (TRT), which is comprised of many layers of gaseous straw tube elements interleaved with transition radiation material. The TRT is divided into a barrel detector, covering the small pseudorapidity region  $|\eta| < 1$ , and two end-cap detectors covering the large pseudorapidity region  $1 < |\eta| < 2.1$ . The lack of TRT detector elements at higher pseudorapidities is the reason for all the results presented in this note having a cut-off at  $|\eta| = 2.1$ .

The amount of material in the tracker given in radiation lengths as a function of pseudorapidity can be seen in Fig. 2 [6]. As mentioned earlier, the probability of a photon converting in any given layer is proportional to the amount of material in that layer. Overall, as many as 60 % of the photons will convert into an electron-positron pair before reaching the face of the calorimeter [6]. This number varies greatly with pseudorapidity as can be seen in Fig. 3 [6], for the case of photons with  $p_T > 1$  GeV in minimum-bias events. The probability is lowest in the most central region  $|\eta| < 0.5$ , where the amount

of tracker material is at its minimum. A plot showing the true position of photon conversions in the ATLAS tracker, as obtained from a sample of 500,000 simulated minimum-bias events, can be seen in Fig. 4 [6]; the three pixel layers and disks as well as the four barrel SCT layers and their corresponding end-cap layers can be clearly seen.

Figure 3: Probability of a photon to have converted as a function of radius for different values of pseudorapidity.

Finally, the energies of the electrons resulting from photon conversions are measured in the electromagnetic calorimeter segments. These are lead-liquid argon detectors with accordion-shaped absorbers and electrodes. Their fine-grained lateral and longitudinal structure, ensures high reconstructed energy resolution for photons with  $E_T > 2 - 3$  GeV, as described in reference [7]. Although the daughter electron tracks and the vertices resulting from the converted photons are reconstructed without any calorimetric information, the latter plays a crucial role later in the reconstruction and particle identification process.

## 2 Track reconstruction

The current track reconstruction process consists of two main sequences, the primary *inside-out* track reconstruction for charged particle tracks originating from the interaction region and a consecutive *outside-in* track reconstruction for tracks originating later inside the tracker. Both methods reconstruct tracks that have both silicon (Si) and transition radiation tracker (TRT) hits and place these tracks in two distinct track collections. A third track category contains those tracks that have only TRT hits and no Si hits; these TRT-only tracks are placed in their own distinct track collection. All three track collections are then examined to remove ambiguities and double counting and are finally merged into a global track collection to be used later during the vertex-reconstruction phase. For a track to be reconstructed by any of these methods, a minimum transverse momentum  $p_T > 0.5$  GeV is required throughout. In the following section, brief descriptions of the various tracking algorithms are provided. More detailed descriptions, in particular of the *inside-out* tracking, can be found in reference [8].

Figure 4: Location of the inner detector material as obtained from the true positions of simulated photon conversions in minimum-bias events.

## 2.1 Inside-out track reconstruction

After the reconstruction of space points inside the pixel and SCT sub-detectors, candidate tracks (seeds) are then formed using three space-point combinations. These seeds are subject to some constraints, such as the curvature, to limit the number of possible combinations. Seeds which pass these constraints then become the starting points for reconstructing tracks. Once a seed has been formed a geometric tool is then invoked in order to provide a list of Si-detector elements that should be searched for additional hits. A combinatorial Kalman-fitter/smoothing formalism is then used to add successive hits to the track. The track information is updated after every step in the search and extraneous outlier hits are efficiently eliminated through their large contribution to the  $\chi^2$  of the track fit. Not all space-point seeds coming from Si hits result in a track; the rate at which seeds give rise to a fully reconstructed track is on the order of 10% in a typical  $t\bar{t}$  physics event.

A large fraction of the reconstructed track candidates either share hits, are incomplete, or may be fakes resulting from random combinations of hits. It is therefore necessary to evaluate the tracks based on a number of quality criteria and score them accordingly, with the score providing an indication of the likelihood of a specific track to describe a real particle trajectory. Tracks with the highest score are refitted and used as the quality reference for all the remaining tracks. Shared hits are removed in this stage and the remaining part of the track is evaluated again and refitted. Track candidates with too many shared hits are then discarded as well as any other track candidate that fails to comply with any of the quality criteria during evaluation.

At this stage, each one of the resolved track candidates is assigned a TRT extension. First, a geometric extension of the Si track is built inside the TRT and compatible measurements are selected. Possible TRT-track extensions are constructed by combining all such TRT measurements. The full track, including any TRT extension, is then refitted and scored in a way analogous to that during the previous ambiguity-

resolving stage. If the new track has a quality score which is higher than that of the original Si track, the TRT extension is kept and added to the Si track, thus creating a “global” Inner Detector track. In other cases only the original Si track is kept, without the TRT extension. The final reconstructed tracks, with or without TRT extensions, are then stored in a dedicated track collection. At this stage they can be classified into three categories:

1. Tracks without TRT extensions (e.g.  $|\eta| > 2$ );
2. Tracks with extensions which are used in the final fit;
3. Tracks with extensions which are not used in the final fit (outliers).

This last category is characteristic of tracks that have suffered large material interactions as they propagated through the tracker material.

The *inside-out* track reconstruction (as described in the previous section) is a very powerful technique for reconstructing tracks, especially in busy environments where the high granularity of the Si sub-detectors (and in particular that of the pixel detector) can provide the necessary resolution for recovering the track-hit pattern. However, it may also lead to fake tracks if not carefully implemented. In order to reduce the number of fake reconstructed tracks, a minimum number of Si hits is required for a track to be reconstructed; in the present implementation of the algorithm this number is seven. This requirement immediately leads to a decreased efficiency in reconstructing tracks that originate late inside the tracker, i.e. in the SCT. Furthermore, tracks which are present only inside the TRT will not be reconstructed at all. These tracks can appear in the cases of secondary decays inside the tracker (e.g.  $K_s$  decays) or during photon conversions, the latter being of special interest to this note.

## 2.2 Outside-in track reconstruction

The *outside-in* track reconstruction (also referred to as back-tracking) can offer a remedy to the inefficiency in reconstructing tracks which originate after the pixel detector.

The starting point for this type of track reconstruction is the TRT, where initial track segments are formed using a histogramming technique. The TRT tracker can be divided in two parts, a barrel and an end-cap one, the dividing line being at the  $|\eta| = 0.8$  pseudorapidity range. In the  $R - \phi$  plane of a TRT barrel sector or the  $R - z$  plane of a TRT end-cap sector, tracks which originate roughly at the primary interaction region appear to follow straight lines (this is exactly true in the second case). These straight-line patterns can be characterised by applying the Hough transform [9], which is based on the simple idea that in the  $R - \phi$  ( $R - z$ ) plane, a straight line can be parametrised using two variables:  $(\phi_0, c_T)$  or  $(\phi_0, c_z)$  respectively, where  $c_T$  and  $c_z$  are the corresponding azimuthal and longitudinal curvatures and  $\phi_0$  is the initial azimuthal angle. As a result, in a two-dimensional histogram formed by these two parameters, TRT straw hits lying on the same straight line will fall within a single cell. Straight lines can therefore be detected by scanning for local maxima in these histograms. To improve the accuracy in the longitudinal direction, the TRT is divided into 13 pseudorapidity slices on either side of the  $\eta=0$  plane. The slice size varies, it being smaller around the TRT barrel/end-cap transition region and bigger inside the TRT barrel or end-cap regions. The two-variable approximate track parameters can then be used to define a new set of geometric divisions inside the TRT, within which all straws that could possibly be crossed are included. Using the transformation described in [10], the curved trajectory suggested by the straw hits may be transformed into a straight line in a rotated coordinate system. This is the initial step for a “local” pattern recognition process, in which the best TRT segment may be chosen as the one that crosses the largest number of straws in this straight-line representation. A cut on the minimum number of straw hits necessary to consider the segment as valid is applied during this step. A final Kalman-filter smoother procedure is then applied to determine as accurately as possible the final track parameters of the

Figure 5: Track reconstruction efficiency for conversions from 20 GeV  $p_T$  photons as a function of the conversion radius. The gain in track reconstruction efficiency when tracks reconstructed moving inwards from the TRT are combined with tracks reconstructed by the *inside-out* algorithm, is evident particularly at higher radial distances.

segment. The above TRT-segment reconstruction procedure has been adopted from the original ATLAS track reconstruction algorithm *xKalman* as described in the references [11].

The reconstructed TRT segments are then fed into the second step of the back-tracking algorithm in which extensions are added to them from the Si sub-detectors. Space-point seeds are searched for in narrow  $R - \phi$  wedges of the Si tracker, indicated by the transverse TRT-segment track parameters derived in the previous step. A minimum of two space points is required in this case, the search being confined to the last three SCT layers. To reduce the number of space-point combinations cuts on the curvature are then applied, with the third measurement point provided by the first hit in the initial TRT segment. As soon as seeds with pairs of space points are formed, the initial-segment track parameters can then be significantly improved, especially the longitudinal components. A new geometric section through the Si-detector elements is then constructed and a combinatorial Kalman-fitter/smoother technique, as in the case of the *inside-out* tracking, is applied to produce Si-track extension candidates. The Si-track extensions provide a much improved set of track parameters, which can be used to find new TRT extensions to be assigned to every Si-track candidate, thus creating once more a “global” track. Ambiguity resolving and track refitting follow afterwards in the appropriate manner. The final set of resolved tracks from this process is stored in a dedicated track collection. In order to reduce the time required for the reconstruction and minimise double counting, the *outside-in* tracking procedure excludes all the TRT-straw hits and Si-detector space points that have already been assigned to *inside-out* tracks. The enhancement of the track reconstruction efficiency after the *outside-in* reconstructed tracks are included is shown in Fig. 5. Here the track reconstruction efficiency for photon conversions is plotted as a function of the radial distance of the conversion for the case of 20 GeV  $p_T$  single photons, before and after the *outside-in* tracking

is performed. The bulk of the gain in tracking efficiency is, as expected, at larger radii. The inefficiencies of this method as a function of radius are discussed further in Section 2.3 and again in Sections 4.3 and 4.4. Due to the more limited pseudorapidity coverage of the TRT tracker, the *outside-in* tracking can be used to efficiently reconstruct tracks up to a pseudorapidity value of  $|\eta| = 2.1$ . All the results presented here have therefore been restricted to within this pseudorapidity range.

### 2.3 Stand-alone TRT tracks and final track collection.

Figure 6: Track reconstruction efficiency for conversions from 20 GeV  $p_T$  converted photons (left) and 5 GeV  $p_T$  converted photons (right) as a function of conversion radius.

Figure 7: Track reconstruction efficiency for conversions from 20 GeV photons (left) and 5 GeV photons (right) as a function of pseudorapidity.

After the *inside-out* track collection has been formed, all TRT segments that have not been assigned any Si extensions are then used as the basis of one more distinct track collection. These segments are first transformed into tracks, and the segment local parameters are used as the basis for producing the corresponding track parameters assigned to the surface of the first straw hit. Perigee parameters are also computed, but no overall track refitting is performed. These new TRT tracks are then scored and arranged accordingly and a final ambiguity resolving is performed in order to reject any tracks that share too many straw hits. Finally, these stand-alone TRT tracks are then stored in a special track collection.

At the end of the track reconstruction process, and before any primary or secondary vertex fitters are called or other post-processing tasks are executed, the three track collections described above are merged. One last ambiguity resolving is performed in order to select unique tracks from all three collections, although this is mostly for consistency since the straw hits and Si space points associated with the *inside-out* tracks have already been excluded before the *outside-in* track reconstruction. This merged track collection is then used by the photon conversion reconstruction algorithm.

The overall tracking efficiency after all three track collections discussed above are merged, is shown in Fig. 6 for both the case of a 20 GeV  $p_T$  single photon sample, and also for a 5 GeV single photon sample, which is more indicative of the case of low track momenta. Two competing effects become apparent as one observes these two plots. The overall track reconstruction efficiency for conversions that happen early inside the tracker, i.e. in  $R < 150$  mm, is higher in the case of the 20 GeV  $p_T$  photons than that for the 5 GeV  $p_T$  ones. This is a clear indication of the larger effect that bremsstrahlung losses have on low  $p_T$  tracks, especially on those that originate early inside the tracker. Furthermore it is possible that, depending on the amount of the incurred losses, only part of the track will be reconstructed, i.e. its TRT component, with the pattern recognition failing to recover the corresponding Si clusters. The small fraction of stand-alone TRT tracks that enhance the track reconstruction efficiency from early conversions, is primarily due to this effect. On the other hand the overall track reconstruction efficiency at higher radii is much better for the case of the 5 GeV  $p_T$  photons. This is due to the fact that the radius of curvature, being much larger for those tracks, enables them to separate from each other faster as they traverse the tracker under the influence of the applied magnetic field. It is therefore easier in this case to distinguish the two tracks and reconstruct them during the pattern recognition stage. Figure 7 shows the track reconstruction efficiency as a function of pseudorapidity, for both 20 GeV and 5 GeV  $p_T$  photons. The overall track reconstruction efficiency is very uniform along the whole pseudorapidity range, starting only to significantly fall off as one approaches the limit of the TRT pseudorapidity extent ( $|\eta| = 2.1$ ). The reduction in efficiency observed around  $|\eta| = 1$ , is due to the gap at the transition from the barrel to the end cap TRT. The seemingly higher overall tracking efficiency in this plot compared to that in Fig. 6, is due to the fact that the great majority of converted photons originate from the earlier layers of the Si tracker. In this region, as Fig. 6 demonstrates, the converted photon track reconstruction efficiency is very high.

### 3 Vertex fitting

Track finding is only the first step in reconstructing photon conversions; the next step is being able to reconstruct the conversion vertex using the pair of tracks produced by the converted photon. Reconstruction of the conversion vertex is quite different from finding the primary interaction vertex, since for conversions additional constraints can be applied that directly relate to the fact that the converted photon is a massless particle. A specific vertex algorithm, appropriately modified in order to take into account the massless nature of the conversion vertex, has been developed for use by the photon conversion algorithm.

The vertex fit itself is based on the fast-Kalman filtering method; different robust versions of the fitting functional can also be set up in order to reduce the sensitivity to outlying measurements. The vertex fitting procedure uses the full 3D information from the input tracks including the complete error matrices [12].

#### 3.1 Algorithm description

The goal of a full 3D vertex fit is to obtain the vertex position and track momenta at the vertex for all tracks participating in the fit as well as the corresponding error matrices. From the input tracks, the

helix perigee parameters defining the particle trajectory along with their weight matrix are extracted as described in the references [13, 14]. If one assumes that the particle is created at the vertex  $\vec{V}$ , then the trajectory parameters  $q_i$  may be expressed as a function of the vertex position and the particle momentum at this vertex  $q_i = T(\vec{V}, \vec{p}_i)$ . A vertex is then obtained by minimising:

$$\chi^2 = \sum_{i=1}^2 (q_i - T(\vec{V}, \vec{p}_i))^T w_i (q_i - T(\vec{V}, \vec{p}_i)), \quad (4)$$

where  $w_i$  is the  $5 \times 5$  weight matrix from the track fit. In order to find the  $\vec{V}$  and  $\vec{p}_i$  which minimise the above  $\chi^2$ , equation 4 can be linearised at some convenient point close to the vertex as:

$$\chi^2 = \sum_{i=1}^2 (\delta q_i - D_i \delta \vec{V} - E_i \delta \vec{p}_i)^T W_i (\delta q_i - D_i \delta \vec{V} - E_i \delta \vec{p}_i), \quad (5)$$

where  $D_i = (\partial T(\vec{V}, \vec{p}_i)) / (\partial \vec{V})$  and  $E_i = (\partial T(\vec{V}, \vec{p}_i)) / (\partial \vec{p}_i)$  are matrices of derivatives. A fast method to find a solution that minimises equation 5 has been proposed in the references [13, 14]. It can be shown that this method is completely equivalent to a Kalman-filter based approach [15], where the vertex position is recalculated after every new track addition.

If the initial estimation of the vertex position is far from the fitted vertex, then the track perigee parameters and the error matrix are extrapolated to the fitted point, all derivatives are recalculated and the fitting procedure is repeated. The official tracker extrapolation engine, along with a magnetic field description based on the actual measurement of the ATLAS tracker solenoidal field, is used in this case.

### 3.2 Vertex fit constraints

Constraints are included in the vertex fit algorithm via the Lagrange multiplier method. A constraint can be viewed as a function

$$A_j(\vec{V}, \vec{p}_1, \vec{p}_2, \dots, \vec{p}_n) = \text{const} \quad (6)$$

which is added to the fitting function of equation 4 as

$$\chi^2 = \chi_0^2 + \sum_{j=1}^{N_{\text{const}}} \lambda_j \cdot A_j^2 \quad (7)$$

Here  $\chi_0^2$  is the function without constraints,  $\lambda_j$  is a Lagrange multiplier and  $j$  is the constraint number.  $A_j^2(\dots)$  can be linearised around some point  $(\vec{V}_0, \vec{p}_{0i})$  to obtain

$$\chi^2 = \chi_0^2 + \sum_{j=1}^{N_{\text{const}}} \lambda_j \cdot (A_{j0}^2 + H_j^T \delta V + \delta V^T H_j + F_{ij}^T \delta p_i + \delta p_i^T F_{ij}) \quad (8)$$

where  $H_j = (\partial A_j) / (\partial \vec{V})$ ,  $F_{ij} = (\partial A_j) / (\partial \vec{p}_i)$ ,  $A_{j0}$  is an *exact* value of  $A_j$  at the  $(\vec{V}_0, \vec{p}_{0i})$  point,  $\delta \vec{V} = \vec{V} - \vec{V}_0$  and  $\delta \vec{p}_i = \vec{p}_i - \vec{p}_{0i}$ .

The solution of equation 8 then has the form  $\vec{V} = \vec{V}_0 + \vec{V}_1$ ,  $\vec{p}_i = \vec{p}_{0i} + \vec{p}_{1i}$ , where  $\vec{V}_0, \vec{p}_{0i}$  is the solution of the corresponding problem without the constraint  $\chi^2 = \chi_0^2$ . The second component  $\vec{V}_1, \vec{p}_{1i}$  of the above solution is obtained through the normal Lagrange multiplier system of equations. In the case of the conversion vertex, a single angular constraint needs to be implemented. This requires that the two tracks produced at the vertex should have an initial difference of zero in their azimuthal and polar angles  $\delta \phi_0, \delta \theta_0 = 0$ . This is a direct consequence of having an initial massless particle, but it has the advantage of being much easier to implement.

The right-hand plot in Fig. 8 shows the reconstructed photon inverse transverse momentum after vertex fitting for conversions where neither of the emitted electrons suffered significant bremsstrahlung (less than 20% of the energy of each electron is lost in the inner detector material), while the left-hand plot shows the transverse momentum for the cases where significant bremsstrahlung energy losses occurred. Similarly, the corresponding radial position resolution for conversions with/without significant energy losses due to bremsstrahlung is shown in Fig. 9. Single converted photons with  $p_T = 20$  GeV were used for the plots above, and the emitted electron tracks were required to have at least two silicon space points. The angular constraints  $\delta\phi, \delta\theta = 0$ , implemented as described earlier, have been used throughout. The overall vertex reconstruction efficiency will be discussed in the following section. It is evident that the presence of bremsstrahlung significantly deteriorates the performance of the vertex fitter.

Figure 8: Reconstructed inverse transverse momentum from 20 GeV  $p_T$  converted photons with (left) and without (right) significant energy losses due to bremsstrahlung.

As a further check of the performance of the vertex algorithm described in this section, one can apply it to the case of  $K_s^0 \rightarrow \pi^+ \pi^-$  decays. The absence of losses due to bremsstrahlung for the pion tracks, as well as the non-zero opening angle, provide a good test scenario for the constrained vertex fitting. Instead of the angular constraint used in the case of the photon conversions, a straightforward mass constraint is implemented in this case. Figure 10 shows the resolution of both the reconstructed  $1/p_T$  and the radial position for 10 GeV  $p_T$   $K_s^0$  decays. The absence of a bremsstrahlung-related tail in the left-hand plot compared to those in Fig. 8 is striking.

In a direct comparison to the converted photon case, Fig. 11 shows the relative  $1/p_T$  resolution, with and without significant bremsstrahlung losses (20%) respectively, for reconstructed 20 GeV  $p_T$  converted photons, together with that for 10 GeV  $p_T$   $K_s^0$  decays, as a function of the radial distance from the beam axis. In the case of the  $K_s^0$  decays, the reconstructed momentum resolution is better than 2% irrespective of the radial distance from the beam axis, deteriorating only slightly as one moves away from the beam axis. For the case of the photon conversions though, a deterioration in the transverse momentum reconstruction resolution due to the presence of bremsstrahlung losses, is clearly observable when compared to the  $K_s^0$  case. Due to the bremsstrahlung losses, the reconstructed  $1/p_T$  distribution has a non-gaussian shape, characterised by a tail towards the higher  $1/p_T$  ranges, as shown in Fig. 8. As a result, a gaussian

Figure 9: Reconstructed vertex radial positions for 20 GeV  $p_T$  converted photons, compared to their true values, with (left) and without (right) significant energy losses due to bremsstrahlung.

Figure 10: Overall reconstructed relative  $1/p_T$  resolution (left) and radial position resolution (right) for  $K_s^0$  decays (to charged pions) with  $p_T = 10$  GeV. Only tracks with at least two silicon space points are used.

fit performed on the core of the  $1/p_T$  distribution, will result in a worse overall reconstructed momentum resolution, even in the case of small bremsstrahlung losses, as Fig. 11 demonstrates. The effect is even more significant if one recalls that the reconstructed converted photons have a transverse momentum which is twice that of the  $K_s^0$  decays shown in the same figure. The fact that the photon is a massless particle, resulting in an extremely small angular opening of the emitted tracks, makes it also more difficult to reconstruct accurately the position of the conversion vertex, as shown in Fig. 12.

Figure 11: Reconstructed relative  $1/p_T$  resolution as a function of radial distance from the beam axis for 20 GeV  $p_T$  converted photons and 10 GeV  $p_T$   $K_s^0$  decays to charged pions. In the plot on the left, only converted photons, where both of the daughter electrons lost less than 20% of their energy due to bremsstrahlung, are shown. In the plot on the right, all conversions are included.

## 4 Conversion reconstruction

With the three track collections and the vertex fitting algorithm described in the previous two sections, we now have all the necessary tools in place in order to fully reconstruct photons which convert as far as 800 mm away from the primary interaction point. Beyond that radius, the track reconstruction efficiency drops off dramatically due to the lack of a sufficient number of hits in any sub-detector to reliably reconstruct the particle trajectory and accurately predict its track parameters. The conversion reconstruction algorithm is run within the framework of the overall Inner Detector reconstruction software; it is one of the last algorithms run during the post-processing phase. The basic components of the conversion reconstruction are: the track selection and subsequent track classification, the formation of pairs of tracks with opposite charge, the vertex fitting and reconstruction of photon conversion vertex candidates, and finally the reconstruction of single-track conversions. The conversion candidates are then stored in a separate vertex collection, to be retrieved and further classified through matching with electromagnetic clusters during the next level of the event reconstruction. In the results presented in this section, the reconstruction efficiency is estimated for those photon conversions that happen as far as 800 mm away from the primary interaction point, emit daughter electrons with each having at least  $p_T = 0.5$  GeV and are within the  $|\eta| = 2.1$  pseudorapidity range. This amounts to  $\sim 77\%$  of the total photons converted inside the ATLAS tracker volume in the case of the  $H \rightarrow \gamma\gamma$  sample.

### 4.1 Track selection

Only a fraction of the possible track pairs reconstructed by the tracking algorithms and included in the final track collection come from converted photons. Although the wrong-track combinations may be

Figure 12: Reconstructed radial resolution as a function of radial distance from the beam axis for 20 GeV  $p_T$  converted photons and 10 GeV  $p_T$   $K_s^0$  decays to charged pions. In the case of the converted photons, all daughter electrons regardless of bremsstrahlung losses have been included.

Cut	Efficiency	Rejection
No Cuts	0.7378	1.00
Impact d0	0.7334	1.16
Impact z0	0.7316	1.18
TR ratio	0.7119	2.12

Table 1: Track selection cuts: cumulative efficiencies and rejection rates are presented.

rejected later during the conversion reconstruction process or by physics specific analysis, it is important to remove them as efficiently as possible at an early stage, not least because of the large amount of CPU time involved in processing every possible track pair. Cuts on the perigee impact and longitudinal track parameters, as well as the transverse momentum, are first applied. Tracks that are most probably associated to electrons are then selected by cutting on the probability reconstructed by using the ratio of high-threshold TRT hits over the total number of TRT hits on each track. These cuts have been tuned using  $H \rightarrow \gamma\gamma$  events, with background present due to the underlying event. All the efficiencies and rejection factors due to track selection cuts which are quoted in this note refer to this physics sample. Table 1 shows the performance of these cuts in accepting tracks produced by converted photons and rejecting non-conversion related tracks. The starting efficiency of  $\sim 74\%$  reflects entirely the inefficiency of reconstructing all the conversion related tracks during tracking. After applying these cuts, the surviving tracks are then arranged into two groups with opposite charges.

## 4.2 Track-pair selection

At this point in the reconstruction process, all possible pairs of tracks with opposite signs are formed and further examined. There are three possible types of track pairs:

1. Pairs in which both tracks have Si hits;
2. Pairs in which one of the two tracks is a stand-alone TRT track;
3. Pairs in which both tracks are stand-alone TRT tracks.

Cut	Efficiency	Rejection
Polar angle	0.7070	10.8
Radial distance between first hits	0.7049	12.5
Minimum distance	0.6970	16.5
Vertex radius	0.6959	16.6
Minimum arc length	0.6935	40.3
Maximum arc length	0.6890	111.6
Distance in $z$	0.6870	111.9

Table 2: List of cuts employed during the track-pair selection for the three possible types of track pairs. The cumulative efficiencies and rejection rates are presented (see text for the definition of the cut variables).

In order to reduce the combinatorial background, a series of cuts are applied during the pair formation. These are common to all three track-pair types described above, although their actual values may differ. Table 2 lists those cuts along with the corresponding efficiencies and rejection factors for selecting the correct track pairs and discarding fakes resulting from wrong track combinations. The first criterion for accepting a track pair is that the difference in polar angles between the two daughter tracks in a conversion should be small, based on the fact that the photon is massless. Furthermore, the distance between the first hits of the two tracks in the pair should be reasonably close; this is particularly true in the case where both of them are stand-alone TRT tracks. Finally, the distance of minimum approach between the two tracks in the pair is checked. An iterative method has been implemented that uses the Newton approach to find the set of two points (one on each track) which are closest to each other. The distance of minimum approach between the two tracks is then calculated and a cut is applied to reject those cases where the tracks fail to come within a specified distance from each other.

In order to enhance the performance of the constrained vertex fitter, it is important to begin with a reasonable initial estimate of the vertex position. Using the perigee parameters of the two tracks in the pair, the corresponding radius of curvature and the centre of curvature of the track-helix projection in the  $R - \phi$  plane can be derived. As this track-helix projection is circular in the case of a uniform magnetic field such as that of the ATLAS tracker, the estimated vertex position can be identified as either the point of intersection of two circles, or in the case of non-intersecting circles, as the point of minimum approach between two circles. If the two circles do not intersect or approach each other closer than a set minimum distance then the pair is discarded. In principle, two circles may intersect at two points. Since two tracks originating from a conversion vertex (or any vertex for that matter) should also intersect in the  $R - z$  plane, the correct intersection point in the  $R - \phi$  plane is then chosen to be the one which is closer to the point of minimum approach of the two tracks in the  $R - z$  plane. The points of minimum approach both in the  $R - \phi$  and the  $R - z$  planes should clearly be sufficiently close to each other. If they are separated by more than a set minimum distance, then the track pair is discarded. A cut is also applied on the arc length of the  $R - \phi$  plane projection of the two track helices between the line connecting the centres of curvature of the two circles and the actual intersection points. This arc length is required to fall within a specific range which again ideally should tend to be very small. Finally, the distance from the track origin (the candidate conversion vertex location) and the actual points of intersection should also be small. Only track pairs with intersection or minimum-approach points that satisfy the above criteria are further examined. Estimating the initial vertex position allows for a larger number of quality criteria of the track pair to be used in the overall selection process. All the cuts applied during this step have been tested using the 120 GeV  $H \rightarrow \gamma\gamma$  physics sample; the cuts are tuned so that at least two orders of magnitude of the combinatorial background can be rejected at this point without significant loss in overall conversion reconstruction efficiency. As a consequence, cut values have been intentionally kept fairly loose since even correct track pairs could be characterised by less than optimal selection quantities. This is especially true in cases where at least one of the two tracks involved has only TRT hits resulting in reduced reconstructed track parameter accuracy along the  $z$ -axis, or in cases where the tracks have suffered substantial bremsstrahlung losses during their propagation through the ATLAS tracker. In general, the position of the initially estimated vertex falls within a few millimetres of the actual conversion vertex for the correct pair combinations, all deviations being due to the reasons mentioned just before.

Cut	Efficiency	Rejection
Fit convergence	0.6870	171.5
Fit $\chi^2$	0.6710	288.9
Invariant mass	0.6626	353.9
Photon $p_T$	0.6625	377.1

Table 3: Post-vertex fit selection cuts: cumulative efficiencies and rejection rates are presented.

### 4.3 Vertex fitting

The original track perigee assigned during the track reconstruction process is set at the primary interaction point and for the case of photon conversions, especially those that happen far inside the tracker, this is a rather poor assignment. Using the initial estimate for the vertex position described previously, we can redefine the perigee at this point. The new perigee parameters need to be recomputed by carefully extrapolating from the first hit of each track in the pair to this new perigee, taking into account all the material encountered on the way. It is these tracks with their newly computed perigee parameters that are passed to the vertex fitter. This also has the desirable effect of avoiding long extrapolations during

the various iterations of the vertex fitting process, which might lead to distortions due to unaccounted-for material effects. At the end of the process the new vertex position along with an error matrix and a  $\chi^2$  value for the fit are computed. A vertex candidate is then reconstructed that also contains the track parameters as they are redefined at the fitted conversion vertex. The fit is always successful in the case of the correct track pairs, and it often fails otherwise. After the fit is executed, post-selection cuts on the  $\chi^2$  of the fit, on the reconstructed photon invariant mass and on the reconstructed photon  $p_T$  can be applied, to reduce even further the wrong pair combinations. These are listed in Table 3.

The track pair selection and the vertex fitting process result in a reduction in the combinatorial background rate by more than two orders of magnitude, with only a rather small loss in overall conversion reconstruction efficiency, amounting to  $\sim 8\%$  in the case of  $H \rightarrow \gamma\gamma$  decays with  $m_H = 120$  GeV. A more quantitative description of the conversion reconstruction efficiency in such decays is presented in Section 5.3. At this stage of the conversion vertex reconstruction, which is still within the tracking software framework, vertices which come from the combinatorial background outnumber the correct conversion vertices by almost a factor of six. The main part of this remaining background consists of reconstructed vertices where at least one of the participating tracks is not an electron at all. This is primarily due to the rather weak particle identification capabilities of the tracker without any access to the electromagnetic calorimeter information. Part of this background can be reduced by some more stringent requirements on the reconstructed conversion vertices after the constrained fit is preformed. But effective improvement is only expected during the subsequent stages of the photon conversion reconstruction, when information from the calorimeter becomes available. Use of the electromagnetic calorimeter should also help to reduce a different type of combinatorial background originating when two electrons from different sources are combined in order to form a track pair. Recent studies indicate significant reduction of both types of the combinatorial background, both by applying tighter vertex selection criteria after the vertex fit is performed and by using the electromagnetic calorimeter information, although they are beyond the scope of this note. The possibility of using the reconstructed photon  $p_T$  in order to reduce the number of reconstructed fake vertices, is worth investigating. Figure 13 shows the  $p_T$  distribution of the reconstructed conversion vertices along with the distribution for fake vertices resulting from wrong combinations. It is clear that the latter tend to concentrate at the lower  $p_T$  region. Nevertheless a final cut on the reconstructed photon  $p_T$  will not be as efficient as expected, due to the limited ability at present to correct the reconstructed track momentum for losses due to bremsstrahlung. This is evident in the figure when comparing the reconstructed converted photon  $p_T$  distribution with (top row) and without (bottom row) significant bremsstrahlung losses. It becomes even more striking once it is compared to the truth  $p_T$  distribution of the converted photon. In the remaining part of this section, the overall performance of the conversion reconstruction software, without utilising the electromagnetic calorimeter information, is examined in the case of single 20 GeV  $p_T$  photons, where the combinatorial background is minimal.

Figure 14 shows the track, track-pair, and vertex reconstruction efficiencies for conversions coming from 20 GeV  $p_T$  photons as a function of both conversion radius and pseudorapidity. Both the track and track pair efficiencies shown in the figure are measured before any of the selection criteria described above are applied. The large drop in the efficiency at  $R > 400$  mm is primarily due to the inefficiency of reconstructing both tracks in the track pair from the photon conversion. It is noteworthy that both the track and the conversion vertex reconstruction efficiency are essentially constant as a function of pseudorapidity. For completeness, Fig. 15 shows the slightly different version of the left-hand plot in Fig. 14 as published in Ref. [6].

Finally, Fig. 16 shows the overall vertex reconstruction efficiency for converted photons with low transverse momenta as a function of conversion radial position. The two competing effects, the bremsstrahlung losses that affect more severely the low  $p_T$  tracks, and the higher radii of curvature that result in increased resolving ability of the smaller  $p_T$  tracks, that were discussed in Section 2.3, are once more evident here.

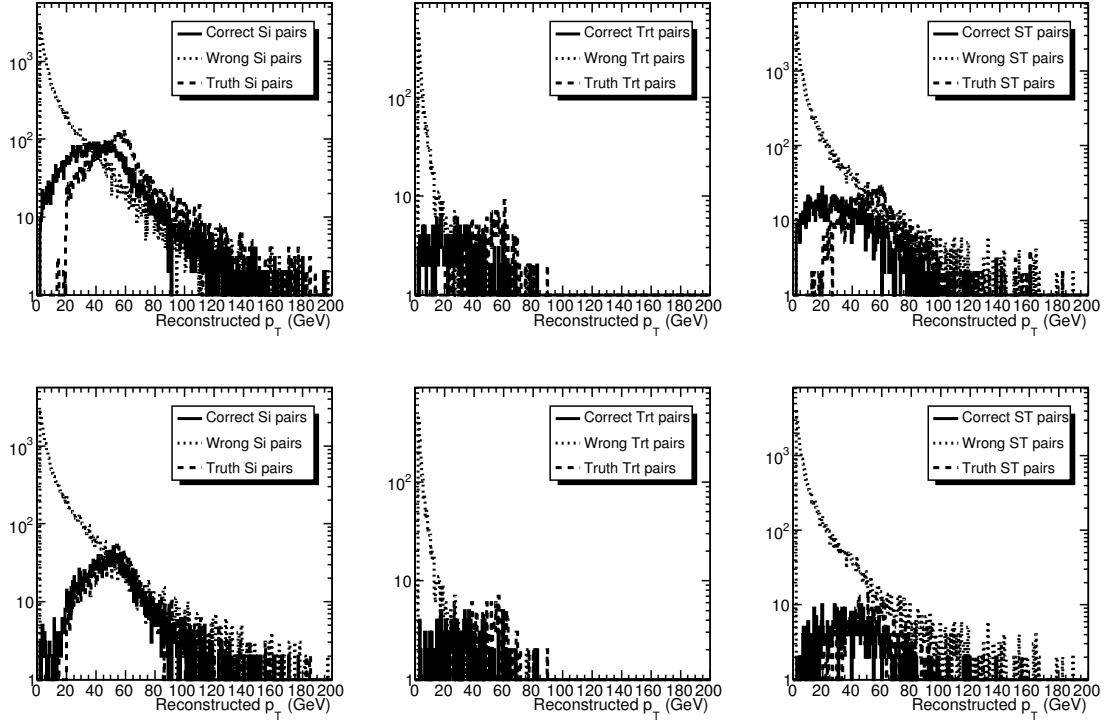

Figure 13: Transverse momentum distribution of reconstructed photon conversions for both correct and wrong track pairs for all three types of pairs: Silicon-Silicon (Si, left column), TRT-TRT (Trt, centre column), and Silicon-TRT (ST, right column). In the top row all electron tracks regardless of bremsstrahlung energy losses are considered for the case of the correct track pairs. In the bottom row only track pairs where both electrons have lost less than 20% of their energy due to bremsstrahlung are shown. For comparison the truth  $p_T$  of the converted photon is also shown.

#### 4.4 Single-track conversions

Due to conversions which decay asymmetrically (as described in Section 1.1), as well as cases where the conversion happens so late that the two tracks are essentially merged, there are a significant number of conversions where only one of the two tracks from the photon conversion is reconstructed. Depending on the photon momentum scale, these “single-track” conversions become the majority of the cases for conversions that happen late in the tracker and especially inside the TRT. The ability of the TRT to resolve the hits from the two tracks is limited, especially if those tracks do not traverse a long enough distance inside the tracker for them to become fully separated. As a result, only one track is reconstructed, but it will still be highly desirable to recover these photon conversions.

At the end of the vertex fitting process, all of the tracks that have been included in a pair that successfully resulted in a new photon conversion vertex candidate, are marked as “assigned” to a vertex. The remaining tracks are then examined once more on an individual basis in order to determine whether or not they can be considered as products of a photon conversion. For a track to be considered, it should have its first hit beyond the pixel vertexing layer. Furthermore, the track should be electron-like, where again the probability reconstructed by using the ratio of the high threshold TRT hits over the total number of TRT hits (as in the initial track selection described earlier in this section, but requiring a higher value) is used to select likely electron tracks. At the end of this selection tracks wrongly identified as emerging

Figure 14: Conversion reconstruction efficiency for conversions from 20 GeV  $p_T$  photons as a function of conversion radius (left) and pseudorapidity (right). The solid histograms show the track reconstruction efficiency, the dashed histograms show the track-pair reconstruction efficiency, and the points with error bars show the conversion vertex reconstruction efficiency.

Figure 15: Conversion reconstruction efficiency for conversions coming from 20 GeV  $p_T$  photons as a function of conversion radius. The solid histogram shows the track reconstruction efficiency, the dashed histogram shows the track-pair reconstruction efficiency, and the points with error bars show the conversion vertex reconstruction efficiency as published in Ref. [6].

Figure 16: Conversion vertex reconstruction efficiency as a function of conversion radius for photons with transverse energy of 2 and 5 GeV.

Figure 17: Reconstruction efficiencies for conversions from 20 GeV  $p_T$  photons as a function of conversion radius (left) and pseudorapidity (right). The points with error bars show the total reconstruction efficiency, the solid histograms show the conversion vertex reconstruction efficiency, and the dashed histograms show the single-track conversion reconstruction efficiency.

Figure 18: Conversion reconstruction efficiency for conversions coming from 20 GeV  $p_T$  photons as a function of conversion radius. The points with error bars show the total reconstruction efficiency, the solid histogram shows the conversion vertex reconstruction efficiency, and the dashed histogram shows the single-track conversion reconstruction efficiency as published in Ref. [6].

from photon conversions, outnumber the actual photon conversion electron tracks, by almost a factor of two. These are tracks which are not electrons at all, misidentified as such due to the inherent weakness of the particle identification process without the presence of any information from the electromagnetic calorimeter.

A conversion vertex candidate is then reconstructed at the position of the first track hit. It is clear that, especially in the case where the first hit is inside the Si part of the tracker, the position of the conversion vertex reconstructed in this way can be off by as much as a detector layer. This discrepancy is normally much smaller in the case of a vertex inside the TRT due to the higher straw density. On the technical side, this type of reconstruction requires a careful transformation of the local track parameters and error matrix into global ones that are directly assigned to the newly defined vertex. A new vertex candidate is then stored, identical in structure to the one derived from a vertex fit with the important difference that it has only one track assigned to it. The effect of including the single-track conversions into the overall conversion reconstruction efficiency is significant as is shown in Fig. 17. The plot shows the conversion reconstruction efficiency for 20 GeV  $p_T$  photons as a function of both radius and pseudorapidity. As expected, the single-track conversions become more and more dominant at higher radial positions, and single-track conversions are fairly uniformly distributed across the full pseudorapidity range. For completeness, Fig. 18 shows the slightly different version of the left-hand plot in Fig. 17 as published in Ref. [6]. While it is not possible to reconstruct the two merged tracks in these single-track conversions, it should be possible to separate such cases from very asymmetric conversions with the lower-energy partner of the pair not reconstructed: the transition radiation information should correspond on average to that expected from two electrons and the drift-time information should be inconsistent with that expected from a single track (resulting in a significant fraction of unused drift circles in the track fit).

## 5 Physics applications: low- $p_T$ conversions, $\gamma/\pi^0$ separation, $H \rightarrow \gamma\gamma$

In this section some interesting applications of the usage of the photon conversions are presented. Only results from photon conversions where both of the daughter electron tracks have been reconstructed are included. It needs to be stressed at this point, that everything that is presented here is meant only as an application example and that no full-scale analysis has been made.

### 5.1 Low- $p_T$ photon conversions

Of particular interest during initial data taking is the use of the reconstruction of converted photons as a tool to obtain a measurement of the amount of material inside the ATLAS tracker, including passive material. The abundance of low- $p_T$  neutral pions in minimum bias events represents a very rich source of photons and makes this approach particularly promising. The number of photon conversions measured on a detector volume of known  $x/X_0$  can be used as a normalisation point to extract the amount of material at any other location inside the detector by counting the relative number of conversions occurring in that portion. To obtain an unbiased map of the tracker material it is necessary to correct the measured number of conversions by the conversion reconstruction efficiency. Several methods are being investigated to measure this efficiency from data, e.g. embedding Monte Carlo photon conversions in data or extracting it from the measure of decays with similar topology like  $K_s^0 \rightarrow \pi^+ \pi^-$ .

Figure 19: Reconstructed radial positions for conversions of 5 GeV  $p_T$  photons. The black histogram shows the truth radial position of the conversion vertices, and the gray histogram shows the radial positions of the reconstructed vertices, regardless of the bremsstrahlung losses of their daughter electrons.

Figure 19 shows the reconstructed radial positions of photon conversions with 5 GeV  $p_T$ . A few structures may be identified: the initial peak caused by the beampipe, the three layers of the pixel detector and then with lower resolution and significance the SCT layers and the TRT. The observed smearing of the reconstructed position of the conversion vertex is mainly due to bremsstrahlung effects. The position resolutions (in the radial direction) of the reconstructed conversion vertex, for photon conversions

produced by the decay of neutral pions with various energies, are shown in Fig. 20 as a function of the distance from the beam axis. All conversions regardless of the amount of energy lost due to bremsstrahlung by the daughter electrons, have been used. In the case of the lower  $p_T$  neutral pions, more relevant in the case of minimum bias events, the radial position resolution improves somewhat, as might be expected from the larger angular separation between the produced electrons. On the other hand the use of low  $p_T$  tracks can be limited by the lower tracking efficiency caused by multiple scattering and especially bremsstrahlung.

In order to be able to determine the amount of material at a given position, it is necessary to compare the number of reconstructed converted photons at that position with the number of conversions reconstructed at the position of some reference point. This necessitates being able to resolve the position of the reference, which may not be trivial.

Figure 20: Reconstructed radial position resolution for converted photons produced by the decay of neutral pions with various energies.

## 5.2 $\gamma/\pi^0$ Separation

Another application of conversion reconstruction is the possibility of using the converted photons to identify, and subsequently remove, neutral pions in which at least one of the photons resulting from the decay of the pion has converted. Low multiplicity pions constitute the dominant background to the photon signal after all the calorimeter-specific cuts have been applied during photon identification [16]. In the case of converted photons from  $\pi^0$  decays, additional handles could be derived as soon as their reconstructed transverse momentum is made available. About 30% of the neutral pions will have at least one of their daughter photons converted and subsequently reconstructed as such, thus providing an estimate of their  $p_T$ .

The transverse momentum reconstruction resolution is important when attempting to use conversions to identify low  $p_T$  neutral pions. The ratio of the reconstructed  $p_T$  of a converted photon inside the ATLAS tracker to the  $E_T$  measured by the electromagnetic calorimeter is different for photons from  $\pi^0$  decays and for prompt photons. Figure 21 shows such distributions for the case of converted 20 GeV  $p_T$  single photons and converted photons from the decay of a 20 GeV  $p_T$  neutral pion. The photon  $p_T$

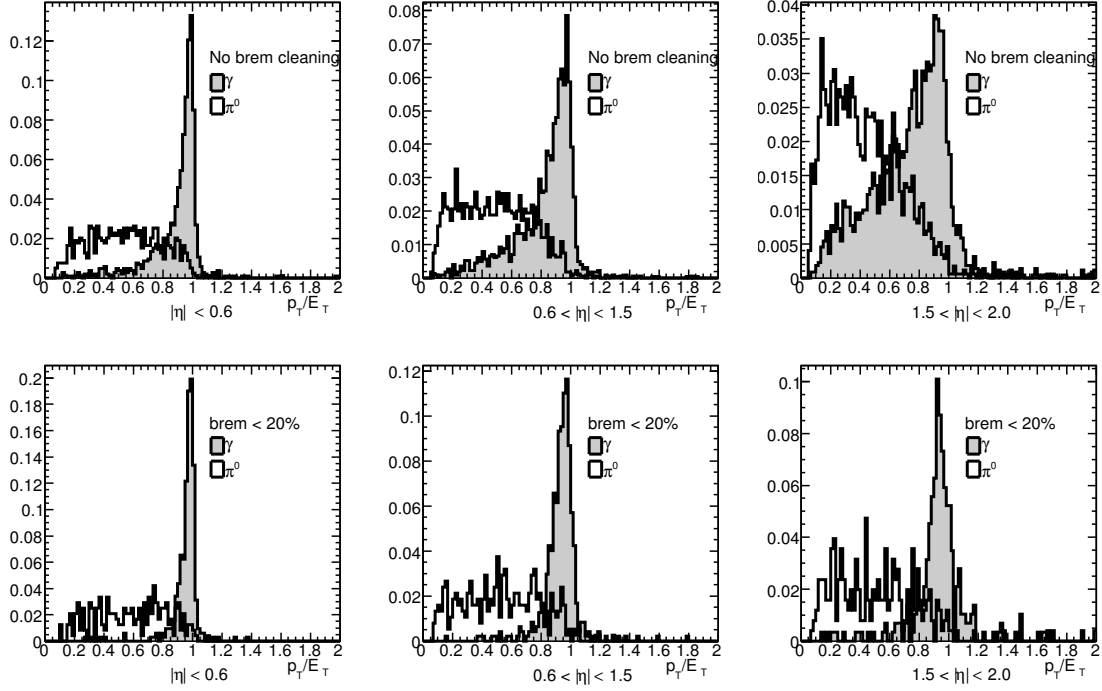

Figure 21:  $p_T/E_T$  distribution for 20 GeV  $p_T$  converted photons and for photons from a 20 GeV  $\pi^0$ . The top row shows the distribution for all photons irrespective of the daughter electron energy losses due to bremsstrahlung. The bottom row shows the distribution only for those photon conversions in which the daughter electrons have lost less than 20% of their energy to bremsstrahlung. Three different pseudorapidity ranges are shown, corresponding to the barrel (left), the barrel/end-cap transition (centre) and the end-cap (right) regions.

shown is that reconstructed by the conversion algorithm, while the  $E_T$  shown is taken from the truth value from the simulation. Three regions in pseudorapidity are shown separately, namely those corresponding approximately to the tracker barrel, barrel/end-cap transition and end-cap regions. The top row of plots include all converted photons, irrespective of losses due to bremsstrahlung of their daughter electrons, while the bottom row has only those converted photons where both of their daughter electrons have lost  $< 20\%$  of their energy due to bremsstrahlung. Clearly the distinction between conversions from single photons and conversions from photons produced in neutral pion decays is less pronounced in the case of strong bremsstrahlung losses, although an effective bremsstrahlung recovery mechanism should be able to significantly improve the separation between the two distributions. A certain degradation is also evident as we move from the barrel to the end-cap tracker, due to the less accurate reconstruction of the transverse momentum of the daughter electron tracks at higher pseudorapidities. Figure 22 shows the fraction of remaining  $\pi^0$  particles as a function of converted photon efficiency, both with and without significant losses due to bremsstrahlung. The overall  $\pi^0$  rejection corresponding to a photon acceptance of 90 % for the three different pseudorapidity regions, as described above, is shown in Fig. 23. Again a distinction is made for the cases with and without significant energy losses due to bremsstrahlung. Although reduced, the discriminatory power against  $\pi^0$  is significant even when severe losses due to bremsstrahlung are present.

Figure 22: Fraction of remaining  $\pi^0$  as a function of converted photon efficiency with (left) and without (right) significant bremsstrahlung losses of the corresponding daughter electrons, for three pseudorapidity regions as described in the text.

Figure 23: Rejection factors against  $\pi^0$  corresponding to photon acceptance efficiencies of 90 %, with and without significant energy losses due to bremsstrahlung for the three pseudorapidity regions described in the text. The results are shown for converted photons and  $\pi^0$  with a  $p_T$  of 20 GeV.

### 5.3 $H \rightarrow \gamma\gamma$ decays

As mentioned in the introduction, the recovery of converted photons is of primary importance in the search for physics processes in which photons are the primary decay product. In particular, accurate reconstruction of the  $H \rightarrow \gamma\gamma$  process is heavily dependent on the ability to properly reconstruct photon conversions for the following reasons:

1. A significant fraction of photons will convert inside the ATLAS tracker volume. Efficient reconstruction of these photons will enhance the signal statistics for this process.
2. Photon identification, using a combination of inner detector and electromagnetic calorimeter selection criteria, will be improved with effective conversion reconstruction. Even single-track conversions will be useful in this context.
3. The electromagnetic calorimeter calibration will be significantly enhanced when converted photons are identified as such. Again, even single-track conversions will be very useful.
4. The ability to accurately point back to the mother Higgs particle is dramatically enhanced for the case of reconstructed converted photons where both daughter electron tracks are properly recovered.

It is important, therefore, to investigate the performance of the conversion reconstruction strategy in this case, not least because of the higher transverse momenta which characterise the photons produced in  $H \rightarrow \gamma\gamma$  decays. Decays to photon pairs from a Standard Model Higgs boson with 120 GeV mass have been studied throughout this section.

Figure 24: Track, track-pair, and vertex reconstruction efficiencies for converted photons from  $H \rightarrow \gamma\gamma$  decays with  $m_H = 120$  GeV, as a function of radial distance from the beam axis (left) and pseudorapidity (right). The efficiency reduction at  $|\eta| \sim 0.8$ , is due to the track reconstruction inefficiencies in the gap region between the TRT barrel and end-cap detectors.

Figure 24 shows the converted photon reconstruction efficiency as a function of both radius and pseudorapidity for photons coming from  $H \rightarrow \gamma\gamma$  decays. The reduced efficiency at higher radii is primarily due to the smaller distance which the produced electron tracks travel inside the magnetic field, reducing the separation between them. The conversion reconstruction efficiency as a function of pseudorapidity is fairly flat, independent of the material distribution inside the ATLAS tracker, as expected. The effect of including the single-track conversions into the overall conversion reconstruction efficiency is also significant for  $H \rightarrow \gamma\gamma$  decays with large conversion radius and over the full pseudorapidity range, as shown

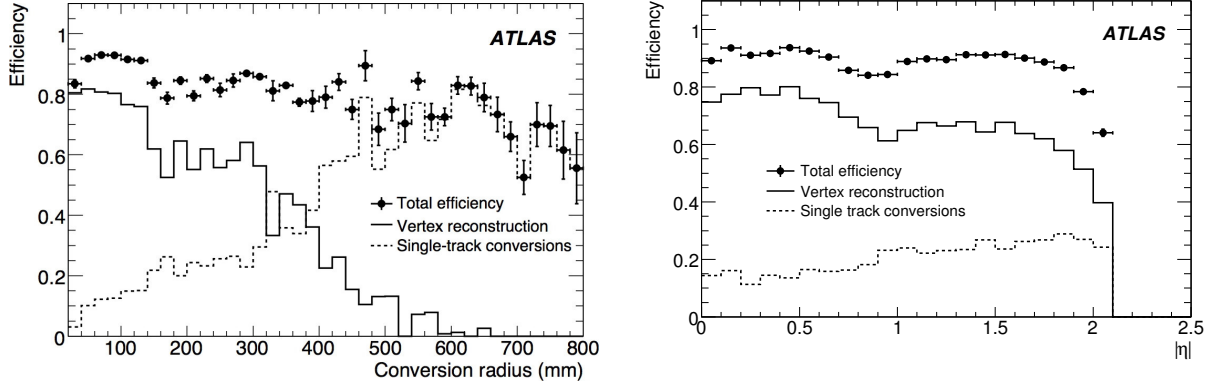

Figure 25: Reconstruction efficiencies for converted photons from  $H \rightarrow \gamma\gamma$  decays with  $m_H = 120$  GeV, as a function of conversion radius (left) and pseudorapidity (right). The points with error bars show the total reconstruction efficiency, the solid histograms show the conversion vertex reconstruction efficiency, and the dashed histograms show the single-track conversion reconstruction efficiency.

Figure 26: Reconstructed vertex radial position resolution (in mm) for converted photons from  $H \rightarrow \gamma\gamma$  decays with  $m_H = 120$  GeV. For comparison, the two cases where the participating tracks have lost  $> 20\%$  ( $< 20\%$ ) of their energy due to bremsstrahlung are also shown separately.

Figure 27: Reconstructed polar angle resolution (in radians) for converted photons from  $H \rightarrow \gamma\gamma$  decays with  $m_H = 120$  GeV.

in Fig. 25. The reconstructed conversion vertex radial position resolution is shown in Fig. 26 for reconstructed converted Higgs photon vertices where the participating tracks have lost  $> 20\%$  ( $< 20\%$ ) of their energy due to bremsstrahlung, along with all vertices put together. The results are fairly comparable to the ones shown for single photons in Section 4, despite the fact that the resulting photon momenta in this case are on average at least a factor of two bigger and the fact that the presence of the underlying event causes additional complications for the track reconstruction.

Of particular interest for the reconstruction of the Higgs invariant mass is the resolution on the measurement of the polar angle of the reconstructed converted photon. This is shown in Fig. 27 for the case of conversions where both electron tracks have Si hits. These account for  $\sim 58\%$  of the reconstructed converted photons inside the ATLAS tracker volume. The resulting resolution is of the order of 0.5 mrad regardless of the transverse momentum of the converted photon. This is an improvement of at least an order of magnitude with respect to the polar angle resolution derived using the electromagnetic calorimeter response [6].

## 6 Summary and conclusions

This note has described and presented a detailed performance evaluation of the conversion reconstruction algorithm which will be used to reconstruct and study early data at the LHC. All three types track collections delivered by the tracking software have been combined and used. A dedicated vertex fit algorithm has been developed for the purpose of reconstructing converted photon vertices. Special care has been given to flagging possible conversions where only one of the produced electron tracks has been reconstructed (or where the two tracks are merged into one in the case of late conversions). Combining all of these tools, a reconstruction efficiency of almost 80% has been achieved for conversions that occur up to a distance of 800 mm from the beam axis. A transverse momentum reconstruction resolution of the order of 5% has been found for converted single photons of various energies. This has also been shown to be valid for the case of photons produced by the decay of a Standard Model Higgs boson with a mass

of 120 GeV, as well as for those coming from the decay of low  $p_T$  neutral pions. The position resolution is found to be better than 5 mm in the radial direction, making this a promising method for mapping the material inside the ATLAS inner detector. The angular resolution is found to be below 0.6 mrad, giving effective pointing to converted photons from physics processes.

# Reconstruction of Low-Mass Electron Pairs

## Abstract

This note discusses the reconstruction of  $J/\psi$  and  $\Upsilon$  decays to electron pairs based on ATLAS Monte Carlo simulated signal and background samples. The possible trigger strategies are described, one geared to select two low-energy electromagnetic objects in direct production, the second one taking advantage of the possible presence of a muon in the final state in  $b\bar{b}$  production followed by the decay of one  $b$ -quark to  $J/\psi + X$ . The low-energy electrons are reconstructed using a dedicated algorithm seeded by a track reconstructed in the inner detector and identified combining information from the inner detector and the electromagnetic calorimeter. The performance of this algorithm is presented and the potential of using such events for early LHC data studies is investigated.

## 1 Introduction

When switched on, the LHC will produce charm and beauty quarks in abundance which will be collected by the ATLAS experiment [1], even during the low luminosity periods. The number of produced quarkonium states such as  $J/\psi$  and  $\Upsilon$ , important for many physics studies, will be equally numerous. On average, one in every hundred collisions will contain a  $b\bar{b}$  pair. The large  $b\bar{b}$  cross-section and the high luminosity of the machine give therefore a high rate for  $B$ -hadrons, making  $B$ -physics an interesting and competitive subject at the LHC. Low energy resonances, such as  $J/\psi$  and  $\Upsilon$  will be one of the main sources of isolated electrons in the early data. Both the  $J/\psi$  and  $\Upsilon$  signal samples are important for understanding the production of prompt quarkonia. But there is another aspect which is the main focus of this note: these samples are ideal to study the performances of trigger and offline reconstruction at low energies as well as being potentially useful for the in-situ calibration of the electromagnetic calorimeter.

This note is organised as follows: Section 2 gives a description of the data-samples used in this note, Section 3 details the trigger selections, and Section 4 describes the offline electron reconstruction and identification procedure. Finally, in Section 5, the physics potential of these channels is explored with initial data, assuming an instantaneous luminosity of  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  and an integrated luminosity of  $100 \text{ pb}^{-1}$ .

## 2 Data samples

The different data samples used in this study are summarised in Table 1. The total cross-sections for charm production at LHC is 7.8 mb and the one for bottom production is 0.5 mb. Quarkonium production was originally described by the colour singlet model which failed to reproduce the direct  $J/\psi$  production cross section measured by the CDF experiment [2]. The colour octet model [3] was proposed as a solution to this quarkonium deficit. Direct quarkonia Monte Carlo samples comprise of directly produced  $J/\psi$  or  $\Upsilon$  in colour singlet and octet states, along with promptly-produced  $\chi$ 's, which decay into  $J/\psi$ 's or  $\Upsilon$ 's [4] [5]. The inclusive production cross sections of  $J/\psi$  and  $\Upsilon$  are respectively  $\sim 90 \mu\text{b}$  and  $\sim 0.7 \mu\text{b}$ . A minimum transverse momentum of 3 GeV and a pseudo-rapidity  $\eta < 2.7$  are required for the two electrons. The resulting cross sections for the used data samples are respectively  $\sim 117 \text{ nb}$  and  $\sim 47 \text{ nb}$ . Another sample used in this study is originated from Drell-Yan production. In addition to the electron filter also applied to the  $J/\psi$  and  $\Upsilon$  samples, the generated di-electron invariant mass  $m_{ee}(DY)$  has to be  $1 < m_{ee}(DY) < 60 \text{ GeV}$ . Studies also include non-diffractive minimum-bias events with a total assumed cross section of 70 mb.

Table 1: Data samples: process, production cross-section and total number of events available.

Process	Cross section	Number of events ( $\times 10^3$ )
Direct production		
$pp \rightarrow J/\psi(e3e3)X$	116.3 nb	160
$pp \rightarrow \Upsilon(e3e3)X$	47.6 nb	150
$pp \rightarrow \text{Drell-Yan}(e3e3)$	2.9 nb	250
minimum-bias	70 mb	1,000
$b\bar{b}$ production		
$bB_d \rightarrow \mu(6)J/\psi(e2e2)X$	0.2 nb	50

For the production via the decay of  $b\bar{b}$ , only  $J/\psi$  events are considered. The signal sample is made of  $bB_d \rightarrow \mu(6)J/\psi(ee) + X$  events, where the  $\mu(6)$  refers to a muon coming from the  $b$  quark with a transverse momentum above 6 GeV. A minimum transverse momentum threshold of 2 GeV is applied to the generated electrons.

The simulated data have been produced for the ATLAS Computing System Commissioning [6]. All samples have been generated using the Pythia 6.403 [7] Monte Carlo event generator. More details on the Monte Carlo generators used can be found in [8]. Data have been simulated using GEANT4 [9], with the ATLAS software ATHENA [10], with a realistic geometry including material distortions in front of the electromagnetic calorimeter. Studies presented here correspond to very early data taking, with an initial luminosity of  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ . No pile-up has been included. Detailed information about these samples is given in Table 1.

Signal electrons come from  $J/\psi$  and  $\Upsilon$  decays<sup>1</sup>. The background electrons arise from other direct ( $b \rightarrow e$ ,  $c \rightarrow e$ ) and cascade ( $b \rightarrow c \rightarrow e$ ) semileptonic decays of meson with an electron in the final state and  $b \rightarrow \tau \rightarrow e^-$  decays<sup>2</sup>. Other background electrons arise from  $\pi^0$  Dalitz decays,  $\gamma$ -conversions occurring in the inner detector and decays of light hadrons. Distributions of generator level transverse momentum  $p_T$  and pseudorapidity  $\eta$  for electrons and pions are shown for the  $pp \rightarrow J/\psi(ee) + X$  sample on Fig. 1. The  $\eta$  distribution of electrons from conversion reflects the amount of material in front of the electromagnetic calorimeter. Ref. [13] details the reconstruction of such electrons. Table 2 gives the mean  $p_T$  for each population in the different samples.

Fig. 2 shows the distance  $\Delta R$ , at generator-level, between the two signal electrons from  $J/\psi$ . On average, electrons from direct reconstructed  $J/\psi(e3e3)$  are separated by  $\Delta R = 0.7$ , and are restricted from being produced at separations larger than 1.1. Electrons from  $J/\psi$  originated from  $B$  hadrons on the contrary are on average more collimated, with a mean  $\Delta R = 0.6$  and with a larger spread. In comparison, the higher mass of  $\Upsilon$  requires the electrons to have a much larger opening angle, with a broad distribution in  $\Delta R$ , the two electrons being almost back-to-back.

### 3 Trigger selection

#### 3.1 General requirements

ATLAS has a three level trigger system which reduces the 40 MHz bunch crossing rate to about 200 Hz to be recorded. The first level (L1) is a hardware-based trigger which makes a fast decision (in  $2.5 \mu\text{s}$ ) about which events are of interest for further processing, with a rate reduced down to below 40 kHz in its

<sup>1</sup>The corresponding branching ratio [11] is  $Br(J/\psi \rightarrow ee) = (5.94 \pm 0.06)\%$  and  $Br(\Upsilon \rightarrow ee) = (2.38 \pm 0.11)\%$ .

<sup>2</sup>The corresponding branching ratios [12] are  $Br(b \rightarrow l^-) = (10.71 \pm 0.22)\%$ ,  $Br(b \rightarrow c \rightarrow l^+) = (8.01 \pm 0.18)\%$ ,  $Br(b \rightarrow \bar{c} \rightarrow l^-) = (1.62^{+0.44}_{-0.36})\%$ ,  $Br(b \rightarrow \tau \rightarrow e^-) = (0.419 \pm 0.055)\%$  and  $Br(b \rightarrow (J/\psi, \Upsilon) \rightarrow ee) = (0.072 \pm 0.006)\%$ .

Figure 1: Normalised distributions of generator-level transverse momentum  $p_T$  (left) and pseudorapidity  $|\eta|$  (right) in the  $pp \rightarrow J/\psi X$  sample are shown for signal electrons (hatched histograms), electrons from conversions (dotted line histogram), and pions (plain histograms).

Figure 2: Distance  $\Delta R$  at generator-level between the two signal electrons for direct  $J/\psi$  events (top left), direct  $\Upsilon$  (top right) and  $J/\psi$  from b decays (bottom).

initial implementation. Coarse granularity information from the calorimeter and muon trigger systems are used at this stage of the trigger to identify regions of the detector which contain interesting signals corresponding to, for instance, electrons, muons, taus, and jets. These are called “Regions of Interest” (RoIs) and are used to guide the later stages of the trigger reconstruction. The high level trigger (HLT) is software-based and is split into two levels. At level 2 (L2) the full granularity of the detector is used to confirm the L1 signals and then to combine information from different sub-detectors within the RoIs identified at L1. Fast algorithms are used for the reconstruction at this stage and the rate is reduced to 1 – 2 kHz with an average execution time of about 40 ms. Lastly, at the event filter (EF), the whole event is

Table 2: Mean generator-level  $p_T$  (in GeV) for electrons and pions having  $p_T > 2$  GeV. Typical RMS on distributions of Fig. 1 is 1.4 GeV.

sample	electrons			pions

available and “offline-like” algorithms are used along with better alignment and calibration information to form a final decision whether or not an event is accepted. With an execution time of about 4 s, the rate is reduced to 200 Hz.

The expected ATLAS trigger performance at an initial luminosity of  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  is studied using the samples described in the previous section. Two trigger menus are considered here: the first is a purely electromagnetic menu which could be used only for early data taking; the second menu relies on the  $B$ -trigger and could be extended for data taking at low luminosity  $10^{33} \text{ cm}^{-2} \text{ s}^{-1}$ . More details about the overall trigger strategy, in particular for these channels, can be obtained in [14] and [15].

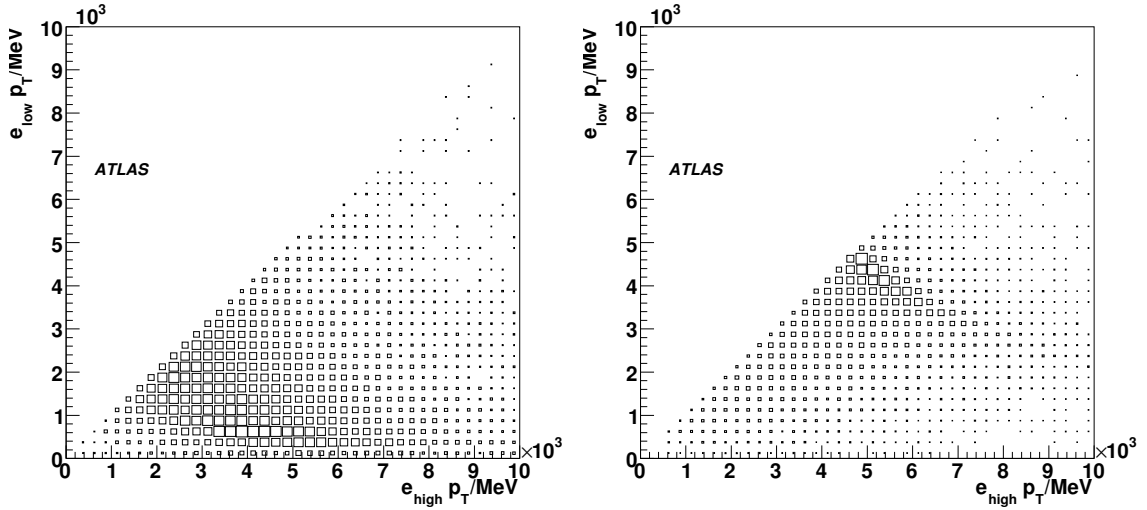

Figure 3: Distribution of the generator-level transverse momentum of the less energetic electron versus the transverse momentum of the most energetic electron in the direct  $J/\psi$  (left) and  $\Upsilon$  (right) decays.

### 3.2 Electron selection

$J/\psi \rightarrow ee$  and  $\Upsilon \rightarrow ee$  events are very demanding for the trigger system. Due to their relatively low masses, the electrons produced in the  $J/\psi$  and  $\Upsilon$  decays are very soft. Figure 3 shows the distribution of the transverse momentum of the less energetic electron versus the transverse momentum of the most energetic electron in  $J/\psi$  (left) and  $\Upsilon$  (right) decays [5]. This poses a huge challenge for the L1 calorimeter trigger. Its performance at the low-energy end is limited by the noise of typically 0.5 GeV per RoI and a

3 GeV threshold is the limit of what is feasible for the L1 trigger. The 6.5 kHz L1 output rate for 2EM3 (corresponding to two L1 electromagnetic clusters greater than 3 GeV) makes it one of the biggest consumers of the total bandwidth [14]. The strategy to trigger on  $J/\psi$  and  $\Upsilon \rightarrow ee$  events is based on low  $E_T$  L1 electromagnetic RoIs and further electron identification using calorimeter and inner detector information at the HLT. The inner detector tracks are reconstructed in regions of half-size  $\Delta\eta \times \Delta\phi = 0.1 \times 0.1$  around these electromagnetic RoIs.

Figure 4 shows the distribution of the invariant mass of the pairs of electrons for signal and background events after the L1 selection. The  $J/\psi$  and  $\Upsilon$  samples can be easily recognised by the resonance peaks. Table 3 gives the number of events which are expected to pass the L1 selection. The L1 trigger efficiency is calculated with respect to the number of generated events, which in particular include a requirement on the minimum transverse momentum of 3 GeV on each electron as detailed in Section 2. The selected events are in the tail of the  $J/\psi$  distribution (see Figure 3). Additionally the requirement of  $E_T > 3$  GeV at L1 implies  $E_T \geq 4$  GeV thus starting to cut into the peak of the  $\Upsilon$  distribution. The efficiency of this level is measured to be 27% for  $J/\psi$  and  $\Upsilon$  events. About 43% of Drell-Yan events pass the L1 in the generated mass range. A total of  $4.2 \times 10^6$   $J/\psi \rightarrow ee$ ,  $1.2 \times 10^6$   $\Upsilon \rightarrow ee$  and  $0.12 \times 10^6$  Drell-Yan events are expected after this level. For the minimum bias sample, the enhancement above

Figure 4: Expected differential cross section for low-mass electron pairs using the 2EM3 trigger menu item after L1 selection for  $J/\psi$  decays (dotted histogram),  $\Upsilon$  decays (dashed histogram), Drell-Yan production (solid histogram) and expected background (full circles). The invariant mass is reconstructed with calorimeter only information available at L1.

6 GeV arises from the requirement of the presence of two L1 clusters with energy greater than 3 GeV. Studies and implementation of an efficient HLT selection, based on the selection of two electrons with  $E_T > 5$  GeV (2e5 menu) is ongoing. Typical rates are expected to be  $\sim 40$  Hz at L2 and 6 Hz at EF.

Table 3: Performance of the 2EM3 trigger at the luminosity of  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  for the direct production of  $J/\psi$ ,  $\Upsilon$ , Drell-Yan and background events. For signal events the efficiency  $\varepsilon$  is given as well as the number of expected events. For background the rate is provided. Quoted errors are statistical only.

	$J/\psi$		$\Upsilon$		Drell-Yan		background
	$\varepsilon$ (%)	$10^6 \text{ ev} / 100 \text{ pb}^{-1}$	$\varepsilon$ (%)	$10^6 \text{ ev} / 100 \text{ pb}^{-1}$	$\varepsilon$ (%)	$10^6 \text{ ev} / 100 \text{ pb}^{-1}$	Rate (Hz)
L1	$27.4 \pm 0.3$	$4.17 \pm 0.04$	$27.3 \pm 0.3$	$1.22 \pm 0.01$	$43.0 \pm 0.5$	$0.12 \pm 0.001$	$6500 \pm 27$

### 3.3 *B*-physics

The *B*-trigger is expected to account for 5-10% of the total ATLAS trigger resources. The trigger for *B*-physics is initiated by a single- or a di-muon selection at L1. At  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ , a threshold  $p_T > 4 \text{ GeV}$  will be used, rising to about 6 GeV at  $10^{33} \text{ cm}^{-2} \text{ s}^{-1}$  to match the rate capabilities of the HLT. For final states such as the  $bB_d \rightarrow \mu(6)J/\psi X$  events, inner detector tracks are combined to reconstruct the  $J/\psi$  particles. Two different strategies are used for finding the tracks, depending on luminosity [16]. At  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  full reconstruction over the whole inner detector can be performed, since the L1 muon rate is comparatively modest, while at higher luminosities reconstruction will be limited to L1 electromagnetic RoIs with  $E_T > 3 \text{ GeV}$ . For the  $bB_d \rightarrow \mu(6)J/\psi X$  events the L1 trigger efficiency is  $\sim 88\%$ . This latter approach has lower efficiency for selecting the signal but requires fewer HLT resources for a fixed L1 rate. If one combines triggers for electromagnetic final states and pre-scaled single muon-triggers needed for trigger efficiency measurements, the overall rate for *B*-physics triggers is approximately 20 Hz at  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ .

## 4 Electron reconstruction and identification

The standard electron reconstruction procedure [17], optimised for high energetic electrons, is based on calorimeter clusters to which tracks are associated in a second step. An alternative procedure will be used for the reconstruction of electrons originated from  $J/\Psi$  and  $\Upsilon$  decays. It takes full advantage of the tracking capabilities of the inner detector as well as the granularity of the electromagnetic calorimeter. The method is seeded by a track which is extrapolated into the electromagnetic calorimeter and allows for efficient reconstruction of electrons in jets for *b*-tagging purpose (cf. [18]) and very low  $p_T$  electrons.

### 4.1 Electron reconstruction

The track-based algorithm could handle any charged track particles with a transverse momentum greater than 0.5 GeV. Still, as it will be detailed further, in order to reduce the amount of fake candidates, in particular in jets, only particles with  $p_T > 2 \text{ GeV}$  are considered. The inner detector coverage goes to pseudorapidity values up to 2.5, except for the transition radiation tracker (TRT) which extends up to 2. This subdetector being crucial nonetheless in the identification procedure but also to preselect tracks, the electron reconstruction is limited to  $|\eta| < 2$ . Strict selection criteria, similar to the *b*-tagging ones, are required to have at least nine precision hits (pixel and silicon detectors); at least two hits in the pixel detector and at least one hit in the vertexing layer. The TRT plays a central role in electron identification. Selection criteria are thus required to have at least 20 hits in the TRT and at least one high energy hit (HTR hit) in the TRT detector along the track. After these criteria, only 50% of initial tracks remain. All the tracks that pass these criteria are extrapolated [19] to the second sampling of the electromagnetic calorimeter. Around this position a cluster of size  $\Delta\eta \times \Delta\phi = 0.075 \times 0.125$  ( $3 \times 5$  in units of cells in the middle sampling) in the barrel and  $\Delta\eta \times \Delta\phi = 0.125 \times 0.125$  ( $5 \times 5$ ) in the end-caps is built. The cell with the maximum energy is searched within a small  $\eta$  and  $\phi$  window,  $0.075 \times 0.075$  in the middle layer, around the extrapolation point. Shower shapes are estimated with respect to this position.

Since the algorithm is the same as for the reconstruction of electrons in jets [18], a set of *preselection* criteria are applied to decrease the number of fake candidates:

- the fraction of energy reconstructed in the core of the shower in the first sampling  $E_1(\text{core})/E > 0.03$ ;
- the fraction of energy reconstructed in the core of the shower in the third sampling  $E_3(\text{core})/E < 0.5$ ;
- the ratio of the energy  $E$  reconstructed in the electromagnetic calorimeter over the momentum  $p$  reconstructed in the inner detector  $E/p > 0.7$ .

The above selection rejects about 5% of signal electrons but also ensures that the shower shapes in the first sampling are correctly defined. Finally, candidates which are also reconstructed as originating from a conversion [13] are vetoed, corresponding to a loss of 1-3% of signal electrons and pions.

By fitting electron tracks in such a way as to allow for bremsstrahlung, it is possible to improve the reconstructed track parameters, as shown in Fig. 5 on the ratio between the reconstructed and the true momentum for electrons. These algorithms rely exclusively on the inner detector information. The method of dynamic-noise-adjustment extrapolates track segments to the next silicon layer. If it finds a significant  $\chi^2$  contribution, compatible with an energy loss by the track due to bremsstrahlung, the fraction of radiated energy is estimated and a corresponding additional noise term is included in the Kalman filter [1] [20].

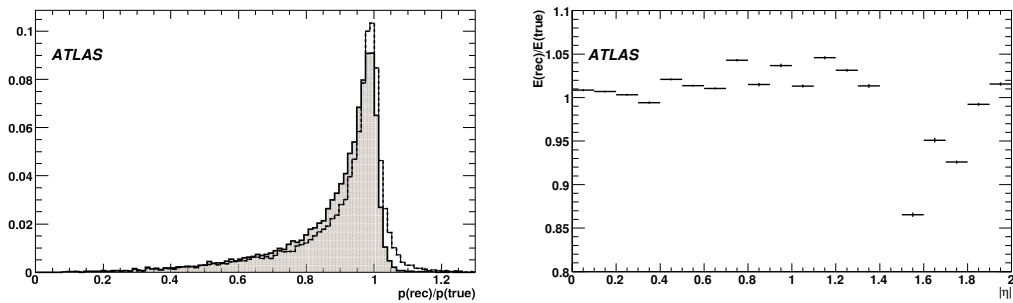

Figure 5: Left : ratio of the reconstructed to true momentum for electrons, for the default Kalman filter (hatched histogram) and for bremsstrahlung recovery algorithm (plain histogram) in the  $J/\psi$  samples. Right : ratio of the reconstructed to true energy versus  $\eta$  for electrons.

Position and energy corrections are applied in the precise reconstruction of the electromagnetic cluster and are described in [21]. These corrections have been tuned for high energy clusters and are not optimal for low energy electrons. Moreover, they have been determined with electron samples simulated with a detector taken to be perfectly aligned. In Fig. 5 the ratio between the reconstructed and the true energy is shown as a function of  $|\eta|$  for signal electrons from  $J/\psi$  samples. It can be seen that these corrections over-estimate the electron energy except in the crack region where the effect of extra-material in front of the calorimeter is important. Work is on going to improve the energy reconstruction at low energy.

By default the four-momentum of an electron is defined as the energy reconstructed in the calorimeter, whereas direction is taken from the associated track. As in this note the main physics processes result in electron transverse momenta of less than 15 GeV, the tracker momentum is used instead of the energy unless stated otherwise. Future developments in ATLAS will ensure an optimal combination of calorimeter and tracker measurements in the energy definition.

## 4.2 Electron identification

The most common background processes for producing electron-like showers in the calorimeters were described in section 2. Because the development of showers is different for electrons and hadrons, the electron identification algorithm incorporates variables that describe the shower shapes, quality of the match between the track and its corresponding cluster and the fraction of high threshold hits in the transition radiation tracker.

#### 4.2.1 Identification of isolated electrons

The identification for isolated electrons is based on cuts on the shower shapes, on information from the reconstructed tracks and on the combined reconstruction [17]. To be consistent with the trigger selection, only particles having a transverse energy  $E_T > 5$  GeV are considered in the following. Three levels of selection are available:

- “loose”, consisting of simple shower-shape cuts (longitudinal leakage, shower shape in the middle layer of the electromagnetic calorimeter) and very loose matching cuts between reconstructed tracks and calorimeter clusters;
- “medium”, which adds shower shape cuts making use of the important information contained in the first layer of the electromagnetic calorimeter and track-quality cuts; and
- “tight”, with tighter track matching criteria and the cut on the energy-to-momentum ratio. This selection also explicitly requires the presence of a vertexing-layer hit on the track (to further reject photon conversions) and a large ratio of high-threshold to low-threshold hits in the TRT detector (to further reject the background from charged hadrons). Additionally, further isolation of the electron may be required by using calorimeter energy isolation beyond the cluster itself. Two sets of tight selection cuts are used to estimate the overall performance of the electron identification. They are labeled as “tight(TRT)”, in the case where a TRT cut with approximately 90% efficiency for electrons is applied, and as “tight(isol)”, in the case where a TRT cut with approximately 95% efficiency is applied in combination with a calorimeter isolation cut.

The discriminating variables show a significant dependence on the pseudorapidity and a less pronounced one on the transverse momentum. In  $\eta$  the dependence corresponds to varying granularities, lead thickness and material in front of the electromagnetic calorimeter. The separation between the distributions obtained for electrons and pions can vary also with  $\eta$ . The thresholds applied for cuts have been optimised in five  $\eta$  bins, (0,0.8), (0.8,1.37), (1.37,1.52), (1.52,1.8), (1.8,2.0), and for transverse energies below 7.5 GeV, between 7.5 and 15 GeV and above 15 GeV.

The electron identification efficiency is defined as  $\epsilon_e = N_e^t / N_e$ , where  $N_e$  is the number of signal electron tracks, which pass the track cuts and  $N_e^t$  is the number of signal electrons which pass identification cuts. The charged pion rejection is defined as  $R_\pi = N_\pi / N_\pi^t$ , where  $N_\pi$  is the number of *good quality* pion tracks and  $N_\pi^t$  is the number of *good quality* pion tracks misidentified as signal electrons. Table 4 shows the electron identification efficiency and pion rejection factor after loose, medium, tight with no isolation requirement and tight selections for the different data samples. For tight selection the efficiency is  $\epsilon_e \sim 65\%$  for direct  $J/\psi$  production. Performance is similar for the  $\Upsilon$  sample, despite the higher average momentum of the signal electrons, due to the cut on  $E_T > 5$  GeV. Figure 6 shows in more detail the overall reconstruction and identification performance: the  $p_T$  and  $\eta$  dependences of the efficiencies for electrons. There is still an important  $\eta$  dependence due to a few discriminating variables and work is ongoing to improve it.

#### 4.2.2 Identification of electrons from $b$ quark

Another identification procedure is optimised for non-isolated electrons and is thus particularly useful for  $b\bar{b}$  events. The trigger anticipated for these events is based on a muonic decay mode of either the  $b$  or the  $\bar{b}$  quark. All good quality tracks are considered above a transverse momentum  $p_T > 2$  GeV. When possible we use the same variables as for the isolated electron identification but some variables - like the hadronic leakage by the fraction of energy reconstructed in the third sampling - are replaced or only the core of the electromagnetic shower is used. In addition to the traditional cut-based analysis, multivariate techniques have been developed, based on the similar variables, and in particular a likelihood

Table 4: Expected efficiencies  $\varepsilon_e$  for electrons from  $J/\psi$  and  $\Upsilon$  decay for the four standard levels of cuts used for isolated electron identification. Only electrons with  $E_T > 5$  GeV, corresponding to the HLT threshold, are considered. The crack region in the electromagnetic calorimeter, between  $1.37 < |\eta| < 1.52$  is removed. The quoted errors are statistical only.

Selection	$pp \rightarrow J/\psi X$		$pp \rightarrow \Upsilon X$	
	$\varepsilon_e$ (%)	$R_\pi$	$\varepsilon_e$ (%)	$R_\pi$
Loose	$84.3 \pm 0.1$	$36 \pm 3$	$83.7 \pm 0.4$	$32 \pm 7$
Medium	$78.4 \pm 0.1$	$72 \pm 9$	$78.4 \pm 0.4$	$49 \pm 13$
Tight(TRT)	$71.4 \pm 0.1$	$109 \pm 17$	$71.3 \pm 0.4$	$57 \pm 16$
Tight (isol)	$65.5 \pm 0.1$	$900 \pm 400$	$66.1 \pm 0.5$	$740 \pm 300$

Figure 6: Electron identification efficiency with “Tight(TRT)” cuts level as a function of the pseudorapidity (left) and the transverse momentum (right) in direct  $J/\psi$  events.

technique can also be used. Figure 7 shows the obtained pion rejection curve as a function of the electron identification efficiency. In the following the working point is an electron identification efficiency of

Figure 7: Pion rejection as a function of the electron identification efficiency, in  $bB_d \rightarrow \mu J/\psi X$  sample.

80%, corresponding to a pion rejection factor of  $\sim 1300$ . Figure 8 shows the overall reconstruction and identification performance in more details: the  $p_T$  and  $\eta$  dependencies of the efficiencies are shown for electrons.

Figure 8: Electron identification efficiency in  $bB_d \rightarrow \mu(6)J/\psi X$  sample as a function of the pseudorapidity (left) and the transverse momentum (right). The mean electron identification efficiency is  $\varepsilon_e = 80\%$ .

## 5 Expected physics studies for early data

### 5.1 Number of expected events

As described in section 3, for an initial luminosity of  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ , the trigger selection of two low energy electrons (2EM3 menu at level 1) should provide good statistics for  $J/\psi \rightarrow ee$  and  $\Upsilon \rightarrow ee$  decays. Fig. 9 shows the expected differential cross-section for low-mass electron pairs using the 2EM3 trigger menu item and the offline selection in linear (left) and log (right) scale. The invariant mass is reconstructed with direction taken from the inner detector and energy from the electromagnetic calorimeter which allows a better reconstruction of the invariant mass than using calorimeter only information as done at level 1. The signal-to-background ratio obtained is greater than one at the  $J/\psi$  and  $\Upsilon$  peaks. With an integrated luminosity of  $100 \text{ pb}^{-1}$  and an efficient identification and reconstruction of these low-mass pairs, approximately two hundred thousand  $J/\psi$  decays could be extracted (see table 5).

Table 5: Number of expected events for direct production of  $J/\psi$ ,  $\Upsilon$  and Drell-Yan events passing the 2EM3 trigger and offline analysis. Numbers are given for an integrated luminosity of  $100 \text{ pb}^{-1}$  with early data taking at  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ . Quoted errors are statistical only.

	$J/\psi$	$\Upsilon$	Drell-Yan
	$10^3 \text{ ev} / 100 \text{ pb}^{-1}$	$10^3 \text{ ev} / 100 \text{ pb}^{-1}$	$10^3 \text{ ev} / 100 \text{ pb}^{-1}$
offline + $E_T > 5 \text{ GeV}$	$256 \pm 9$	$45 \pm 5$	$13.9 \pm 0.3$
offline + $E_T > 5 \text{ GeV} + \text{L1}$	$230 \pm 9$	$43 \pm 5$	$13.3 \pm 0.3$

Moreover, the standard  $B$ -physics trigger, using a single muon above a threshold of  $p_T > 4 \text{ GeV}$ , can give access to a sample of  $J/\psi$  events originating from the  $b\bar{b}$  production, without possible bias on the selection of electromagnetic objects. Due to its lower cross-section, the expected number of events is much less, around  $2.3 \times 10^3$  after offline selection and  $\sim 1.9 \times 10^3$  after trigger and offline selection, but

Figure 9: Expected differential cross section for low-mass electron pairs using the 2EM3 trigger menu item and the offline selection in linear (left) and log (right) scale. Shown is the invariant di-electron mass distribution reconstructed using tracks for  $J/\psi \rightarrow ee$  decays (dotted histogram),  $\Upsilon \rightarrow ee$  decays (dashed histogram) and Drell-Yan production (full histogram). Also shown is the expected background (full circles). The invariant mass is reconstructed with direction taken from the inner detector and energy from the electromagnetic calorimeter.

without any selection on the electrons themselves. A better estimation of this number requires combining a single muon trigger with a trigger for electromagnetic final states as described in section 3.3.

## 5.2 Quality of the mass reconstruction with initial data

In this section, we study the offline reconstruction of the  $J/\psi$  and  $\Upsilon$  particles from their decay products. After a short description of the algorithm, we study the performance of the reconstruction for  $J/\psi$ s originating from the  $b\bar{b}$  decays. The invariant mass has been reconstructed with the inner detector only, combining information from the inner detector and the electromagnetic calorimeter, and using only the latter information. For the reconstruction with inner detector information we present results with and without the bremsstrahlung recovery procedure included. For direct production of  $J/\psi$  and  $\Upsilon$ , we only show results using mass reconstruction with the inner detector.

### 5.2.1 Reconstruction of $J/\psi$ and $\Upsilon$ events

The identification of electrons is performed using the electron reconstruction algorithm described above. Electrons are identified with either the “tight” cuts for isolated electrons, or based on the likelihood method tuned to an electron identification efficiency of 80%. Pairs of electrons are thus selected. These pairs define the overall detection efficiency of  $J/\psi$  (or  $\Upsilon$ ) events which is the product of the losses due to the removal of clusters located in the crack in the electromagnetic calorimeter, the track quality cuts, and the electron identification efficiency.

Pairs of reconstructed opposite-charge tracks are fitted to a common vertex. Only events with a quality of the fit with  $\chi^2$  per degree of freedom  $< 6$  are retained. Fig. 10 shows the distribution of the reconstructed transverse decay length  $L_{xy}$  for direct  $J/\psi$  events and events originated from  $B$  hadrons decay. It is defined as:  $L_{xy} = \frac{\vec{D} \cdot \vec{p}_T(J/\psi)}{\|\vec{p}_T(J/\psi)\|}$ , where  $D$  is the distance between the primary and secondary vertices and  $p_T(J/\psi)$  is the  $J/\psi$  reconstructed transverse momentum. It is used to distinguish between the prompt  $J/\psi$ , which have a pseudo-proper time of zero ( $L_{xy} < 0.4$  mm), and  $B$ -hadron decays into  $J/\psi + X$  having an exponentially decaying pseudo-proper time distribution due to the non-zero lifetime of the parent  $B$ -hadrons ( $L_{xy} > 0.25$  mm).

Figure 10: Distributions of the reconstructed transverse decay length direct  $J/\psi$  events (left) and  $J/\psi$  events originated from  $B$  hadrons decay (right).

### 5.2.2 Reconstruction of $J/\psi$ from $b\bar{b}$ decays

After selection, only  $\sim 2000$  events are reconstructed. This statistics is scaled to  $1.9 \times 10^3$  events, corresponding to the expected statistics for an integrated luminosity of  $100 \text{ pb}^{-1}$ .

#### Reconstruction in the inner detector:

Fig. 11 shows the electron pair invariant mass distribution using only the inner detector information for signal events. The fitted function behaves as a Breit-Wigner distribution  $\sim \Gamma/(\Delta m_0^2 + (\Gamma/2)^2)$  to the left of the peak  $m_0$ , and as a Gaussian of width  $\sigma_{\text{right}}$  to the right, as shown in Fig. 11. The parameter  $\sigma_{\text{right}}$

Figure 11: The electron pair invariant mass distribution for  $bB_d \rightarrow \mu(6)J/\psi X$  events. The energy and direction information are taken from the inner detector. An asymmetric fit is performed with a function which behaves as a Breit-Wigner distribution to the left of the peak and as a Gaussian to the right of the peak. Results are shown without (crosses) and with (bullets) bremsstrahlung recovery included. Selection of events includes L1 trigger and offline and number of events is scaled to  $100 \text{ pb}^{-1}$ .

characterises the effective resolution in the invariant mass distribution of the pair, while  $\Gamma$  is a measure of the intensity of energy loss by the electrons due to the bremsstrahlung.  $\Delta m_0 = m_0 - M_{J/\psi}$ , where  $M_{J/\psi} = 3096$  MeV is the nominal  $J/\psi$  mass. The fitted values of the parameters are shown in Table 6. The  $J/\psi$  reconstruction performance is assessed separately for the three cases: TRT barrel, when both electrons have their track pseudorapidity  $|\eta| < 0.7$ , the TRT end-caps, when at least one electron has  $|\eta| > 0.7$ , and the full  $\eta$  range. In general the quality of the fit is not very high, in particular we see

Table 6: Results of an asymmetric fit to the invariant mass distributions for  $bB_d \rightarrow \mu(6)J/\psi X$  events, with a function that behaves as a Breit-Wigner distribution to the left of the peak and as a Gaussian to the right of the peak. The direction and energy information are taken from the inner detector.

brem fit	$\eta$ range	$\Delta m_0$ (MeV)	$\Gamma$ (MeV)	$\sigma_{\text{right}}$ (MeV)
No	all	$-77 \pm 7$	$557 \pm 20$	$67 \pm 4$
	Barrel	$-71 \pm 7$	$393 \pm 19$	$65 \pm 4$
	End-caps	$-178 \pm 17$	$688 \pm 43$	$123 \pm 11$
Yes	All	$-66 \pm 6$	$540 \pm 18$	$99 \pm 4$
	Barrel	$-45 \pm 7$	$417 \pm 19$	$77 \pm 5$
	End-caps	$-128 \pm 12$	$657 \pm 33$	$155 \pm 8$

difficulties with correctly reproducing the peak. Table 6 shows the results of the fit of the invariant mass. A shift in the reconstructed mass is measured around 77 MeV, larger in the end-caps than in the barrel. As mentioned in [5], such mass shifts may be due to detector alignment, material effects, magnetic field scale and its stability. The CDF collaboration extensively and successfully used this method but it took many years at the Tevatron to collect sufficient statistics to allow for the disentanglement of various detector effects [22]. The parameter  $\Gamma$  is around 550 MeV. The Gaussian width, estimated from the right part of the distribution is around 67 MeV. One can also notice the improvement in the mass reconstruction from bremsstrahlung recovery. Without any bremsstrahlung recovery, only 47% of events are reconstructed within  $\pm 200$  MeV of the nominal  $J/\psi$  mass, whereas with the use of the bremsstrahlung recovery, this fraction increases to approximately 55% for the dynamic-noise-adjustment algorithm.

#### Combined reconstruction:

The  $J/\psi$  mass can be also determined combining information from the inner detector and the electromagnetic calorimeter. The energy is taken from the electromagnetic calorimeter and the direction from the more accurate measurements provided by the inner detector, taking into account the bremsstrahlung recovery procedure. Figure 12 shows the di-electron invariant mass distribution obtained from the signal sample only. An asymmetric gaussian function is fitted, with different width,  $\sigma_{\text{left}}$  and  $\sigma_{\text{right}}$ , either side of the fitted peak mass  $m_0$ . It is performed in a narrow mass interval, between 2.5 and 3.6 GeV. The parameter  $\sigma_{\text{right}}$  characterises the effective resolution in the invariant mass, while  $\sigma_{\text{left}}$  is a measure of the deterioration of this resolution due to bremsstrahlung. The fitted values of the parameters are shown in Table 7. Performance is assessed separately for the three cases: TRT barrel, when both electrons have their track pseudorapidity  $|\eta| < 0.7$ , the TRT end-caps, when at least one electron has  $|\eta| > 0.7$ , and the full  $\eta$  range. The resolution obtained is highly asymmetric,  $\sim 387$  MeV on the left and  $\sim 189$  MeV on the right. It can be also noticed that the quality of the fit is rather poor.

#### Reconstruction in the electromagnetic calorimeter:

Finally it is interesting to investigate the performance if we rely only on the information from the electromagnetic calorimeter. Fig. 13 shows the electron candidates invariant mass distribution obtained from the signal sample only. The same function defined for the combined reconstruction is used to fit the distributions. The fitted values of the parameters are shown in Table 8. Performance is assessed separately in three cases: the barrel region of the electromagnetic calorimeter, when both electrons have their

Figure 12: The electron pair invariant mass for  $bB_d \rightarrow \mu(6)J/\psi X$  events. The energy is taken from the electromagnetic calorimeter and the direction from the inner detector (including bremsstrahlung recovery). Selection of events includes L1 trigger and offline and number of events is scaled to  $100 \text{ pb}^{-1}$ .

Table 7: Asymmetric Gaussian fit results for  $bB_d \rightarrow \mu(6)J/\psi X$  events. The energy is taken from the electromagnetic calorimeter and the direction from the inner detector.

$\eta$	$\Delta m_0$ (MeV)	$\sigma_{\text{left}}$ (MeV)	$\sigma_{\text{right}}$ (MeV)
All	$101 \pm 14$	$327 \pm 12$	$189 \pm 11$
Barrel	$94 \pm 16$	$285 \pm 12$	$183 \pm 12$
End-caps	$113 \pm 28$	$385 \pm 27$	$191 \pm 21$

pseudorapidity  $|\eta| < 1.4$ ; the end-cap region, when at least one electron has  $|\eta| > 1.4$ ; and for the full  $\eta$  range. The resolution obtained from the width of the Gaussian is  $\sim 550 \text{ MeV}$ .

Table 8: Asymmetric Gaussian fit results for  $bB_d \rightarrow \mu(6)J/\psi X$  events. The energy and direction information is taken from the electromagnetic calorimeter only.

$\eta$	$\Delta m_0$ (MeV)	$\sigma_{\text{left}}$ (MeV)	$\sigma_{\text{right}}$ (MeV)
all	$-17 \pm 54$	$567 \pm 46$	$541 \pm 53$
barrel	$-9 \pm 62$	$558 \pm 50$	$560 \pm 60$
end-cap	$-68 \pm 102$	$629 \pm 125$	$414 \pm 74$

### 5.2.3 Reconstruction of direct $J/\psi$ and $\Upsilon$ events

After selection, only  $\sim 4000$  events are reconstructed. This statistics is scaled to  $2.3 \times 10^5$  events, corresponding to the expected statistics for an integrated luminosity of  $100 \text{ pb}^{-1}$ . Figure 14 shows the electron pair invariant mass distribution using only the inner detector information. The same function as defined

Figure 13: The electron pair invariant mass for  $bB_d \rightarrow \mu(6)J/\psi X$  events. The energy and direction are taken from the electromagnetic calorimeter. Selection of events includes L1 trigger and offline and number of events is scaled to  $100 \text{ pb}^{-1}$ .

Figure 14: The electron pair invariant mass distribution for  $pp \rightarrow J/\psi X$  events. The energy and direction information are taken from the inner detector. An asymmetric fit is performed with a function which behaves as a Breit-Wigner distribution to the left of the peak and as a Gaussian to the right of the peak. Selection of events includes L1 trigger, offline and a cut on  $E_T > 5 \text{ GeV}$  for each electron to mimic the HLT. The number of events is scaled to  $100 \text{ pb}^{-1}$ .

previously is fitted. The fitted values of the parameters  $\Delta m_0$ ,  $\Gamma$  and  $\sigma_{\text{right}}$  are shown in Table 9. The fitted mass value is shifted by about 100 MeV, the  $\Gamma$  factor is  $\sim 300 \text{ MeV}$  and the resolution term is  $\sim 70 \text{ MeV}$ .

Table 9: Results of an asymmetric fit to the invariant mass distributions for  $pp \rightarrow J/\psi X$  events, with a function that behaves as a Breit-Wigner distribution to the left of the peak and as a Gaussian to the right of the peak. The direction and energy information are taken from the inner detector.

$\eta$	$\Delta m_0$ (MeV)	$\Gamma$ (MeV)	$\sigma_{\text{right}}$ (MeV)
All	$-98 \pm 1$	$298 \pm 2$	$71 \pm 1$
Barrel	$-77 \pm 1$	$255 \pm 2$	$62 \pm 1$
End-caps	$-142 \pm 2$	$354 \pm 3$	$87 \pm 2$

### 5.2.4 $\Upsilon$ reconstruction

After selection, only  $\sim 1000$  events are reconstructed. This statistics is scaled to  $4.3 \times 10^4$  events, corresponding to the expected statistics for an integrated luminosity of  $100 \text{ pb}^{-1}$ . Fig. 15 shows the electron pair invariant mass distribution from the inner detector information. The fitted values of the parameters

Figure 15: The electron pair invariant mass distribution for  $pp \rightarrow \Upsilon X$  events. The energy and direction information are taken from the inner detector. An asymmetric fit is performed with a function that behaves as a Breit-Wigner distribution to the left of the peak and as a Gaussian to the right of the peak. Selection of events includes L1 trigger, offline and a cut on  $E_T > 5 \text{ GeV}$  for each electron to mimic the HLT. Number of events is scaled to  $100 \text{ pb}^{-1}$ .

are shown in Table 10. The fitted mass value is shifted by about 180 MeV, the  $\Gamma$  factor is  $\sim 1 \text{ GeV}$  and the resolution term is  $\sim 140 \text{ MeV}$ .

### 5.3 Assessment of performance in situ with initial data

Initial studies have been performed for the  $J/\psi \rightarrow ee$  tag-and-probe method briefly outlined below, using events satisfying a single electron trigger with  $E_T > 5 \text{ GeV}$ . Due to too high rate at L1 (40 kHz) it has to be pre-scaled by a factor of 60, which reduces the final statistics. Those events are used to look for an opposite-charge electron pair identified by the offline electron reconstruction with an invariant mass

Table 10: Results of an asymmetric fit to the invariant mass distributions for  $pp \rightarrow \Upsilon X$  events, with a function which behaves as a Breit-Wigner distribution to the left of the peak and as a Gaussian to the right of the peak. The direction and energy information are taken from the inner detector.

$\eta$ range	$\Delta m_0$ (MeV)	$\Gamma$ (MeV)	$\sigma_{\text{right}}$ (MeV)
All	$-181 \pm 5$	$1098 \pm 11$	$137 \pm 3$
Barrel	$-177 \pm 5$	$930 \pm 12$	$137 \pm 3$
End-caps	$-252 \pm 11$	$1335 \pm 25$	$166 \pm 7$

near the  $J/\psi$  peak. Using the second electron as the probe which was not required to pass any trigger selection, the efficiency (relative to the offline selection) of a given trigger signature can be measured. We expect to collect of the order of  $\approx 20 \times 10^3$   $J/\psi$  signal events after the pre-scale with an integrated luminosity of  $100 \text{ pb}^{-1}$ . Similar studies could be performed to study the offline electron selection.

One important ingredient in the calibration strategy for the electromagnetic calorimeter is the use of large statistics samples of  $Z \rightarrow ee$  decays to perform an accurate inter-calibration of regions with a fixed size of  $\Delta\eta \times \Delta\phi = 0.2 \times 0.4$ . To cross-check the calibration obtained from the  $Z^0$  decays and also to check the linearity of the calorimeter, it is important to have calibration coefficients for a lower electron energy range, which can be obtained using the  $J/\psi \rightarrow ee$  and  $\Upsilon \rightarrow ee$  decays as shown in [23]. With the expected statistics, a statistical precision of  $\sim 0.6\%$  can be expected on the inter-calibration of the electromagnetic calorimeter based on  $100 \text{ pb}^{-1}$ . Still, more studies are needed in particular to improve the energy reconstruction and to disentangle effects of inter-calibration with the distribution of material in front of the electromagnetic calorimeter.

More generally, these electron samples will allow us to study the performance of both the reconstruction of tracks in the inner detector and clusters in the electromagnetic calorimeter, as well as the alignment between these two detectors. All these studies are crucial for the very first measurements (such as, for example cross-section measurements) to be performed by the ATLAS experiment on the early data.

## 6 Conclusion

In this note, the strategy to reconstruct  $J/\psi$  and  $\Upsilon$  particles, decaying into electron-positron pairs, has been investigated. The possible trigger strategies have also been described. For initial luminosities of  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ , a trigger on low-energy di-electron pairs (2EM3 at L1) should provide good statistics for the direct production of these particles. Moreover the standard  $B$ -physics trigger, using a single muon above a certain  $p_T$  threshold can give access to these events through the  $b\bar{b}$  production, without biasing the selection of electromagnetic objects. For these studies, the electron reconstruction seeded by a track in the inner detector has been used. Compared to previous studies, the main improvement comes from the identification procedure, which can either use the standard cut-based analysis, with thresholds tuned at low energy, or a dedicated identification developed for non-isolated electrons. The signal-to-background ratio obtained is larger than one at the  $J/\psi$  and  $\Upsilon$  peaks, but the extraction of the Drell-Yan signal requires further studies. With an integrated luminosity of  $100 \text{ pb}^{-1}$  and an efficient identification and reconstruction of these low-mass pairs, approximately two hundred thousand  $J/\psi$  decays could be isolated for detailed studies of the electron identification and reconstruction performance, in particular in terms of matching energy and momentum measurements at a scale quite different from that of the more commonly used  $Z \rightarrow ee$  decays.

# Muons

# Muon Reconstruction and Identification: Studies with Simulated Monte Carlo Samples

## Abstract

The strategy and performance for muon identification and reconstruction in ATLAS are described. Performance metrics include efficiency, fake rates and momentum resolution. Results are based on data simulated and reconstructed in 2007.

## 1 Introduction

The ATLAS experiment will detect particles created in 14 TeV proton-proton collisions produced by the CERN LHC (Large Hadron Collider). Only a tiny fraction of these collisions will correspond to interesting standard model processes and an even smaller fraction to new physics. Muons, especially those with high- $p_T$  (transverse momentum) and those that are isolated (from other activity in the detector), will be much more common in these interesting events than in the background, and thus provide important means to identify such events and to determine their properties. The ATLAS detector has been designed to be efficient in the detection of muons and to provide precise measurement of their kinematics up to one TeV.

In parallel with the construction of the detector, software has been developed to reconstruct these muons, i.e., for each recorded event, to identify muons and measure their position, direction and momentum. Here we describe the strategies being pursued for this reconstruction and the current performance characterized in terms of efficiency, fake rate and precision and accuracy of measurement. The results reported here are based on simulation data generated and reconstructed in 2007.

We begin with descriptions of the detector, the reconstruction algorithms and the means by which we measure the performance. These are followed by sections documenting this performance for each of the various reconstruction strategies and finally a section summarizing results and commenting on future developments.

## 2 Detector

The ATLAS detector [1] has been designed to provide clean and efficient muon identification and precise momentum measurement over a wide range of momentum and solid angle. The primary detector system built to achieve this is the muon spectrometer, shown in Figure 1. The spectrometer covers the pseudo-rapidity range  $|\eta| < 2.7$  and allows identification of muons with momenta above 3 GeV/c and precise determination of  $p_T$  up to about 1 TeV/c.

The muon spectrometer comprises three subsystems:

- Superconducting coils provide a toroidal magnetic field whose integral varies significantly as a function of both  $\eta$  and  $\phi$  (azimuthal angle). The integrated bending strength (Figure 2) is roughly constant as a function of  $\eta$  except for a significant drop in the transition between the barrel and endcap toroid coils ( $1.4 \lesssim |\eta| \lesssim 1.6$ ).
- Precision detectors are located in three widely-separated *stations* at increasing distance from the collision region. Each station includes multiple closely-packed layers measuring the  $\eta$ -coordinate, the direction in which most of the magnetic field deflection occurs. Monitored drift tubes provide these measurements everywhere except in the high- $\eta$  ( $|\eta| > 2.0$ ) region of the innermost station where cathode strip chambers are used. The measurement precision in each layer is typically better

Figure 1: The ATLAS muon spectrometer.

than  $100 \mu\text{m}$ . The cathode strip chambers additionally provide a rough (1 cm) measurement of the  $\phi$ -coordinate.

- Resistive plate and thin gap chambers provide similarly rough measurements of both  $\eta$  and  $\phi$  near selected stations.

High- $p_T$  muons typically traverse all three stations but there are  $\eta$ - $\phi$  regions where one, two or all three stations do not provide a precision measurement, e.g. those regions with support structures or passages for services. There are also regions where overlaps allow two measurements from a single station. Figure 3 shows the number of station measurements as function of  $\eta$  and  $\phi$ . The resolution and efficiency are degraded where one or more stations do not provide a measurement.

Figure 4 shows how contributions to the muon spectrometer momentum resolution vary as a function of  $p_T$ . At low momentum, the resolution is dominated by fluctuations in the energy loss of the muons traversing the material in front of the spectrometer. Multiple scattering in the spectrometer plays an important role in the intermediate momentum range. For  $p_T > 300 \text{ GeV}/c$ , the single-hit resolution, limited by detector characteristics, alignment and calibration, dominates.

The other ATLAS detector systems also play important roles in achieving the ultimate performance for muon identification and measurement. The calorimeter, with a thickness of more than 10 interaction lengths, provides an effective absorber for hadrons, electrons and photons produced by proton-proton collisions at the center of the ATLAS detector. Energy measurements in the calorimeter can aid in muon identification because of their characteristic minimum ionizing signature and can provide a useful direct measurement of the energy loss [2].

A tracking system inside the calorimeters detects muons and other charged particles with hermetic coverage for  $|\eta| < 2.5$ , providing important confirmation of muons found by the spectrometer over that  $\eta$  range. This *inner detector* has three pixel layers, four stereo silicon microstrip layers, and, for  $|\eta| < 2.0$ , a straw-tube transition radiation detector that records an average of 36 additional measurements on each track. A 2 Tesla solenoidal magnet enables the inner detector to provide an independent precise momentum measurement for muons (and other charged particles). Over most of the acceptance, for  $p_T$  roughly in the range between 30 and 200  $\text{GeV}/c$ , the momentum measurements from the inner detector

Figure 2: ATLAS muon spectrometer integrated magnetic field strength as a function of  $|\eta|$ .

Figure 3: Number of detector stations traversed by muons passing through the muon spectrometer as a function of  $|\eta|$  and  $\phi$ .

Figure 4: Contributions to the momentum resolution for muons reconstructed in the Muon Spectrometer as a function of transverse momentum for  $|\eta| < 1.5$ . The alignment curve is for an uncertainty of  $30 \mu\text{m}$  in the chamber positions.

and muon spectrometer may be combined to give precision better than either alone. The inner detector dominates below this range, and the spectrometer above it.

### 3 Overview of reconstruction and identification algorithms

ATLAS employs a variety of strategies for identifying and reconstructing muons. The direct approach is to reconstruct *standalone* muons by finding tracks in the muon spectrometer and then extrapolating these to the beam line. *Combined* muons are found by matching standalone muons to nearby inner detector tracks and then combining the measurements from the two systems. *Tagged* muons are found by extrapolating inner detector tracks to the spectrometer detectors and searching for nearby hits. Calorimeter tagging algorithms are also being developed to tag inner detector tracks using the presence of a minimum ionizing signal in calorimeter cells. These were not used in the data reconstruction reported here and their performance is documented elsewhere [2].

The current ATLAS baseline reconstruction includes two algorithms for each strategy. Here we briefly describe these algorithms. Later sections describe their performance.

The algorithms are grouped into two families such that each family includes one algorithm for each strategy. The output data intended for use in physics analysis includes two collections of muons—one for each family—in each processed event. We refer to the collections (and families) by the names of the corresponding combined algorithms: Staco [3] and Muid [4]. The Staco collection is the current default for physics analysis.

#### 3.1 Standalone muons

The standalone algorithms first build track segments in each of the three muon stations and then link the segments to form tracks. The Staco-family algorithm that finds the spectrometer tracks and extrapolates

them to the beam line is called Muonboy [3]. On the Muid side, Moore [5] is used to find the tracks and the first stage of Muid performs the inward extrapolation.

The extrapolation must account for both multiple scattering and energy loss in the calorimeter. Muonboy assigns energy loss based on the material crossed in the calorimeter. Muid additionally makes use of the calorimeter energy measurements if they are significantly larger than the most likely value and the muon appears to be isolated [6].

Standalone algorithms have the advantage of slightly greater  $|\eta|$  coverage—out to 2.7 compared to 2.5 for the inner detector—but there are holes in the coverage at  $|\eta|$  near 0.0 and 1.2 (see figure 3). Very low momentum muons (around a few GeV/c) may be difficult to reconstruct because they do not penetrate to the outermost stations.

Muons produced in the calorimeter, e.g. from  $\pi$  and K decays, are likely to be found in the standalone reconstruction and serve as a background of “fake” muons for most physics analyses. There are a few exotic channels for which charged particles appearing in the calorimeter are a signal of interest.

### 3.2 Inner detector

The primary track reconstruction algorithm for the inner detector is described in Ref. [7]. Space points are identified in the pixel and microstrip detectors, these points are linked to form track seeds in the inner four layers, and tracks are found by extending these seeds to add measurements from the outer layers. This strategy is expected to give very high detection efficiency over the full detector acceptance,  $|\eta| < 2.5$ .

### 3.3 Combined muons

Both of the muon combination algorithms, Staco and Muid, pair muon-spectrometer tracks with inner-detector tracks to identify combined muons. The match chi-square, defined as the difference between outer and inner track vectors weighted by their combined covariance matrix:

$$\chi_{match}^2 = (\mathbf{T}_{MS} - \mathbf{T}_{ID})^T (\mathbf{C}_{ID} + \mathbf{C}_{MS})^{-1} (\mathbf{T}_{MS} - \mathbf{T}_{ID}) \quad (1)$$

provides an important measure of the quality of this match and is used to decide which pairs are retained. Here  $\mathbf{T}$  denotes a vector of (five) track parameters—expressed at the point of closest approach to the beam line—and  $\mathbf{C}$  is its covariance matrix. The subscript ID refers to the inner detector and MS to the muon spectrometer (after extrapolation accounting for energy loss and multiple scattering in the calorimeter).

Staco does a statistical combination of the inner and outer track vectors to obtain the combined track vector:

$$\mathbf{T} = (\mathbf{C}_{ID}^{-1} + \mathbf{C}_{MS}^{-1})^{-1} (\mathbf{C}_{ID}^{-1} \mathbf{T}_{ID} + \mathbf{C}_{MS}^{-1} \mathbf{T}_{MS}) \quad (2)$$

Muid does a partial refit: it does not directly use the measurements from the inner track, but starts from the inner track vector and covariance matrix and adds the measurements from the outer track. The fit accounts for the material (multiple scattering and energy loss) and magnetic field in the calorimeter and muon spectrometer.

### 3.4 Tagged muons

The spectrometer tagging algorithms, MuTag [3] and MuGirl [8], propagate all inner detector tracks with sufficient momentum out to the first station of the muon spectrometer and search for nearby segments. MuTag defines a tag chi-square using the difference between any nearby segment and its prediction from the extrapolated track. MuGirl uses an artificial neural network to define a discriminant. In either case, if a segment is sufficiently close to the predicted track position, then the inner detector track is tagged as corresponding to a muon.

At present, both algorithms simply use the inner-detector track to evaluate the muon kinematics, i.e. the inner track and spectrometer hits are not combined to form a new track. This is not very important in the low- $p_T$  regime that these algorithms were originally intended to address. Both algorithms are being further developed to allow extrapolation to other and multiple stations and add the capability to include the spectrometer measurements in a track refit.

There is an important difference in the way these algorithms are run in the standard reconstruction chain. MuGirl considers all inner-detector tracks and redoes segment finding in the region around the track. MuTag only makes use of inner-detector tracks and muon-spectrometer segments not used by Staco. Thus MuTag serves only to supplement Staco while MuGirl attempts to find all muons. Obviously, MuTag is part of the Staco family and most sensibly used in that context. MuGirl muons are recorded as part of the Muid family.

### 3.5 Merging muons

The muon finding efficiency (and fake rate) may be increased by including muons found by multiple algorithms but care must be taken to remove overlaps, i.e. cases where the same muon is identified by two or more algorithms. To a large extent, this is done when the collections are created. Standalone muons that are successfully combined are not recorded separately. In those cases where a standalone muon is combined with more than one inner-detector track, exactly one of the muons is flagged as “best match.” In the Staco collection, the tagged and combined muons do not overlap by construction. In the Muid collection, overlaps between MuGirl and Muid muons are removed by creating a single muon when both have the same inner detector track.

Analysts wishing to merge standalone and tagged muons or muons from different collections may make use of a muon selection tool to remove overlaps. It requires muons have different inner-detector tracks and merges standalone muons that are too close to one another. Closeness is defined by  $\eta$ - $\phi$  separation with a default limit of 0.4.

## 4 Tools for performance evaluation and classification of tracks

Simulation samples were created in the ATLAS framework by running an event generator (PYTHIA [9] or MC@NLO [10, 11]) and using GEANT4 [12] to propagate the final-state particles using ATLAS-specific code to describe the geometry and response of the detector. The data were then reconstructed using the software based on the algorithms described in the previous chapter.

### 4.1 Truth matching and track classification

Muon reconstruction performance is evaluated for each event by comparing selected reconstructed muons with the true muons, i.e. those in the Monte Carlo truth record. The latter include muons created in the initial event generation as well as secondaries produced during propagation through the tracking volume. Muons produced in the calorimeter or muon spectrometer are not included in the truth record. True muons with transverse momentum below 2 GeV/c are also excluded to avoid spurious matches with candidates we do not expect to be able to reconstruct.

For each event, a one-to-one matching is performed between the selected reconstructed muons and the true muons. The matching makes use of two distance metrics:  $D_{ref}$  is the *reference* distance measured from true muon to the reconstructed muon:

$$D_{ref} = \sqrt{\left(\frac{\phi_{reco} - \phi_{true}}{0.005}\right)^2 + \left(\frac{\eta_{reco} - \eta_{true}}{0.005}\right)^2 + \left(\frac{\Delta p_T / p_T}{0.03}\right)^2} \quad (3)$$

and  $D_{eva}$  is the *evaluation* distance measured from the reconstructed muon to the true muon:

$$D_{eva} = \sqrt{(\mathbf{T}_{reco} - \mathbf{T}_{true}) \mathbf{C}_{reco}^{-1} (\mathbf{T}_{reco} - \mathbf{T}_{true})} \quad (4)$$

In the first equation,  $\Delta p_T/p_T$  is the fractional momentum resolution:

$$\frac{\Delta p_T}{p_T} = \frac{1/p_{Treco} - 1/p_{Ttrue}}{1/p_{Ttrue}} = \frac{p_{Ttrue} - p_{Treco}}{p_{Treco}} \quad (5)$$

Here  $p_T$  is signed (i.e. carries the charge sign), but elsewhere in the text it denotes the magnitude of the transverse momentum. In the second distance equation,  $\mathbf{T}$  again denotes the vector of (five) track parameters (expressed at the distance of closest approach to the beam line) and  $\mathbf{C}$  the associated covariance matrix. Note that  $D_{eva}^2$  is a chi-square with five degrees of freedom.

There is a maximum allowed value for each of these distances. For  $D_{eva}$  the maximum value is 1000, a very loose cut. The limit for  $D_{ref}$  is 100 and we see from equation 3 this implies the matched muons must be within a distance of 0.5 in  $\eta$  and  $\phi$  and have the same charge sign with  $p_{Treco} > 0.25 p_{Ttrue}$  or opposite sign with  $p_{Treco} > 0.50 p_{Ttrue}$ .

The matching is carried out by first examining each reconstructed muon and assigning it to the nearest true muon using the evaluation distance. The reconstructed muon is left unmatched if no distance is less than the maximum allowed value. The reference distance is evaluated for each match and the match is discarded if it exceeds the threshold for that quantity. If more than one match remains for any true muon, then only the match with the smallest reference distance is retained.

True muons that are matched are said to be *found* and those left unmatched are *lost*. Found muons are classified as *good* if they have  $D_{eva} < 4.5$  corresponding to a chi-square probability above 0.0011.

Reconstructed muons are said to be *real* if they are matched and *fake* if unmatched. Note that these fakes may correspond to true muons produced outside the tracking volume (e.g. in the calorimeter) and hence not included in the truth record.

## 4.2 Performance measures

Our performance measures include efficiency, fake rate, resolutions and resolution tails. The efficiency or *finding efficiency* is defined to be the fraction of true muons that are found and is typically evaluated for some kinematic selection (applied after matching). The *good efficiency* is the fraction of true muons that are found and classified as good (as defined in the previous section). The *good fraction* is the fraction of found muons that are classified as good. In the sections that follow, we present the overall efficiency for various physics samples and the efficiency as a function of  $\eta$  for the primary benchmark sample.

The fake rate is defined to be the mean number of fake muons per event and it is presented for a variety of  $p_T$  thresholds corresponding to the values that might be chosen for different physics analyses.

Five kinematic variables characterize a track, but here we examine only the measurement of the transverse momentum. The precision and accuracy of the direction measurements are typically much better than that required for any physics analysis. The measurement of the initial position of the track (e.g. at the distance of closest approach to the beam line or vertex) is discussed in another note [13]. For the momentum, we use the fractional residual,  $\Delta p_T/p_T$ , defined in equation 5. This distribution is fitted with a Gaussian and the resolution is defined to be the sigma of this fit. The tails in the distributions are often more important than the core resolution and we characterize these by evaluating the fraction of found muons in five tail categories. The first three are those for which the magnitude of this residual exceeds 5%, 10% or 30%. The last category is the fraction for which the charge sign is incorrectly measured. Finally there is an intermediate category in which either the sign is incorrect or the magnitude of the measured momentum is more than two times larger than the true value.

### 4.3 Monte Carlo samples

Our primary benchmark sample is a collection of  $t\bar{t}$  events requiring the presence of at least one lepton (electron, muon or tau). The initial inclusive sample was produced using MC@NLO in conjunction with Herwig [14]. This sample provides a variety of mechanisms for producing muons and we present results for two: *direct* muons which do not have any quarks in their ancestry and *indirect* muons whose ancestry includes a heavy quark (b or c) but not a tau. In this sample, the former are produced directly in the leptonic decay of a W-boson.

Performance metrics are plotted as a function of  $\eta$  for  $t\bar{t}$  direct muons. In addition, we tabulate efficiencies and fake rates for these muons, for  $t\bar{t}$  indirect muons, and for muons in separate low- and high- $p_T$  samples. The low- $p_T$  sample is taken from direct PYTHIA  $J/\psi$  production with the  $J/\psi$  forced to decay to two muons and a filter selecting only those events where both muons have  $|\eta| < 2.5$  and  $p_T > 4$  GeV/c. Muons produced by other processes in these events are suppressed by restricting the analyzed sample to muons that have a c-quark in their ancestry. The high- $p_T$  sample consists of direct muons in PYTHIA production of  $Z' \rightarrow \mu\mu$  with a  $Z'$  mass of 2 TeV. The generation also includes  $Z/\gamma$  and interference but a dimuon mass cut ( $m_{\mu\mu} > 500$  GeV/c) ensures that the average muon  $p_T$  is above 500 GeV/c.

At design luminosity, ATLAS will have many interactions in each beam crossing (pileup) and there will be significant background in the muon chambers from low-energy photons and neutrons (cavern background). To get an estimate of the effect this will have on our reconstruction algorithms, we processed a  $t\bar{t}$  sample overlaid with the backgrounds expected for a reference luminosity of  $10^{33}$  cm<sup>-2</sup>s<sup>-1</sup>. The cavern background was included with a safety factor of 2.0, i.e. at twice the value expected for this luminosity. In the following, this sample is called the high-luminosity  $t\bar{t}$  sample. Low luminosity refers to samples without any pileup or cavern background.

There is considerable uncertainty in the estimate of the cavern background and active development is underway to improve reconstruction in this environment, and so the results presented here provide only a rough indication of the performance we expect at high luminosity.

Figure 5 shows the  $p_T$ ,  $\eta$  and isolation energy distributions for the true muons in the samples studied in this note. The isolation energy was obtained by summing the calorimeter transverse energy in an  $\eta$ - $\phi$  cone of radius 0.2 about the muon. The most probable value for the muon energy loss (as discussed in reference [2]) is subtracted from these values.

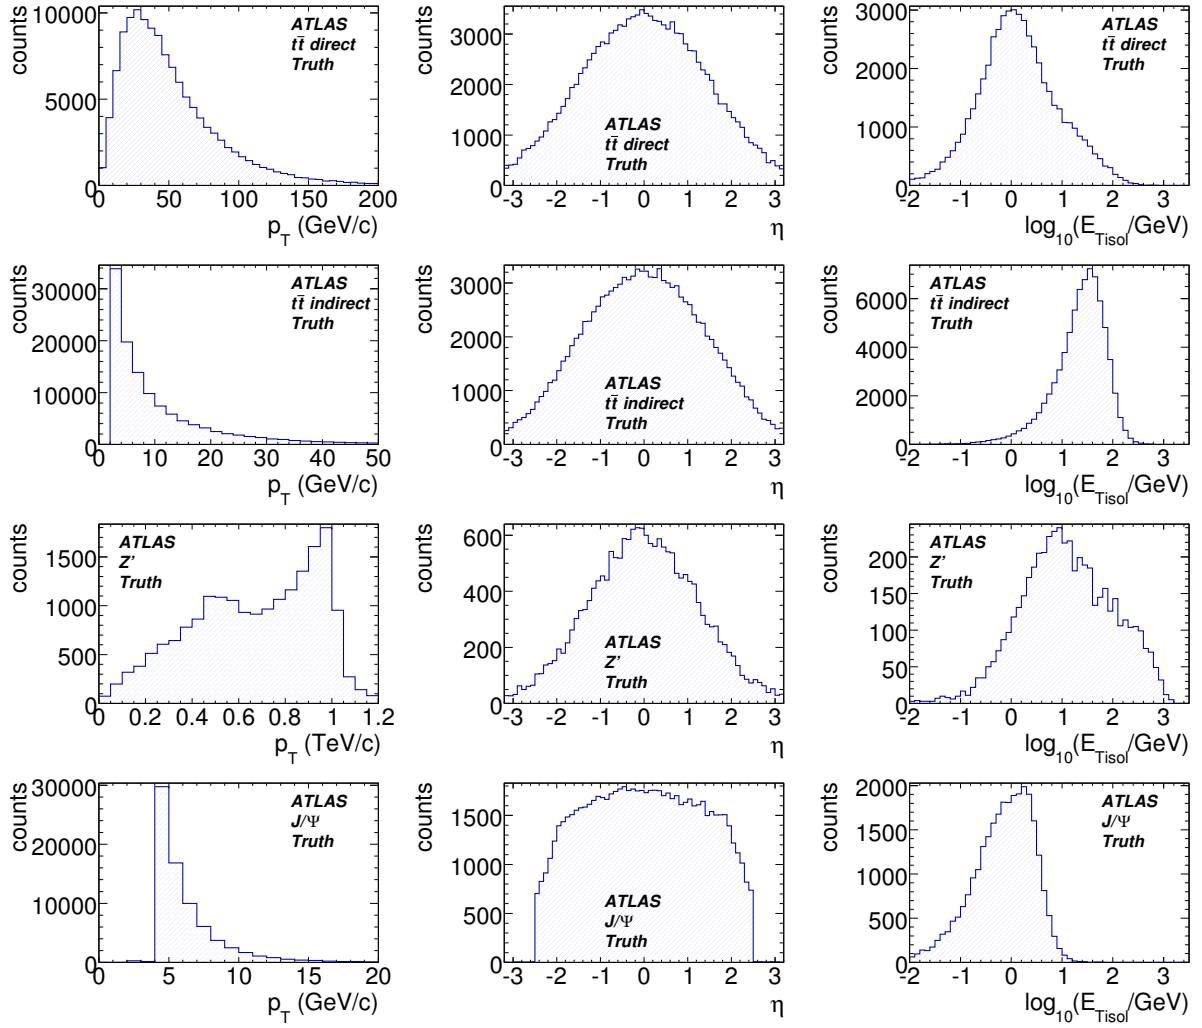

Figure 5: True  $p_T$  (left),  $\eta$  (center) and isolation (right) distributions for the  $t\bar{t}$  direct muons (top),  $t\bar{t}$  indirect muons (second from top),  $Z'$  (mass 2 TeV) direct muons (third from top) and  $J/\psi$  muons (bottom). Note that the  $p_T$  range is different in each of the plots of that variable.

## 5 Standalone muon performance

### 5.1 Efficiencies and fake rates

Figure 6 shows the standalone  $t\bar{t}$  direct muon efficiencies and fake rates as functions of  $\eta$  at low luminosity (i.e. without any pileup or cavern background) and at our reference luminosity ( $10^{33}$  /cm<sup>2</sup>/sec with cavern background safety factor 2.0). Table 1 gives the integrated efficiencies and fake rates for these and other samples.

Sample	Efficiency		Fakes/(1000 events) above $p_T$ limit (GeV/c)			
	found	good	3	10	20	50
Muonboy						
$t\bar{t}$ direct	0.951 (1)	0.812 (1)	24.0 (3)	4.4 (1)	1.69 (7)	0.52 (4)
$t\bar{t}$ indirect	0.949 (1)	0.783 (2)				
hi- $\mathcal{L}$ $t\bar{t}$ direct	0.950 (2)	0.809 (3)	53 (1)	8.2 (4)	3.9 (2)	1.9 (2)
$Z'$ direct	0.914 (2)	0.781 (3)	141 (4)	79 (3)	61 (3)	37 (2)
$J/\psi$	0.959 (3)	0.764 (6)	51 (1)	5.0 (4)	1.6 (2)	0.6 (1)
Moore/Muid						
$t\bar{t}$ direct	0.943 (1)	0.861 (1)	19.8 (3)	3.9 (1)	1.44 (6)	0.47 (4)
$t\bar{t}$ indirect	0.920 (2)	0.838 (2)				
hi- $\mathcal{L}$ $t\bar{t}$ direct	0.932 (2)	0.836 (3)	984 (4)	301 (2)	156 (2)	61 (1)
$Z'$ direct	0.887 (2)	0.769 (3)	168 (4)	102 (3)	75 (3)	43 (2)
$J/\psi$	0.830 (5)	0.723 (6)	6.7 (4)	1.1 (2)	0.5 (1)	0.13 (6)

Table 1: Muonboy and Moore/Muid efficiencies and fake rates for various samples (section 4.3). Efficiencies are presented both for all found muons and for those with a good truth match ( $D_{eva} < 4.5$ ). Both are calculated for true muons with  $|\eta| < 2.5$  and  $p_T > 10$  GeV/c. Fake rates are presented for a variety of  $p_T$  thresholds.

Comparing with Figure 3, we see most of the efficiency loss occurs in regions where the detector coverage is poor, i.e. for  $|\eta|$  around 0.0 and 1.2. Otherwise, the  $t\bar{t}$  muon efficiency is close to 100% for Muonboy and around 99% for Moore/Muid. The Muid good fraction is significantly higher than for Muonboy, presumably because of better handling of the material in the calorimeter. The algorithms have similar fake rates at low luminosity. At the higher luminosity, the Staco rate increases significantly (by a factor of 2-4) while the Moore/Muid rate increases dramatically (factor of 100). In the high- $p_T$   $Z'$ , the efficiency falls by a few percent for both algorithms. For the low- $p_T$  (and non-isolated)  $J/\psi$  muons, the Moore/Muid efficiency degrades significantly while Muonboy remains high.

### 5.2 Resolution

Figure 7 shows the  $p_T$  resolutions and tails as functions of  $\eta$  and  $p_T$ . The resolution is degraded at intermediate pseudorapidity ( $1.2 < |\eta| < 1.7$ ) because of the reduced number of measurements (figure 3), the low field integral in the overlap between barrel and endcap toroids (figure 2), and the material in the endcap toroid (figure 1). The average resolution is very similar for the two algorithms. Despite having a lower good fraction, Muonboy has fewer muons for which the charge sign is incorrectly measured. This suggests that, at least in the tails, Moore/Muid provides a better estimate of the momentum error while Muonboy provides a better estimate of its value. The Moore/Muid tails are likely due to the assignment of incorrect hits to spectrometer tracks.

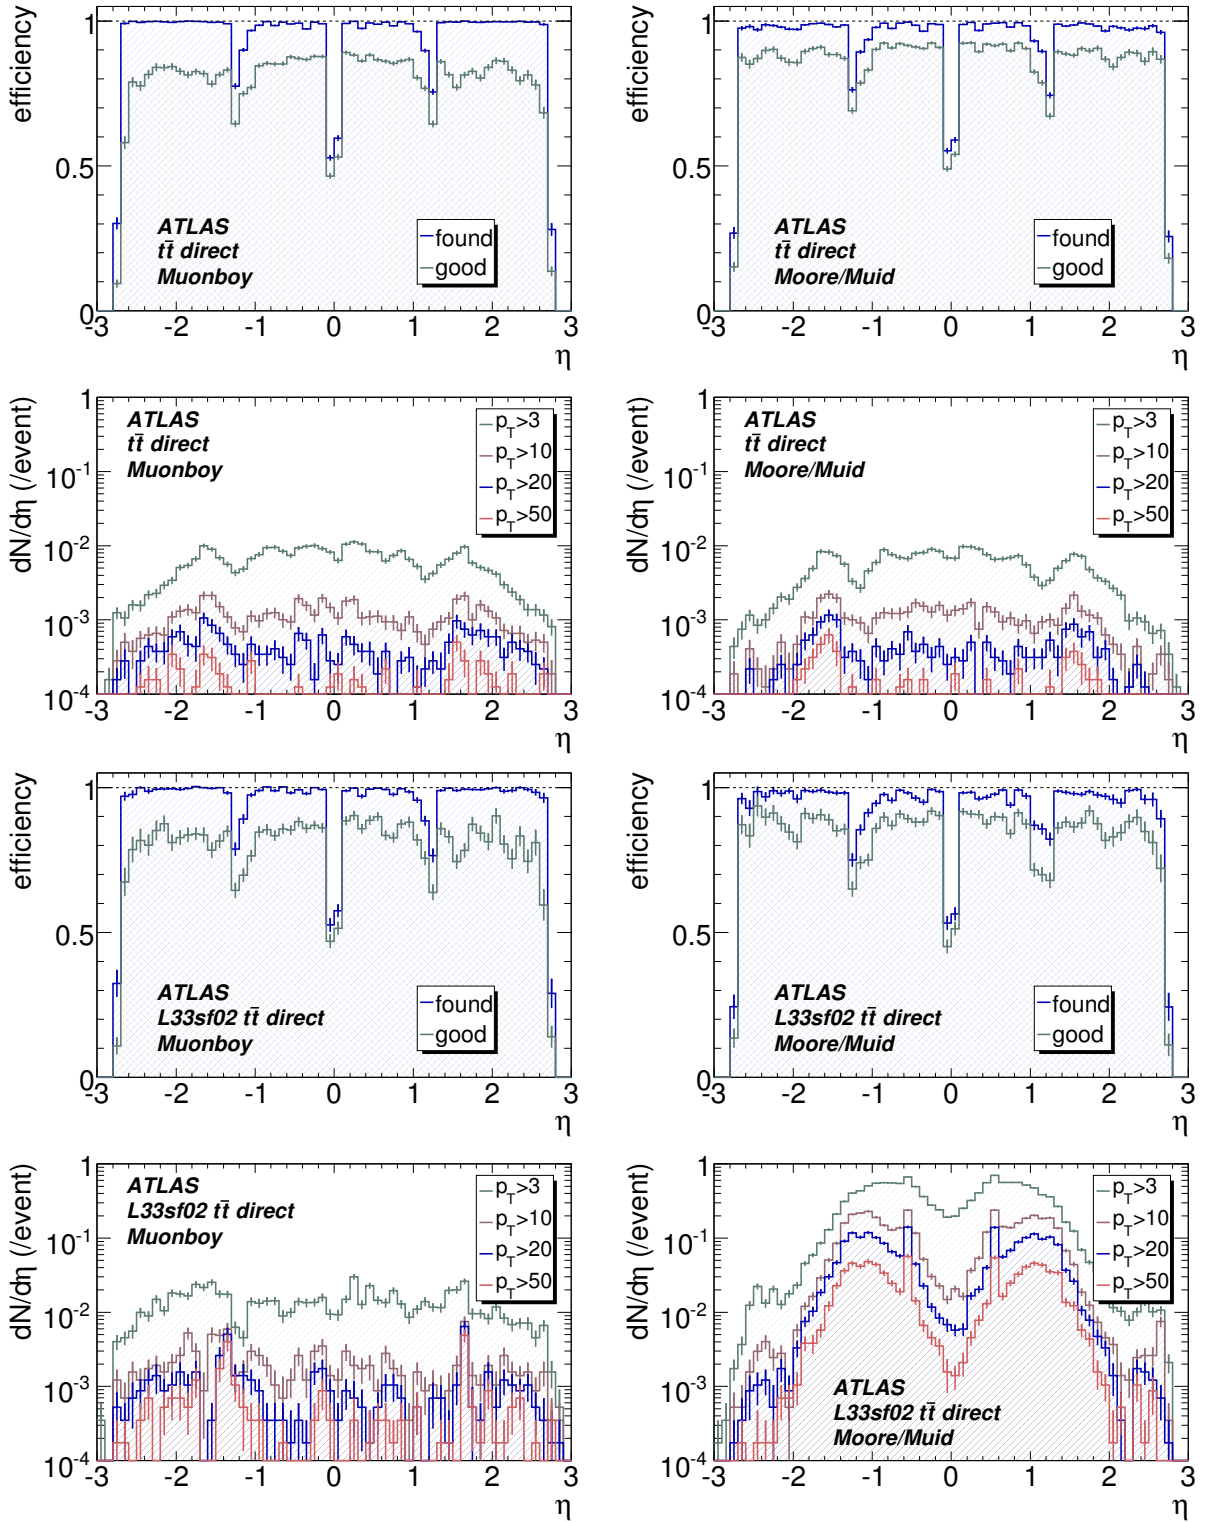

Figure 6: Standalone efficiency and fake rate as functions of true  $\eta$  for Muonboy (left) and Moore/Muid (right) for direct muons in  $t\bar{t}$  at low (top) and high (bottom) luminosity. In the efficiency plots, the upper curve (blue) is the efficiency to find the muon while the lower curve (green) additionally requires a good match ( $D_{eva} < 4.5$ ) between reconstructed and true track parameters. Fake rates are shown for a variety of  $p_T$  thresholds.

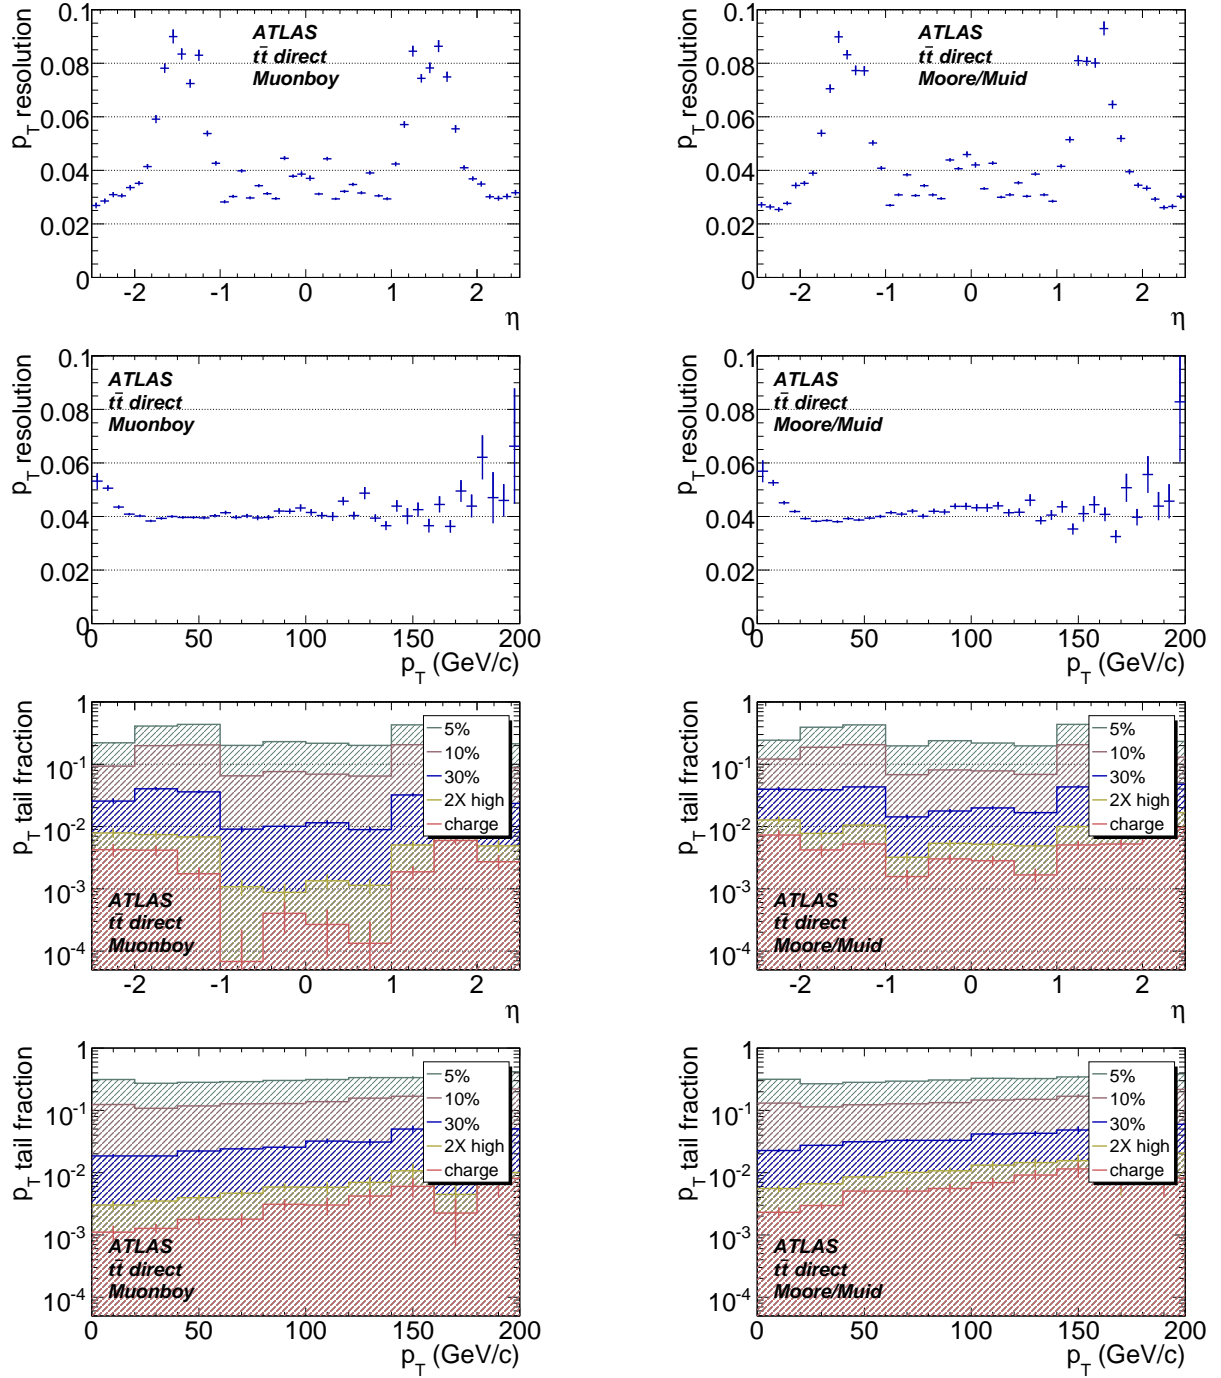

Figure 7: Standalone fractional momentum resolution ( $\Delta p_T/p_T$ ) as function of  $\eta$  (top) and  $p_T$  (2nd row) and tails in that parameter also as functions of  $\eta$  (3rd row) and  $p_T$  (bottom). All are for both Muonboy (left) and Moore/Muid (right). The tail is the fraction of reconstructed muons with magnitude of  $\Delta p_T/p_T$  outside a range and is shown for a wide range of values. The last tail curve (red, “charge”) includes only muons reconstructed with the wrong charge sign. The 4th tail curve (yellow, “2X high”) includes these and those with momentum magnitude more than two times the true value.

## 6 Inner detector performance

Figure 8 shows the efficiency for  $t\bar{t}$  direct muons and Table 2 gives the integrated efficiencies for all of the samples. The efficiency is high for all  $\eta$  (within the acceptance) and all samples. There is no evidence of degradation when pileup is added.

The inner detector momentum resolution is the same as that for tagged muons, reported later: see Figure 13 in section 8.

Figure 8: Inner detector  $t\bar{t}$  direct muon efficiency as a function of true  $\eta$  at low (left) and high (right) luminosity. In each figure, the upper curve (blue) is the efficiency to find the muon while the lower curve (green) additionally requires a good match ( $D_{eva} < 4.5$ ) between reconstructed and true track parameters. The efficiency is for  $p_T > 10$  GeV/c.

Sample	Efficiency	
	found	good
$t\bar{t}$ direct	0.996 (1)	0.950 (2)
$t\bar{t}$ indirect	0.997 (1)	0.833 (5)
hi- $\mathcal{L}$ $t\bar{t}$ direct	0.995 (1)	0.947 (2)
Zprime direct	0.993 (1)	0.966 (1)
$J/\psi$	0.995 (1)	0.941 (3)

Table 2: Inner detector efficiencies. The samples and algorithms are described in the text. Efficiencies are presented both for all found muons and for those with a good truth match ( $D_{eva} < 4.5$ ). Efficiencies are calculated for true muons with  $|\eta| < 2.5$  and  $p_T > 10$  GeV/c.

## 7 Combined muon performance

### 7.1 Efficiencies and fake rates

Figure 9 shows the combined  $t\bar{t}$  direct muon efficiency and fake rates for each algorithm as a function of  $\eta$  for both low and high luminosity. Compared with the performance for standalone muons (figure 6), Staco shows a small drop in efficiency with little reduction of the fake rate except for the lowest  $p_T$  threshold at high luminosity. In fact, the high- $p_T$  fake rates increase at either luminosity because low- $p_T$  standalone muons are matched to high- $p_T$  inner-detector tracks. At low luminosity, Muid  $t\bar{t}$  shows a

small decrease in both efficiency and fake rate. When background is added, the dramatic increase in fakes for Moore standalone is not observed in Muid combined, i.e. the matching suppresses most of the fakes and the Muid high- $p_T$  fake rates are lower than those of Staco. However, the high-luminosity  $t\bar{t}$  Muid efficiency is significantly worse than that of Staco.

When matching inner detector and muon spectrometer tracks, both Staco and Muid calculate  $\chi^2_{match}$  (section 3.3) which serves as a discriminant for separating real and fake muons. The fakes include pion or kaon decays in or near the calorimeter. Figure 10 shows the  $\chi^2_{match}$  distributions for both direct found muons and fakes. We see that with a cut on this quantity, e.g.  $\chi^2_{match} < 100$ , many of the Staco high- $p_T$  fakes can be suppressed with only a modest loss in efficiency. The higher Staco fake rates come from looser cuts during reconstruction and, if the  $\chi^2_{match}$  cuts are adjusted to give the same efficiencies, the Staco fake rate is lower.

Table 3 shows the integrated Staco and Muid muon efficiencies and fake rates for all samples including an entry showing the effect of the above cut on  $\chi^2_{match}$ .

Sample	Efficiency		Fakes/(1000 events) above $p_T$ limit (GeV/c)			
	found	good	3	10	20	50
Staco						
$t\bar{t}$ direct	0.943 (1)	0.875 (1)	22.0 (3)	9.6 (2)	3.4 (1)	0.62 (4)
$t\bar{t}$ indirect	0.933 (1)	0.767 (2)				
$t\bar{t}$ direct cut	0.924 (1)	0.865 (1)	14.8 (2)	3.1 (1)	0.39 (3)	0.01 (1)
hi- $\mathcal{L}$ $t\bar{t}$ direct	0.941 (2)	0.871 (3)	25.9 (7)	11.2 (4)	4.3 (3)	0.7 (1)
$Z'$	0.910 (2)	0.824 (3)	14 (1)	8.4 (9)	5.2 (7)	3.4 (6)
$J/\psi$	0.943 (3)	0.873 (4)	0.9 (2)	0.24 (8)	0.11 (5)	0.0 (0)
Muid						
$t\bar{t}$ direct	0.926 (1)	0.877 (1)	15.4 (2)	2.36 (9)	0.48 (4)	0.05 (1)
$t\bar{t}$ indirect	0.888 (2)	0.748 (3)				
$t\bar{t}$ direct cut	0.917 (1)	0.871 (1)	14.0 (2)	1.96 (8)	0.33 (3)	0.03 (1)
hi- $\mathcal{L}$ $t\bar{t}$ direct	0.904 (2)	0.854 (3)	35.5 (8)	5.0 (3)	1.1 (1)	0.24 (6)
$Z'$ direct	0.872 (2)	0.811 (3)	11 (1)	4.5 (7)	3.1 (6)	2.7 (5)
$J/\psi$	0.793 (5)	0.741 (6)	0.8 (1)	0.03 (3)	0.0 (0)	0.0 (0)

Table 3: Staco and Muid efficiencies and fake rates. The samples and algorithms are described in the text. Algorithm names are followed by “cut” to indicate that reconstructed muons are required to have  $\chi^2_{match} < 100$  for both efficiency and fake calculations. Efficiencies are presented both for all found muons and for those with a good truth match. Both are calculated for true muons with  $|\eta| < 2.5$  and  $p_T > 10$  GeV/c. The fake rates are presented for a variety of  $p_T$  thresholds.

## 7.2 Resolution

Figure 11 shows the  $t\bar{t}$  direct muon  $p_T$  resolutions and tails as functions of  $\eta$  and  $p_T$ . Comparing with the same for standalone reconstruction (figure 7), we see, as expected, the combined resolution is significantly better especially in the overlap region ( $|\eta|$  around 1.5) and for  $p_T$  below 100 GeV/c. There are also significant reductions in the tails of momentum residuals. Misreconstruction and charge misidentification rates are around 0.01% for the combined muons instead of 0.1% for the standalone.

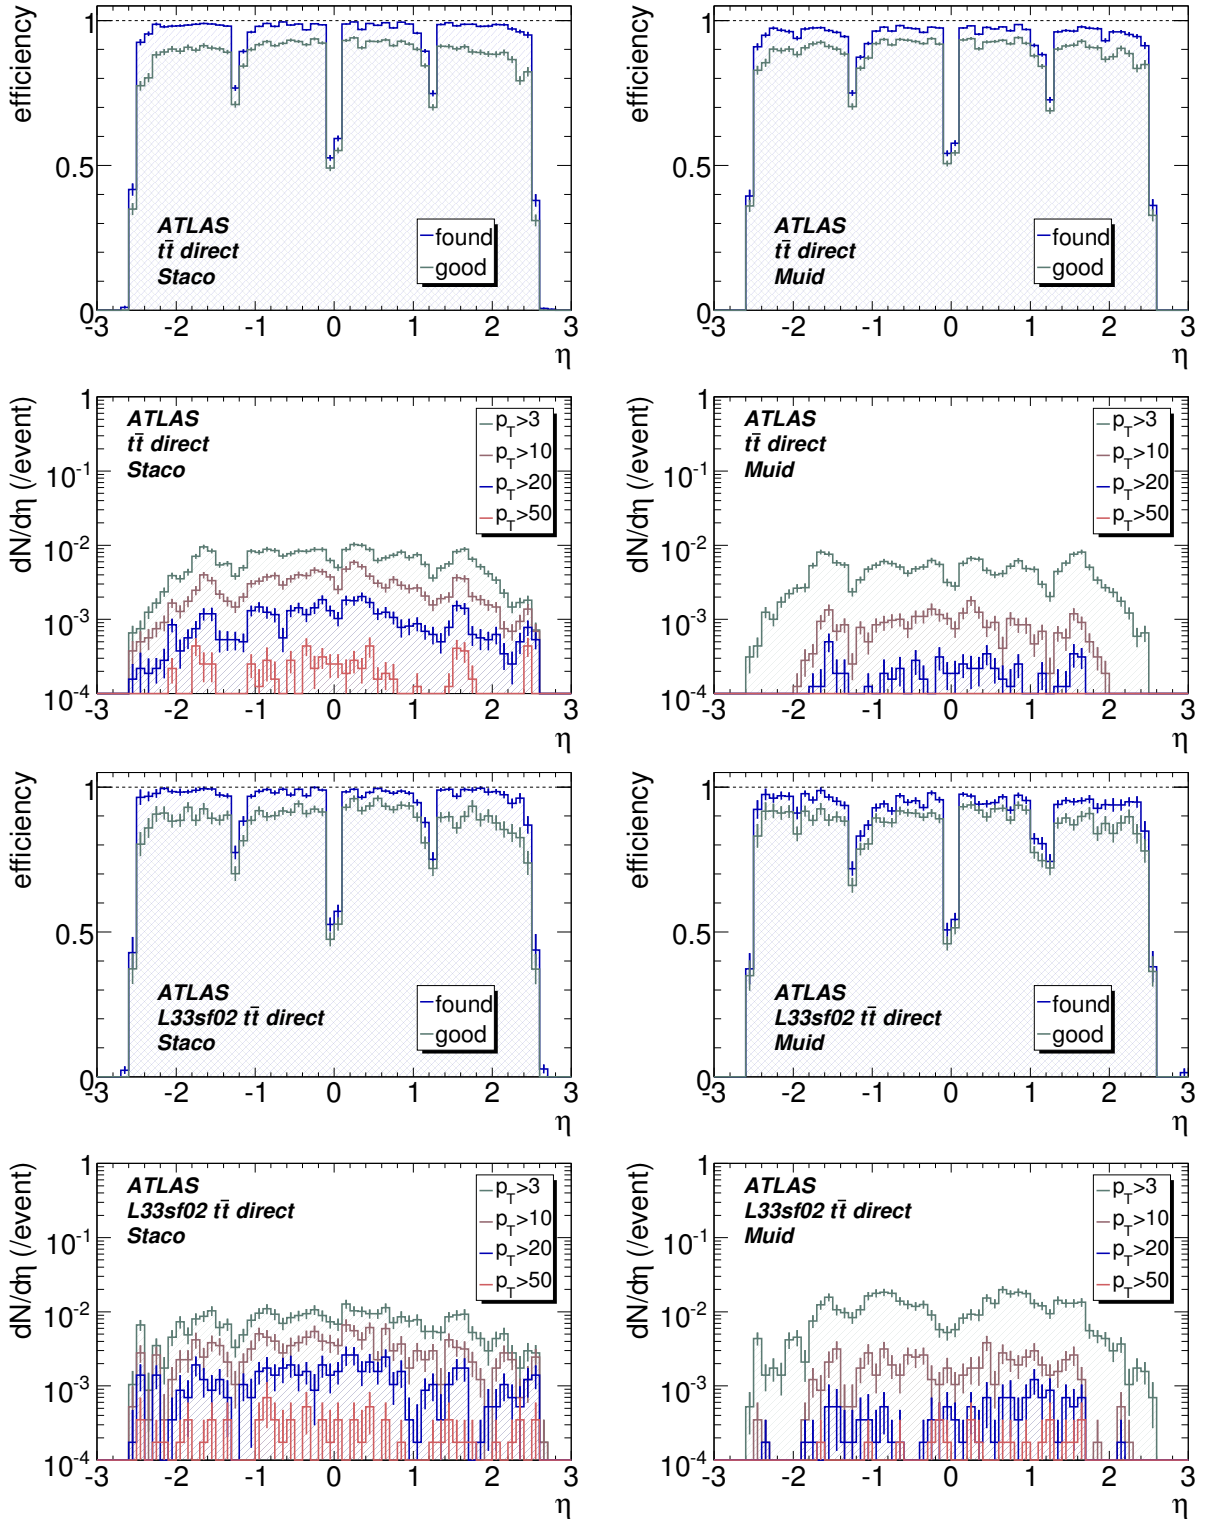

Figure 9: Combined muon efficiency and fake rate for Staco (left) and Muid (right) as functions of true  $\eta$  for direct muons in  $t\bar{t}$  at low (top) and high (bottom) luminosity. In each efficiency plot, the upper curve (blue) is the efficiency to find the muon while the lower curve (green) additionally requires a good match ( $D_{eva} < 4.5$ ) between reconstructed and true track parameters. The efficiencies are for  $p_T > 10$  GeV/ $c$ . Fake rates are shown for a variety of  $p_T$  thresholds.

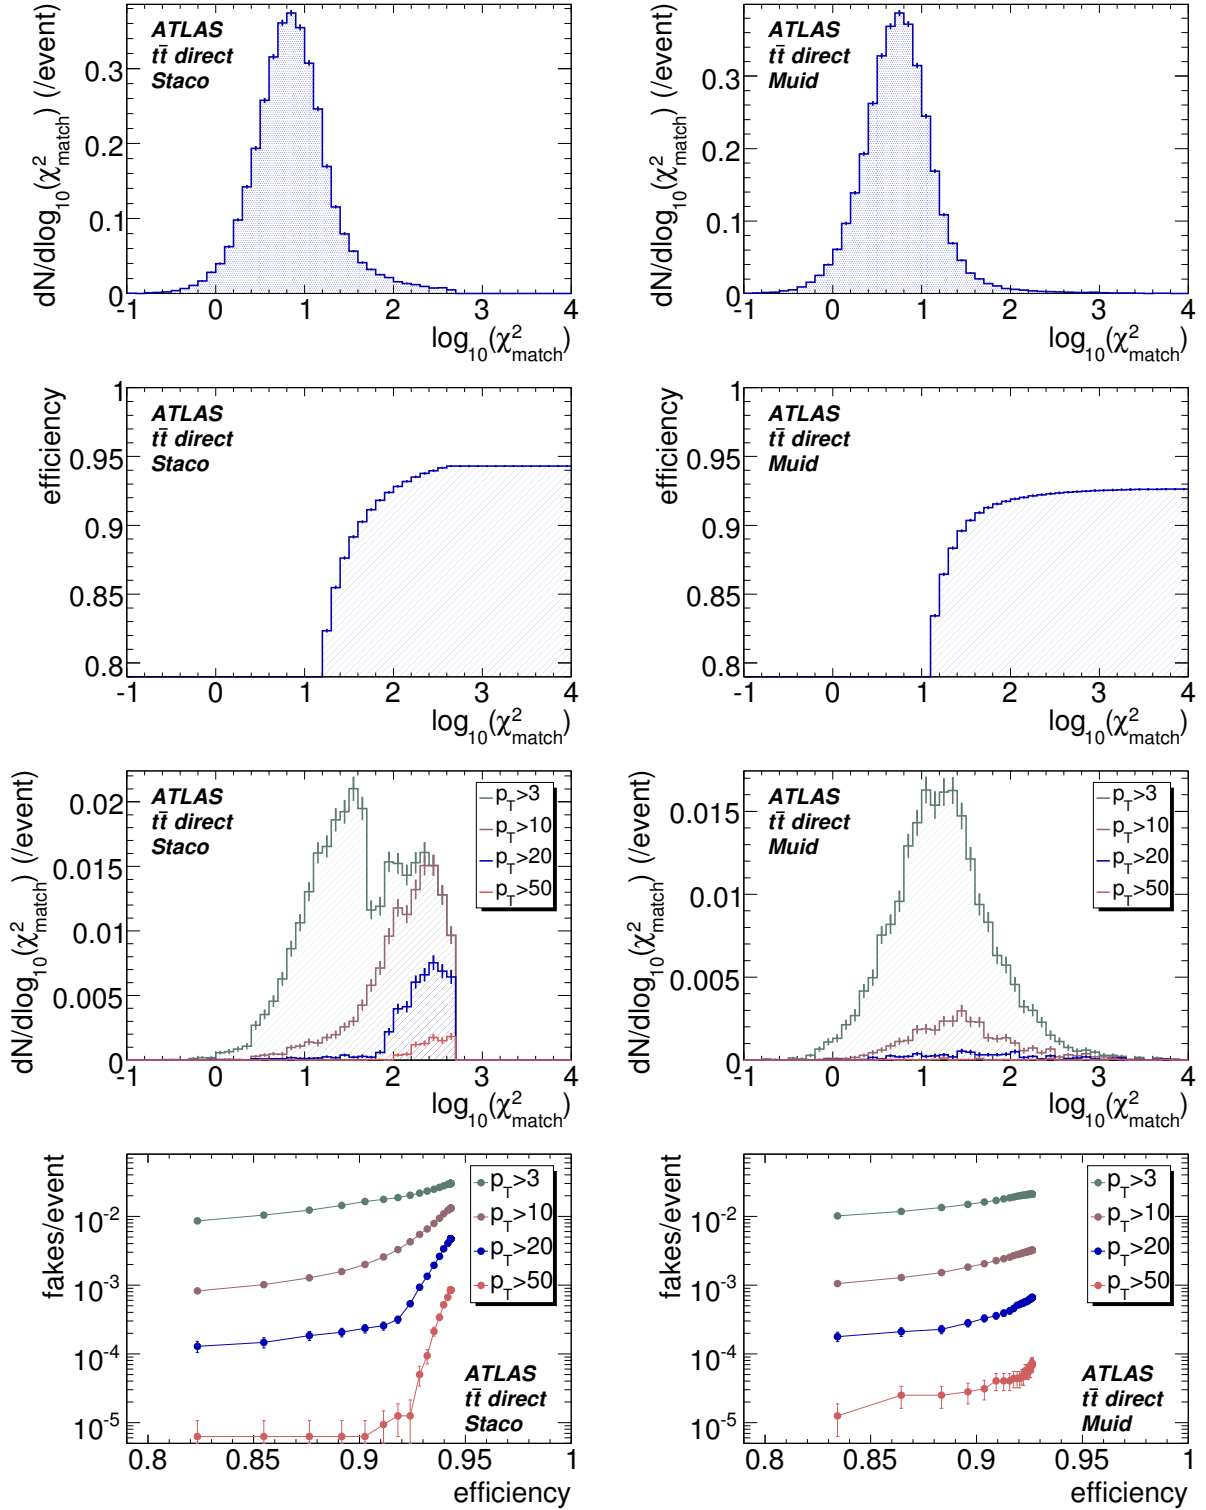

Figure 10: Distributions of  $\chi^2_{\text{match}}$  for direct muons (top) and fakes (third from top). The fakes are shown for a variety of  $p_T$  thresholds. The second row shows the efficiency as function of  $\chi^2_{\text{match}}$  when muons above that value are rejected. The bottom row shows the fake rates as a function of efficiency as that threshold is varied. All are shown for both Staco (left) and Muid (right). The sharp drops in the Staco  $\chi^2_{\text{match}}$  distribution come from cuts on that quantity made during reconstruction, i.e. before filling the output muon collection.

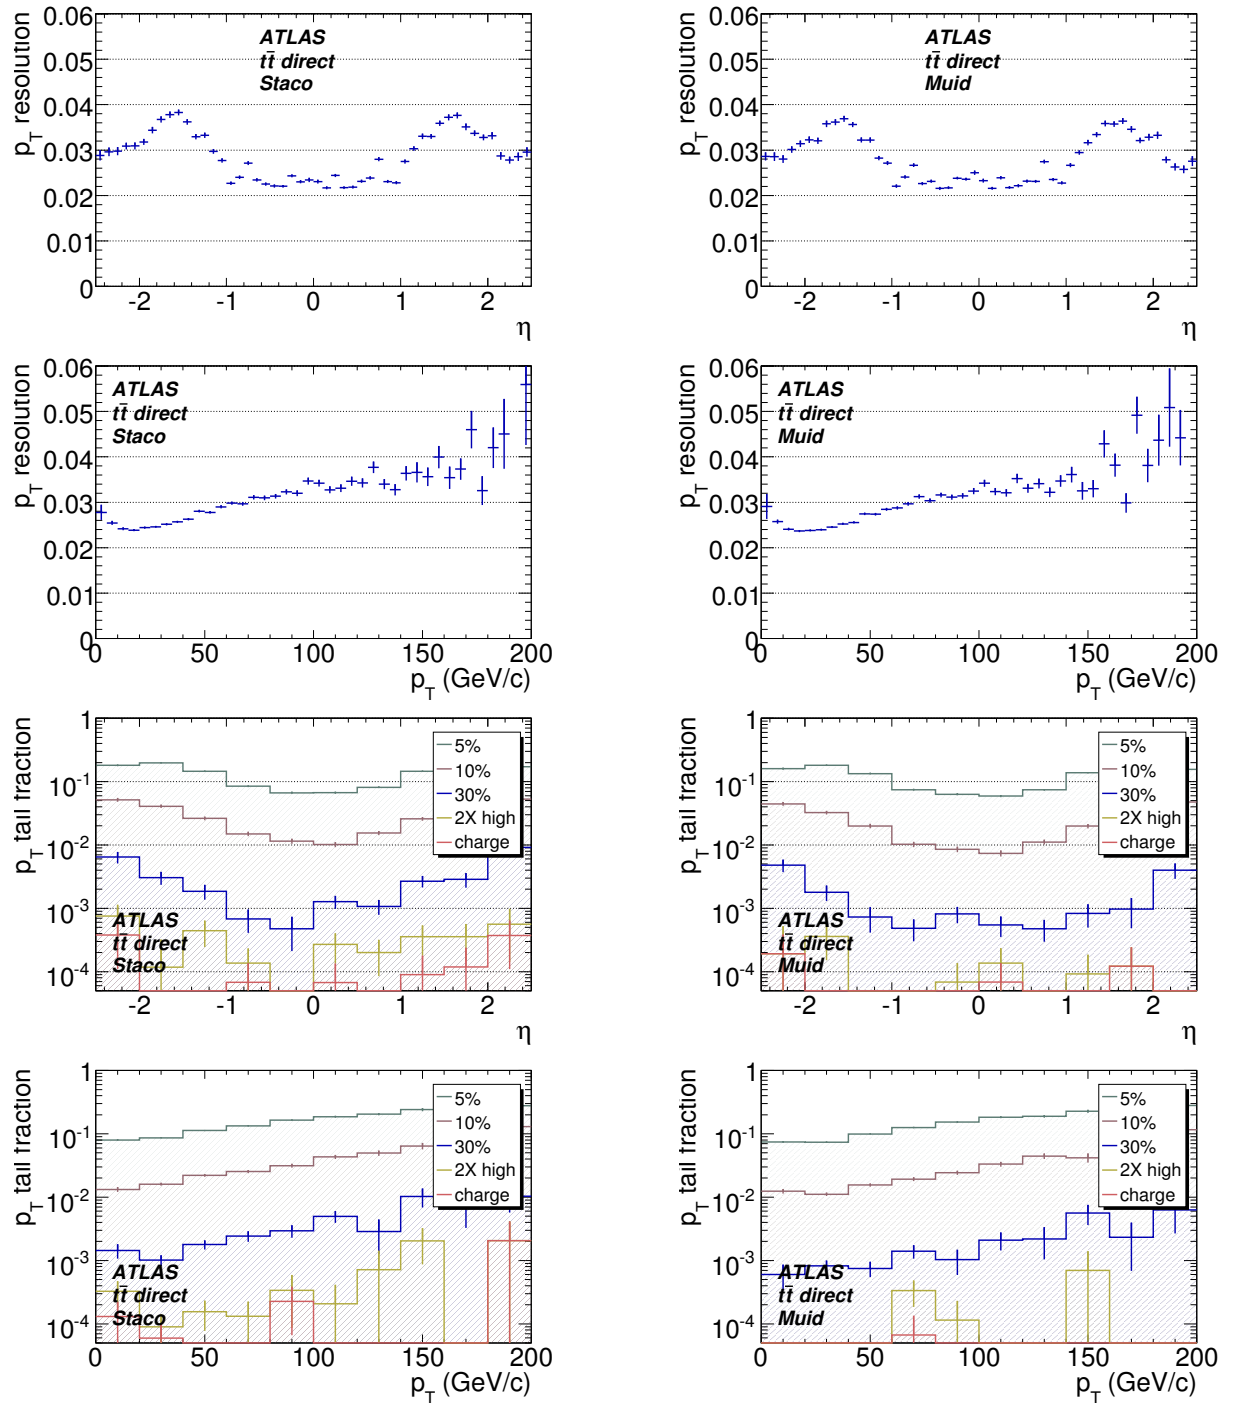

Figure 11: Combined muon fractional momentum resolution ( $\Delta p_T/p_T$ ) as function of  $\eta$  (top) and  $p_T$  (2nd row) and tails in that parameter also as functions of  $\eta$  (3rd row) and  $p_T$  (bottom). All are for both Staco (left) and Muid (right). The tail is the fraction of reconstructed muons with magnitude of  $\Delta p_T/p_T$  outside a range and is shown for a wide range of values. The last tail curve (red, “charge”) includes only muons reconstructed with the wrong charge sign. The 4th tail curve (yellow, “2X high”) includes these and those with momentum magnitude more than two times the true value.

## 8 Tagged muon performance

### 8.1 Efficiencies and fake rates

ATLAS runs two tagging algorithms but only MuGirl attempts to find all muons. MuTag is run in a manner to complement Staco and the performance of the combination of these two is reported in the following section.

Figure 12 shows the MuGirl direct muon efficiency and fake rates as a function of  $\eta$  in  $t\bar{t}$  at low and high luminosity. Table 4 gives the MuGirl integrated efficiencies and fake rates for all our samples.

Comparing with the combined muon results (figure 9 and table 3), we see that MuGirl has lower efficiency and a substantially higher fake rate. We also observe that its performance degrades faster when luminosity background is added. MuGirl has higher efficiency than Muid for reconstructing the low- $p_T$  muons in the  $J/\psi$  sample.

### 8.2 Resolution

Figure 13 shows the MuGirl  $p_T$  resolution and tail as functions of  $\eta$  and  $p_T$ . MuGirl does not refit the tracks and so this is just the resolution of the inner detector. Comparing with the standalone (figure 7) and combined (figure 11), we see how the standalone and inner measurements complement one another to give high precision over the full  $\eta$  and  $p_T$  range of the  $t\bar{t}$  sample.

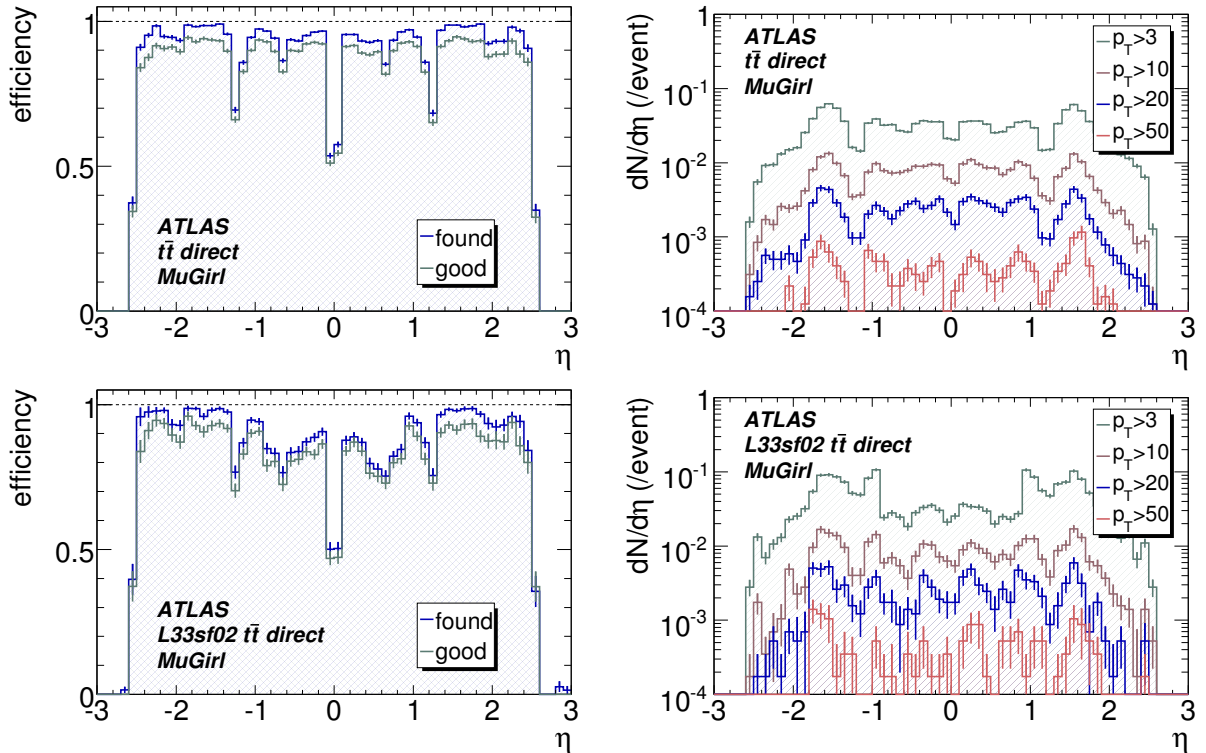

Figure 12: MuGirl efficiency (left) and fake rates (right) as a function of true  $\eta$  in  $t\bar{t}$  at low (top) and high (bottom) luminosity. In each efficiency plot, the upper curve (blue) is the efficiency to find the muon while the lower curve (green) additionally requires a good match ( $D_{eva} < 4.5$ ) between reconstructed and true track parameters. The efficiency is for muons with true  $p_T > 10$  GeV/c. Fake rates are presented for a variety of  $p_T$  thresholds.

Sample	Efficiency		Fakes/(1000 events) above $p_T$ limit (GeV/c)			
	found	good	3	10	20	50
$t\bar{t}$ direct	0.911 (1)	0.870 (1)	105.0 (6)	23.7 (3)	7.3 (2)	1.14 (6)
$t\bar{t}$ indirect	0.899 (2)	0.748 (3)				
hi- $\mathcal{L}$ $t\bar{t}$ direct	0.866 (3)	0.825 (3)	154 (2)	26.1 (7)	7.6 (4)	1.2 (1)
$Z'$ direct	0.802 (3)	0.781 (3)	57 (2)	26 (2)	15 (1)	5.9 (8)
$J/\psi$ $c$ -quark	0.888 (4)	0.839 (5)	4.4 (3)	0.11 (5)	0 (0)	0 (0)

Table 4: MuGirl efficiencies and fake rates. The samples and algorithms are described in the text. Efficiencies are presented both for all found muons and for those with a good truth match. Both are calculated for truth muons with  $|\eta| < 2.5$  and  $p_T > 10$  GeV/c. The fake rates are presented for a variety of  $p_T$  thresholds.

Figure 13: MuGirl fractional momentum resolution ( $\Delta p_T/p_T$ ) as a function of  $\eta$  (top) and  $p_T$  (bottom). Both the distribution (left) and tails (right) are shown for each. The tail is the fraction of reconstructed muons with magnitude of residual greater than a threshold and results are shown for a variety of thresholds. The last tail curve (red, “charge”) includes only muons reconstructed with the wrong charge sign. The 4th tail curve (yellow, “2X high”) includes these and those with momentum magnitude more than two times the true value.

## 9 Merged muon performance

Finally we consider merging the muons produced by different algorithms. There are many possible combinations but we restrict ourselves to two simple but important cases: merging the combined and tagged muons separately within each collection (family), i.e. we examine Staco+MuTag and Muid+MuGirl.

Figure 14 shows the corresponding direct muon efficiencies and fake rates in  $t\bar{t}$  at low and high luminosity. The integrated efficiencies and fake rates for all samples are summarized in table 5. One of the primary goals of the tagging algorithms is to reconstruct low- $p_T$  muons which the standalone reconstruction misses because the energy loss in the calorimeter leaves these muons with very little momentum in the muon spectrometer. Figure 15 shows the low- $p_T$  efficiency as function of  $p_T$  for combined alone and combined supplemented with tagged for each of the collections.

Sample	Efficiency		Fakes/(1000 events) above $p_T$ limit (GeV/c)			
	found	good	3	10	20	50
Staco+MuTag						
$t\bar{t}$ direct	0.948 (1)	0.879 (1)	49.0 (4)	14.4 (2)	4.8 (1)	0.86 (5)
$t\bar{t}$ indirect	0.940 (1)	0.772 (2)				
hi- $\mathcal{L}$ $t\bar{t}$ direct	0.946 (2)	0.876 (3)	58 (1)	16.6 (5)	6.1 (3)	1.1 (1)
$Z'$ direct	0.931 (2)	0.844 (3)	32 (2)	14 (1)	7.1 (9)	4.2 (7)
$J/\psi$	0.954 (3)	0.883 (4)	2.5 (3)	0.3 (1)	0.11 (5)	0 (0)
Muid+MuGirl						
$t\bar{t}$ direct	0.955 (1)	0.903 (1)	113.1 (6)	24.9 (3)	7.6 (2)	1.17 (6)
$t\bar{t}$ indirect	0.946 (1)	0.790 (2)				
hi- $\mathcal{L}$ $t\bar{t}$ direct	0.952 (2)	0.898 (2)	181 (2)	29.8 (7)	8.4 (4)	1.2 (2)
$Z'$ direct	0.929 (2)	0.866 (3)	61 (3)	28 (2)	16 (1)	7.5 (9)
$J/\psi$	0.946 (3)	0.885 (4)	4.7 (4)	0.11 (5)	0 (0)	0 (0)

Table 5: Staco+MuTag and Muid+MuGirl efficiencies and fake rates. The samples and algorithms are described in the text. Efficiencies are presented both for all found muons and for those with a good truth match. Both are calculated for truth muons with  $|\eta| < 2.5$  and  $p_T > 10$  GeV/c. The fake rates are presented for a variety of  $p_T$  thresholds.

The merge provides only a small improvement in the Staco efficiencies and a substantial increase in the fake rates (factor of about four). For Muid, the efficiency gains are more substantial: the indirect  $t\bar{t}$  efficiency increases by 6% and the  $J/\psi$  by 15%. The fake rates are increased by a factor of five, i.e. slightly above the MuGirl rates. Overall, the Muid+MuGirl performance is very similar to that of Staco+MuTag. In both cases, we see the tagging algorithms do provide the significant efficiency improvement for  $p_T$  below 10 GeV/c.

## 10 Summary

### 10.1 Present status

The starting point for most ATLAS analyses are the combined muons, i.e. those muons constructed by combining tracks found independently in the inner detector and muon spectrometer. Their momentum resolution and fake rate (with appropriate quality cuts) are both significantly better than muons reconstructed from either the spectrometer alone or muons identified by tagging inner detector tracks. In  $t\bar{t}$

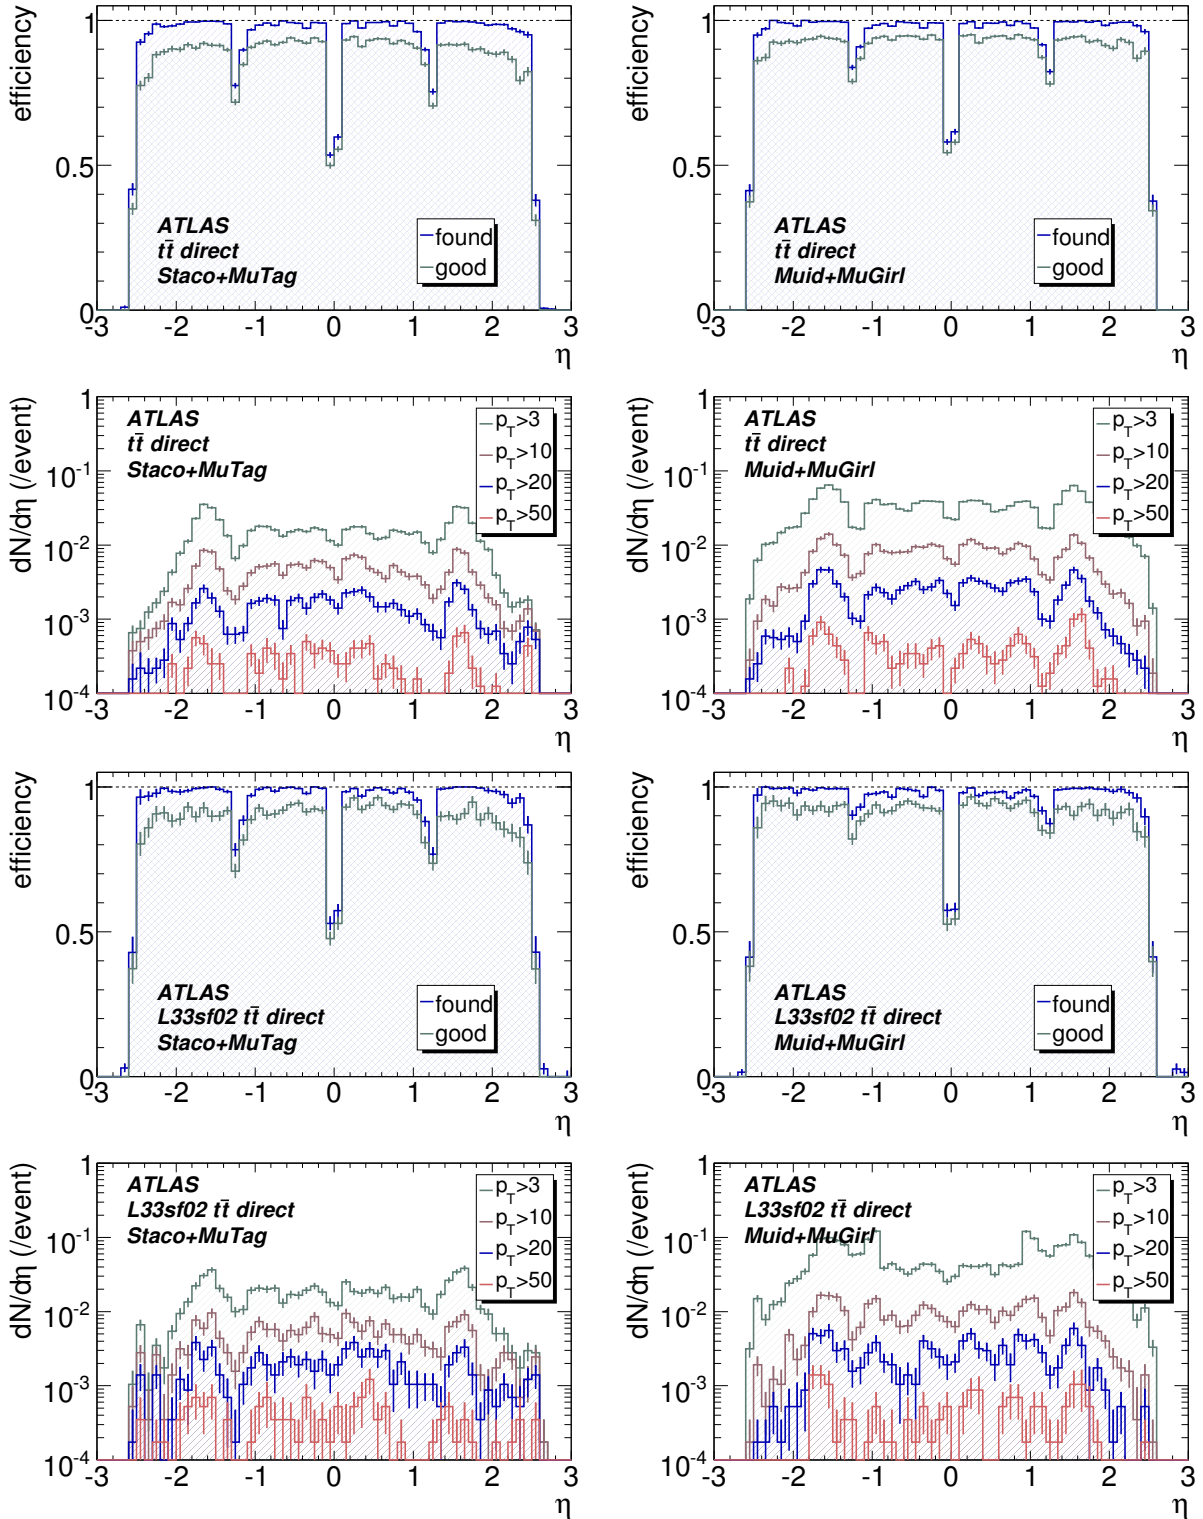

Figure 14: Muon efficiencies and fake rates for Staco+MuTag (left) and Muid+MuGirl (right) as functions of true  $\eta$  in  $t\bar{t}$  at low (top) and high (bottom) luminosity. In each efficiency plot, the upper curve (blue) is the efficiency to find the muon while the lower curve (green) additionally requires a good match ( $D_{eva} < 4.5$ ) between reconstructed and true track parameters. The muon selection is described in the text. The efficiency is calculated for true  $p_T > 10$  GeV/c. The fake rates are presented for a variety of  $p_T$  thresholds.

Figure 15: Low- $p_T$  muon finding efficiencies for combined muons alone and combined plus tagged for the Staco (left) and Muid (right) collections. Results are shown for the  $t\bar{t}$  indirect selection. The other samples show similar behavior but have much poorer statistics at low- $p_T$ . The efficiency is calculated for muons with  $|\eta| < 2.5$ .

events, for muons from  $W \rightarrow \mu\nu$  with  $|\eta| < 2.5$ , the Staco combined muon efficiency is 94% with most of the loss coming from regions of the spectrometer where the detector coverage is thin. The efficiency falls by a few percent when the muon transverse momentum reaches the TeV scale where it is much more likely that a muon will radiate a substantial fraction of its energy. The  $t\bar{t}$  rate for fakes is a few per thousand events for  $p_T > 20$  GeV/c and this can be reduced by an order of magnitude (with a 2% loss in efficiency) by cutting on the muon quality ( $\chi^2_{match}$ ). The performance of the Muid algorithm is only slightly worse for  $t\bar{t}$  but it is significantly less robust, losing additional efficiency at low- $p_T$  and high- $p_T$  and when luminosity background is added.

The combined muons can be supplemented with the standalone muons to extend the  $\eta$  coverage to 2.7 and to recover the percent or so efficiency loss in combination. We do not report on this merge but it is clear from the standalone results that the fake rates will increase significantly especially when luminosity background is present. In the case of Moore, the fake rate is likely intolerable.

We find that merging with MuTag provides only slight improvement to the Staco efficiency with a significant increase in fakes. This may reflect the success of Staco more than deficiencies in MuTag. MuGirl is able to improve the Muid efficiency, so that the merge Muid+MuGirl has performance similar to Staco or Staco+MuTag. By itself, the MuGirl efficiency is somewhat less than that of Staco especially for high- $p_T$  muons, and the fake rates are substantially higher.

## 10.2 Future

The results presented here reflect the status of the ATLAS software used to reconstruct (Monte Carlo) production data in 2007. Work continues both to improve the algorithms described here and to add new ones. The high-luminosity fake rate for Moore is being addressed by introducing timing cuts and investigating alternative approaches to the pattern recognition. The latter also has the goal of reducing the number of false hit assignments. Combined muons with large  $\chi^2_{match}$  are being studied to see if a second stage of pattern recognition can reduce the efficiency loss or resolution tails. Efforts are underway to improve or replace the existing spectrometer-tagging algorithms; in particular, code is already in place to extrapolate to additional stations enabling recovery of much of the standalone/combined efficiency loss near  $|\eta| = 1.2$ . Two calorimeter-tagging algorithms have been developed and offer the possibility of recovering much of the efficiency loss near  $\eta = 0$ . Improvements in modularity will make it possible to mix components from the different algorithms, (e.g. to use Muid to combine Muonboy muons) and

enable algorithms to share common tools such as those being developed to calculate energy loss, refit muon tracks, and repair muons with poor fit quality.

# Muons in the Calorimeters: Energy Loss Corrections and Muon Tagging

## Abstract

The muon spectrometer is the outermost subdetector of the ATLAS detector, beginning after a muon has traversed 100 radiation lengths of material. Muon momentum measurements must be corrected for energy loss in the calorimeters and the inert material before the muons reach the muon spectrometer. Energy lost in the calorimeters can be estimated from parameterizations or from a measurement of the energy deposited in the calorimeters. In addition, the muon energy loss measurement can be used to tag muons not reconstructed in the muon spectrometer due to inefficiencies, spectrometer acceptance or their low momenta.

In this document we discuss different algorithms developed to perform the energy loss correction in the muon reconstruction. We compare the performance of the muon reconstruction algorithms before and after the energy loss correction is applied. In addition, we describe the muon tagging algorithms, based on measurements obtained in the calorimeters, and contrast their performance in different simulated data samples.

## 1 Introduction

Muons traverse the inner detector and the calorimeters in the ATLAS experiment before reaching the muon spectrometer. The material thickness traversed by the muons before reaching the muon spectrometer is over 100 radiation lengths ( $X_0$ ) (see Figure 1). By passing through this material, muons undergo electromagnetic interactions which result in a partial loss of their energy. As over 80% of this material is in the instrumented areas of the calorimeters, the energy loss can be measured. Understanding how this energy loss happens, its magnitude and how to measure it is essential to obtain the best performance in muon reconstruction and identification.

In this document we discuss the aspects of muon reconstruction and identification that make use of all available energy loss information in the ATLAS software. The Muonboy [1] and Muid [2] algorithms for muon reconstruction take into account internally the calorimeter material effects for tracks already found in the muon spectrometer. Algorithms that calculate the energy loss and transport the track anywhere in the detector are also available. The detailed computation of this correction is the main focus of Sections 2 and 3, while Section 4 is devoted to the use of the energy loss information for muon identification. This note gives an overview of the current algorithms and techniques which will be used for the reconstruction of the first data.

## 2 Algorithmic Treatment of Material Effects

When a muon traverses the detector material, it undergoes successive deflections and a loss of energy. The total angular deflection is an accumulation of many small angle deflections, referred to as multiple (Coulomb) scattering; and it is well approximated by a gaussian distribution that is centered at a zero mean value. The expected root mean square of the projected scattering angle can be described by the formula of Highland [4]:

$$\sigma_{ms}^{proj} = \frac{13.6 \text{ MeV}}{\beta c p} \sqrt{t} [1 + 0.038 \ln t], \quad (1)$$

Figure 1: Material distribution before the muon spectrometer in ATLAS as a function of  $\eta$  [3]. The material is expressed in radiation lengths ( $X_0$ ).

where  $t$  is the thickness of the traversed material in units of the radiation length  $X_0$ . The energy loss, on the other hand, is non-gaussian. Throughout this document, we will study the energy loss of muons going through the ATLAS detector in detail. The discussion of multiple scattering, however, will be limited to this section, because it is simpler and it will be based on the Highland formula shown above. The thickness in the formula above is calculated from the geometry description for all algorithms. However, there are small differences in how the multiple scattering information is used in the track fitting. These differences are explained below, as the different track fitting strategies are discussed.

In ATLAS track reconstruction applications, two main track fitting strategies are deployed: the classical least squares method and the progressive method that corresponds to the Kalman filter formalism [5].

**The least squares fit:** In the global fitting technique, most material effects are directly integrated into the  $\chi^2$  function (the energy loss may or may not be fitted). This is done by introducing the deflection angles and, possibly, energy losses as additional parameters to the fit.

The contribution of the fitted scattering angles to the  $\chi^2$  function has to be regulated by the expected range of the scattering process in the traversed material. Scattering effects are applied to the muon on two surfaces along its trajectory, because the scattering effects from material bulk can be accurately described by two scattering centers. The Muonboy algorithm iterates its calculation of the muon trajectory in a complex geometry with many scattering centers. The number of scattering centers is reduced to two after the iteration. The iteration allows for a calculation of the material traversed after the trajectory has been modified to account for the energy loss. On the other hand, the Muid algorithm and the ATLAS tracking global- $\chi^2$  fitter [6] currently use a map of the material from the Monte Carlo on two surfaces. The  $\eta$  coordinate of the track on these two surfaces is then used to calculate the amount of material traversed by the muon.

The least squares fit with the calorimeter energy loss as a fitted variable can only be performed in a combined fit including measurements of both the muon spectrometer segments and the inner detector hits. If no inner detector hits exist, the treatment of the energy loss effects is fundamentally equivalent for both a least-squares-inspired algorithm and a Kalman-filter-inspired algorithm.

To minimize the number of degrees of freedom in the least-squares fit, the number of fitted variables must be minimized. In particular, one energy loss variable in a track fit is preferable. This does not mean that the trajectory cannot be affected smoothly by the energy loss, because an extended set of material

layers can be calculated using a detailed detector description as in Figure 2 and the fitted energy loss

Figure 2: Left: 3-D view of the tracking geometry up to the muon spectrometer. Right: Example set of energy loss update layers (shown as additional surfaces with respect to the figure on the left; update positions shown as squares) created during the extrapolation of a track (black line) through the calorimeter.

distributed proportionally among these layers. This is done for the purpose of transporting the track through the calorimeters inside the Muonboy algorithm. An alternative approach is currently taken in the Muid and ATLAS tracking global- $\chi^2$  fitter. These algorithms apply the energy loss to the track on one surface inside the calorimeters hence approximate the rate of change of curvature within the calorimeter volume (i.e.: they assume the momentum of the muon changes only at one place along its trajectory).

The effect of this simplification on the muon combined reconstruction is expected to be small, because the energy loss only affects the trajectory of the track if the track is bending. However, the area where most of the energy loss happens (the calorimeter) has a small magnetic field. A quantitative estimate of the effect of the simplification can be obtained by comparing the multiple scattering effects on the track and the bending that the track undergoes from its entrance in the calorimeters to its exit. The bending is shown in Figure 3. Equation 1 indicates that a 10 GeV (100 GeV) muon going through the calorimeters scatters following a gaussian distribution with RMS  $\approx 14$ -20 (1.4-2) milliradians (with  $X_0 = 100$ -200 from Figure 1). Figure 3 shows that the deviation of the track due to the magnetic field is comparable to the deviation expected from multiple scattering at least in the  $\phi$  direction. Algorithms that use one surface to apply the energy loss correction approximate the mean trajectory inside the calorimeter with a systematic offset that increases with depth to a maximum value at the calorimeter centre. The magnitude of this offset is proportional to the magnetic bending scaled by the fraction of energy loss to muon energy. It thus remains small with respect to the uncertainties caused by Coulomb scattering.

**Progressive fitting techniques:** In progressive fitting techniques, the particle-detector interaction is part of the transport process of the track to the next surface where a hit may exist (measurement surface). The transported track can then be compared (and updated) with the measurement obtained on the next measurement surface. In this transport process magnetic field and material effects (multiple scattering and energy loss) are applied to the parameterization of the track. Multiple scattering is applied

Figure 3: Calculated difference between the calorimeter entrance and exit coordinates ( $\Delta\eta$ , left, and  $\Delta\phi$ , right) for 10 GeV (solid squares) and 100 GeV muons as a function of  $\eta_0$  of the muon at the interaction point. The lack of mirror symmetry is due to the combined effect of the return flux of the solenoid (unidirectional) and the toroidal magnetic field (symmetric around the  $z$  axis).

by increasing the uncertainties of the angular direction variables, while energy loss effects are taken into account in two ways. A mean energy loss is applied to the track parameterization, and then an uncertainty is added to the corresponding covariance matrix term to account for the stochastic behavior of the energy loss. The resulting increased covariance terms degrade the track prediction for the subsequent measurement surface.

Progressive fitting tools rely, therefore, on a precise description of the detector material and magnetic field. An example is shown in Figure 2. The illustration on the right of Figure 2 shows material layers that are calculated dynamically during the extrapolation process into the calorimeter active volumes.

In ATLAS, the stand-alone muon reconstruction algorithms (MOORE [7] and Muonboy) use exclusively the least-squares formalism to fit tracks in the muon spectrometer. On the other hand, the inner detector reconstruction uses by default the progressive fitting techniques. In combined muon reconstruction, when the hits in the inner detector are used in combination with the muon spectrometer, the Muonboy-based algorithm (STACO) combines tracks reconstructed in the inner detector and muon spectrometer independently, therefore being a mixture of the tracking fit and the least-squares fit carried out by Muonboy. On the other hand, the MOORE-based algorithm (Muid) performs a least-squares fit in both subsystems.

### 3 Corrections for the Energy Loss from the Beam Pipe to the Muon Spectrometer

In this section we describe how the energy loss is calculated from GEANT4 [8] based parameterizations and/or measurements of the energy loss by the calorimeters. Muon isolation is also discussed in this context. Finally, the energy loss corrections are validated as part of the muon reconstruction algorithms.

#### 3.1 Parameterizations of the Energy Loss

Relativistic muons going through matter lose energy mostly through electromagnetic processes: ionization,  $e^+e^-$  pair-production, and bremsstrahlung. Ionization energy loss dominates for muons of momenta  $\lesssim 100$  GeV. Bremsstrahlung and  $e^+e^-$  pair-production energy losses are often jointly referred to as radiative energy losses. Higher energy muons lose energy mostly through radiative energy losses.

However, when passing through materials made of high-Z elements the radiative effects can be already significant for muons of energies  $\approx 10$  GeV [9].

Ionization energy losses have been studied in detail, and an expression for the mean energy loss per unit length as a function of muon momentum and material type exists in the form of the Bethe-Bloch equation [10]. Other closed-form formulae exist to describe other properties of the ionization energy loss. Bremsstrahlung energy losses can be well parameterized using the Bethe-Heitler equation. However, there is no closed-form formula that accounts for all energy losses. Nevertheless, theoretical calculations for the cross-sections of all these energy loss processes do exist. With these closed-form cross-sections, simulation software such as GEANT4 can be used to calculate the energy loss distribution for muons going through a specific material or set of materials.

The fluctuations of the ionization energy loss of muons in thin layers of material are characterized by a Landau distribution. Here “thin” refers to any amount of material where the muon loses a small percentage of its energy. Once radiative effects become the main contribution to the energy loss, the shape of the distribution changes slowly into a distribution with a larger tail. Fits to a Landau distribution still characterize the distribution fairly well, with a small bias that pushes the most probable value of the fitted distribution to values higher than the most probable energy loss [11]. These features are shown for the energy loss distributions of muons going from the beam-pipe to the exit of the calorimeters in Figure 4.

Figure 4: Distribution of the energy loss of muons passing through the calorimeters ( $|\eta| < 0.15$ ) as obtained for 10 GeV muons (left) and 1 TeV muons (right) fitted to Landau distributions (solid line).

As can be seen in Figure 4 the Landau distribution is highly asymmetrical with a long tail towards higher energy loss. For track fitting, where most of the common fitters require gaussian process noise, this has a non-trivial consequence: in general, a gaussian approximation has to be performed for the inclusion of material effects in the track fitting [12].

In order to express muon spectrometer tracks at the perigee, the total energy loss in the path can be parameterized and applied to the track at some specific position inside the calorimeters. As the detector is approximately symmetric in  $\phi$ , parameterizations need only be done as a function of muon momentum and  $\eta$ . The  $\eta$ -dependence is included by performing the momentum parameterizations in different  $\eta$  bins of width 0.1 throughout the muon spectrometer acceptance ( $|\eta| < 2.7$ ). The dependence of the most probable value of the energy loss,  $E_{\text{loss}}^{\text{mpv}}$ , as a function of the muon momentum,  $p_\mu$ , is well described by

$$E_{\text{loss}}^{\text{mpv}}(p_\mu) = a_0^{\text{mpv}} + a_1^{\text{mpv}} \ln p_\mu + a_2^{\text{mpv}} p_\mu, \quad (2)$$

where  $a_0^{\text{mpv}}$  describes the minimum ionizing part,  $a_1^{\text{mpv}}$  describes the relativistic rise, and  $a_2^{\text{mpv}}$  describes the radiative effects. The width parameter,  $\sigma_{\text{loss}}$ , of the energy loss distribution is well fitted by a linear function  $\sigma_{\text{loss}}(p_\mu) = a_0^\sigma + a_1^\sigma p_\mu$ . Some of these fits are illustrated in Figure 5. This parameterization is

Figure 5: Parameterization of the  $E_{\text{loss}}^{\text{mpv}}$  (left) and  $\sigma_{\text{loss}}$  (right) of the Landau distribution as a function of muon momentum for different  $\eta$  regions. One sees a good agreement between the GEANT4 values and the parameterization.

used as part of the Muid algorithm for combined muon reconstruction [3].

An alternative approach exists in the ATLAS tracking. In this approach, the energy loss is parameterized in each calorimeter or even calorimeter layer. The parameterization inside the calorimeters is applied to the muon track using the detailed geometry described in Section 2.

The most probable value and width parameter of the Landau distribution are not affected by radiative energy losses in thin materials in the muon energy range of interest ( $\sim 5$  GeV to a few TeV). This justifies treating energy loss in non-instrumented material, such as support structures, up to the entrance of the muon spectrometer as if it was caused by ionization processes only. The most probable value of the distribution of energy loss by ionization can be calculated if the distribution of material is known [13]. Since material properties are known in each of the volumes in the geometry description used, it is easy to apply this correction to tracks being transported through this geometry.

For the instrumented regions of the calorimeters, a parameterization that accounts for the large radiative energy losses is required. To provide a parameterization that is correct for the full  $\eta$  range and for track transport inside the calorimeters, a study of energy loss as a function of the traversed calorimeter thickness,  $x$ , was performed. Two parameters that characterize fully the pdf of the energy loss for muons were fitted satisfactorily using several fixed momentum samples as

$$E_{\text{loss}}^{\text{mpv},\sigma}(x, p_\mu) = b_0^{\text{mpv},\sigma}(p_\mu)x + b_1^{\text{mpv},\sigma}(p_\mu)x \ln x. \quad (3)$$

The momentum dependence of the  $b_i(p_\mu)$  parameters was found to follow the same form as in Equation 2. Fits for some of the absorber materials are shown in Figure 6. These parameterizations have been validated over the  $\eta$  range from -3 to 3. A direct comparison of the most probable energy loss in GEANT4 simulation and in the geometry of the ATLAS tracking algorithms is shown in Figure 7 for muons propagating from the beam-pipe to the exit of the electromagnetic calorimeters and to the exit of the hadronic calorimeters.

### 3.2 Measurements of the Energy Deposited in the Calorimeters

In this section the measurement of the muon energy loss in the calorimeters is discussed. Understanding this measurement is important because it allows for an improvement in the energy loss determination. This section provides a basic description of the ATLAS calorimeters and their measurements which is important for understanding the topics discussed in Sections 3.3, 3.4 and 4.

Figure 6: Left: Fit to the most probable value and width of the Landau distribution as a function of thickness of iron for muons of momentum 200 GeV. The fitting function has the form  $b_0x + b_1x \ln x$ . Right: Fit to the parameters  $b_0$  and  $b_1$  for the most probable value of the energy loss in lead as a function of muon momentum.

Figure 7: Most probable value of the energy loss as parameterized in the geometry of the ATLAS tracking (points) and in GEANT4 for muons of momentum 10 GeV (left) and 1 TeV (right) as a function of pseudorapidity. The solid line and points correspond to the energy loss of muons propagating from the beam pipe to the exit of the hadronic calorimeters. The filled histogram and hollow points correspond to the energy loss of muons propagating from the beam pipe to the entrance of the hadronic calorimeters.

### 3.2.1 Muons in the Liquid Argon Calorimeters

The electromagnetic calorimeter is a lead-liquid argon sampling calorimeter with accordion shaped absorbers and electrodes, covering the  $|\eta|$  range up to 3.2.

The hadronic end-cap calorimeter, also based on liquid argon technology, covers the  $|\eta|$  range from 1.5 to 3.2. The absorbers are made of parallel plates of copper. The total thickness of the hadronic end-cap calorimeters is 10 interaction lengths ( $\lambda_{\text{int}}$ ). The measurement of a muon signal in the hadronic end-cap is complicated because the noise levels are high compared to the muon signal itself [14].

The detailed geometrical description of the LAr calorimeters is presented in [15]. Only the aspects relevant for muon studies will be recalled. Both barrel and end-cap calorimeters possess up to three longitudinal samplings (called strip, middle and back). They are completed by a liquid argon presampler detector to estimate the energy lost in upstream material. The signal and noise distributions in two longitudinal calorimeter samples in the barrel of the electromagnetic calorimeter are shown in Figure 8

Figure 8: Distribution of the muon energy deposited in one electromagnetic calorimeter cell by 150 GeV muons, fitted to a Landau function convolved with a gaussian [16]. The gaussians on the left of each plot are the distributions of the noise. Left (right): energy deposit in a cell belonging to the first (middle) longitudinal sampling traversed by the muon. The energy is the sum of the energies of the (up to two) cells belonging to the muon cluster (see Section 4). The data were collected in the 2004 Combined Test Beam.

for 150 GeV muons. Further discussion of how these distributions were calculated from the combined test beam data can be found in Section 4. The signal can be separated from the noise, especially in the middle sampling. In addition, comparisons between GEANT4 simulation and test beam data show that, despite the high noise in the first sampling, the electromagnetic calorimeter can measure reliably the energy lost by muons traversing it.

### 3.2.2 Muons in the Tile Calorimeter

The Tile Calorimeter (TileCal) [17] is a plastic scintillator/steel sampling calorimeter, located in the region  $|\eta| < 1.7$ ; it is divided into three cylindrical sections, referred to as the barrel and extended barrels. It extends from an inner radius of 2.28 m to an outer radius of 4.25 m. Modules are segmented in  $\eta$  and in radial depth. In the direction perpendicular to the beam axis, the three radial segments span 1.5, 4.1 and 1.8  $\lambda_{\text{int}}$  in the barrel and 1.5, 2.6, 3.3  $\lambda_{\text{int}}$  in the extended barrels. The resulting typical cell dimensions are  $\Delta\eta \times \Delta\phi = 0.1 \times 0.1$  ( $0.2 \times 0.1$  in the outermost layer). This segmentation defines a quasi-projective tower structure.

The TileCal response to high-energy muons follows a Landau-type distribution with characteristically long tails at high energies caused by radiative processes and energetic  $\delta$ -rays. This response has been extensively studied in test beams with 180 GeV muons incident at projective angles. The peak values of the muon signals vary by more than a factor of two in projective geometry. An example of the muon signal, expressed in units of collected charge (pC), is shown in Figure 9, both for the whole tower and the last radial compartment. The signal is well separated from the noise, with a signal-to-noise ratio ( $S/N$ ) of  $\sim 44$  and  $\sim 18$  respectively. The muon response was shown to be uniform in  $\eta$  to within 1.9 % over all modules tested. The energy deposition spectrum observed in the TileCal test beams is within a few percent of the GEANT4 prediction.

Figure 9: Example of the isolated muon signal as measured at  $\eta = 0.35$  in the whole tower (left) and in the last radial compartment (right). The narrow peaks represent the corresponding noise. The energy is measured in units of collected charge. For a muon 1 pC corresponds to roughly 1 GeV, yielding a noise width of roughly 40 MeV for the last radial compartment. The data were collected in test beams in 2002 and 2003.

### 3.2.3 Measurements in Muon Algorithms

The previous sections discussed the reconstruction of energy depositions at the cell level. To provide estimates of muon energy loss and muon isolation, several cells need to be used along the muon trajectory. In addition, muon calibration factors such as the  $e/\mu$  ratio for minimum ionizing muons, need to be adjusted in order to find the correct energy deposition.

The classical method for measuring the energy loss of muons in calorimeters is based on the concept of a calorimeter tower, where the muon is assumed to follow a straight trajectory inside the calorimeters. A tower is defined as all calorimeter cells within a cone of fixed radius  $\Delta R = \sqrt{\Delta\eta^2 + \Delta\phi^2}$  centered around the muon trajectory. Motivated by this concept, but with a few muon-specific changes, the *Straight Line* method has been developed as part of the Muid algorithm for muon reconstruction. The Straight Line method calculates the coordinates of the relevant track at half the depth of the calorimeter by transporting the track to that position. These coordinates are used to calculate the calorimeter cells included in the measurement cone.

In the *Track Update* method, the muon trajectory through the calorimeters is extrapolated either from inner detector tracks or muon spectrometer tracks. Given this trajectory, the center of the measurement cone is recalculated at each calorimeter layer. Figure 10 shows a qualitative comparison between the Straight Line method and the Track Update method.

Figure 3 illustrated the quantitative differences in the muon trajectories from the two methods. The difference between the Straight Line and Track Update methods can be estimated by comparing the coordinates of the muon at the entrance of the electromagnetic calorimeters and at the exit of the hadronic calorimeters. The difference is clearly negligible for muons of  $p_T > 100$  GeV, even though it can be as big as a third of a hadronic cell width for 10 GeV muons.

In Figure 11, a comparison between the measured energy and the true energy loss is shown for the Track Update method. The average measured transverse energy loss in a cone of 0.2 around the muon trajectory for single muons of momentum 10, 100 and 300 GeV is shown as a function of  $\eta$ . In the same  $\eta$  bins the average true (as obtained from the GEANT4 full simulation) transverse energy lost between the interaction point and the entrance of the muon spectrometer is shown. The energy lost by the muons

Figure 10: Illustration of the Straight Line (left) and Track Update (right) concepts.

Figure 11: Comparison between the average measured transverse energy deposition (points) and true energy lost between the beam-pipe and the muon spectrometer (line) for muons of momentum 10 GeV (left), 100 GeV (center) and 300 GeV (right). The errors shown are statistical only.

is well estimated by measurements in the calorimeters. The region around  $|\eta| = 1$  corresponds to the crack in the TileCal. Consequently, the measurement underestimates the energy loss in that region.

### 3.3 Muon Isolation

The previous studies demonstrate the capabilities of the calorimeters to measure the energy lost by muons. However, these studies were all performed with single muon samples. In real physics samples, muons do not reach the calorimeters alone, but are often accompanied by additional particles that deposit energy in the cells around the muon trajectory and contaminate the muon energy loss measurement. Therefore, in order to determine the energy loss of such muons, isolation criteria must also be defined and optimized for maximum reliability in the energy measurement.

Isolation criteria can be divided into two categories: calorimeter-based and track-based. In muon reconstruction an area is defined around the muon trajectory with a minimum and maximum radius for the purpose of determining calorimeter isolation. This achieves the purpose of excluding the cells where

the muon deposits its energy. The size of this inner radius needs to be optimized to collect most of the energy lost by the muon but as little energy as possible from other particles. The energy deposited in the annulus between the inner radius and the outer radius, where the muon deposits little energy, is what the following paragraphs refer to as *isolation energy*. The optimal radii that define this annulus depend on the underlying event and luminosity. However, the muon shower is contained in a small cone of radius  $\approx 0.1$  [18]. Therefore, a choice of an inner radius much bigger than 0.1 does not achieve the purpose of collecting the energy deposited by the muon, and it adds noise to the measurement.

A study to determine possible isolation criteria [3] has been performed on a fully simulated  $t\bar{t}$  sample, where the  $W$  bosons were forced to decay into a muon and a neutrino. Muons produced by the semi-leptonic decays of  $b$  quarks tend to be non-isolated, while those from  $W$  decays tend to be isolated. In Figure 12 the distribution of the isolation energy for muons originating from quarks and  $W$ s is shown for the electromagnetic and hadronic calorimeters. The isolation energy inner and outer radii are 0.075 (0.15) and 0.15 (0.30) for the electromagnetic (hadronic) calorimeters, respectively. This reflects their different granularities. The electromagnetic isolation energy is a more powerful discriminant for the annuli radii chosen.

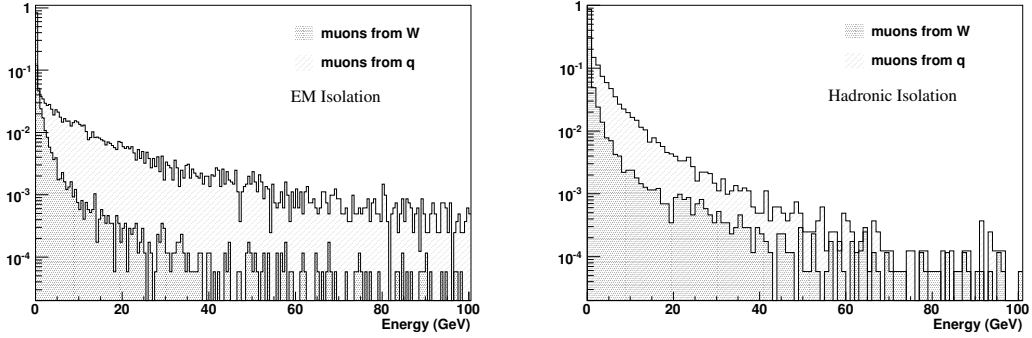

Figure 12: Distribution of the isolation energy in the electromagnetic ( $0.075 < \Delta R < 0.15$ ) (left) and hadronic calorimeters ( $0.15 < \Delta R < 0.30$ ) (right) in muons from a  $t\bar{t}$  sample without pile-up.

Based on this figure, for the purpose of the rest of the studies in this section, a cut of 2 GeV on electromagnetic isolation was used to discriminate isolated muons from non-isolated muons. An additional cut of 10 GeV in hadronic isolation was used, even though this cut does not help rejecting non-isolated muons in the vast majority of events. These cuts were relaxed slightly with increasing muon  $p_T$  to account for a possible slight increase of the transverse radius of the shower caused by muons in the calorimeters.

Tracking-based criteria can be used to determine isolation cuts independent of calorimeter-based criteria. If used together, they can help eliminate non-isolated muons belonging to highly-collimated jets that escape being identified by calorimeter-based criteria. In Figure 13 the number of inner detector tracks around the muon are plotted for muons from quarks and  $W$ s in the same samples used for Figure 12. These distributions were obtained for muons that passed the calorimeter-based isolation cuts mentioned above.

The production rate of low- $p_T$  non-isolated muons from  $b$ -quark decays is expected to be very significant. At the same time, a typical muon from a  $W$  or  $Z$  decay, will have a  $p_T$  of about 40 GeV. Thus, it is unlikely that low momentum muons will be isolated in a  $t\bar{t}$  sample. For this reason, all muons with a  $p_T$  of less than 15 GeV were automatically tagged as non-isolated and are excluded. In most cases, the muon originating from a  $W$  boson is not accompanied by other tracks in the inner detector. In fact, the only track found in the track isolation cone is, essentially, the muon itself as reconstructed in the inner detector. In contrast, several inner detector tracks can be found close to muons originating from quarks. For an isolation cone of  $\Delta R=0.2$ , the most probable value is three tracks, including the muon itself, but it

Figure 13: Distribution of the number of inner detector tracks (including the muon track) with  $\Delta R < 0.2$  around the muon spectrometer track, after the calorimeter isolation and  $p_T$  threshold cuts are applied to muons in a  $t\bar{t}$  sample.

can be much larger. A cut on tracking isolation has been applied that complements the cut on calorimeter isolation. This cut constrains an isolated muon track to be accompanied by at most one extra track inside the tracking isolation cone. Using the criteria described above (electromagnetic and hadronic calorimeter isolation, track isolation and  $p_T^\mu > 15$  GeV) approximately 0.2% of the muons originating from  $b$  quarks have an energy loss overestimated by more than 6 GeV. On the other hand, 80% of the muons originating from  $W$ s are tagged as isolated.

All the cuts mentioned above are used by default as isolation criteria in the Muid muon reconstruction algorithm, to establish the contamination of the calorimeter measurement. If the cuts were not chosen tightly enough, non-isolated muons would exhibit an artificial increase in energy loss. If this measurement was then used in muon reconstruction, the reconstructed momentum at the interaction vertex would be artificially increased. This could significantly deteriorate the momentum measurement. A calorimeter measurement of the energy loss will then only make sense if the muon is tagged as isolated. These cuts were considered conservative enough that they could be used by default without inducing biases in the momentum reconstruction [3]. These cuts have not been studied with pile-up or in other samples with an important source of non-isolated muons, like high- $p_T$ ,  $b\bar{b}$  samples. Studies of this type are important in order to set conservative isolation cuts as default for muon reconstruction involving calorimeter measurements.

In addition, it is worth discussing the relationship between muon isolation in reconstruction and muon isolation in physics analyses. While both concepts represent an attempt to determine whether a muon is inside a jet, analysis cuts are also decided on the basis of criteria such as efficiency or fake rate that are not necessarily important for the momentum reconstruction. It is, however, important to emphasize that the optimization of the cuts on reconstruction isolation for specific analyses is possible. It requires, nevertheless, a refitting of the track with analysis-specific cuts; and it should, therefore, only be attempted when the recovery of the Landau energy loss tails is crucial for the analysis and the standard treatment is not adequate.

For muon tagging, however, isolation criteria can overlap with the criteria derived for specific analyses. Isolation studies are necessary to provide a reliable muon tag and do not affect the momentum reconstruction, because the tracking algorithms are independent of the tagger. Default isolation criteria can, for example, be relaxed based on information from the physics sample and the specific analysis. As an example, Figure 14 shows the rejection on the  $Zb\bar{b}$  background versus the Standard Model  $H(130 \text{ GeV}) \rightarrow ZZ^* \rightarrow \mu^+\mu^-\mu^+\mu^-$  efficiency using the calorimeter isolation cuts [19]. At this stage, after a preselection procedure, the four muon candidates have already been selected. Both absolute and normalized (with respect to muon  $p_T$ ) isolation are presented. In these analyses, the isolation energy was

Figure 14: Rejection of the  $Zb\bar{b}$  background as a function of the  $H(130 \text{ GeV}) \rightarrow 4\mu$  signal efficiency. Different radii ( $0.1 < \Delta R < 0.3$ ) are compared for absolute, left, and normalized (with respect to muon  $p_T$ ), right, calorimeter isolation. No pile up events were simulated.

defined using a cone of fixed radius. The isolation energy of an event was then defined as the isolation energy of the least isolated muon of the event. The optimum cone radius depends on signal efficiency, with  $\Delta R$  of 0.2 being an efficient choice.

### 3.4 Measurement/Parameterization Combination Methods

To integrate energy loss in tracking algorithms, the energy loss is assumed to be gaussian. If the parameterization is used exclusively to correct for the energy loss, any event in which muons undergo a large energy loss will be incorrectly reconstructed. There is, thus, an advantage in using the parameterizations together with measurements in the calorimeters to optimize the energy loss reconstruction. Here we describe two algorithms developed to use the calorimeter information as well as the energy loss parameterizations for the muon reconstruction algorithms: the *Hybrid Method* [3] and the *Bayesian Method*. The Hybrid Method is used by default after isolation cuts as part of Muid. The Bayesian Method is used if specified by the user as part of Muonboy. By default, Muonboy uses a parameterization of the energy loss only.

The Hybrid Method consists in fully separating the two regions of the Landau distribution: the peak region and the tail region. The calorimetric energy loss measurement is used when the energy deposition is significantly larger than the most probable value (tail region); otherwise the parameterization is used (peak region). The transition point between the two regions is taken as  $E_{\text{mpv}} + 2\sigma_{\text{Landau}}$ .

The Bayes Method is based on a statistical combination of the parameterization and the measurement in the calorimeters. This combination is performed using Bayes' theorem. This method uses information from the calorimeters, even when the measurement falls in the peak region. When the calorimeter measurement falls in the tail, the results provided by this method are similar to those obtained by the Hybrid Method. If the measurements falls in the peak region, the measurement still constrains the energy loss pdf, improving the energy loss reconstruction resolution. In addition, this method generalizes the selection procedure of the hybrid method, with an event-by-event optimization and for each calorimeter subsystem. This generalization allows also, in principle, an automatic improvement in the energy loss reconstruction as the calorimeter calibration improves.

The full validation of these methods in muon reconstruction with all muon reconstruction effects is shown in the next section. The most significant of these effects are the intrinsic resolutions of the inner detector and muon spectrometer. However, to validate the methods standalone, it is necessary to do it in a model free of these reconstruction effects.

The Hybrid Method has been validated through the energy loss reconstruction distributions in the ATLAS full simulation using the muon kinematics from the simulation. The ratio of the energy loss resolution for the Hybrid Method,  $\sigma_{\text{hybrid}}$ , with respect to the parameterization alone,  $\sigma_{\text{param}}$ , is presented in Figure 15. The resolution is defined as the square root of the variance of the energy loss resolution. For low- $p_T$  values the ratio is close to unity, as expected due to the smaller fraction of events in the Landau tail. For increasing  $p_T$  values the ratio decreases, approaching 30% at  $p_T = 1$  TeV. Thus, using the Hybrid Method results in a significant improvement in the energy loss estimation with respect to the parameterization alone.

Figure 15: Ratio of the energy loss resolution for the Hybrid Method with respect to the parameterization alone for single muons.

In addition, the performance of the Bayesian Method has been studied in a toy model under the assumption that the calorimeter calibration is understood. Muons of 1 TeV were shot through a block of matter representative of one of the samplings of the hadronic calorimeter. A perfect muon spectrometer was assumed as it is done for the Hybrid Method above. Figure 16 shows some results from this study that demonstrate the potential of the Bayesian Method to reconstruct energy loss. The use of the measurement

Figure 16: Demonstration of the potential of the statistical method to reconstruct the energy loss. The left plot shows the bias in the energy loss reconstruction, while the right plot shows the  $E_{\text{loss}}^{\text{true}} - E_{\text{loss}}^{\text{reco}}$  distribution. Both plots compare the energy loss reconstruction using the parameterization only (triangles, dotted line), the measurement only (filled circles, solid line) and both statistically combined through Bayes' theorem (open circles, dashed line).

by itself biases the energy loss reconstruction. The Bayesian Method, on the other hand, shows no biases. Incidentally, there are no biases in the energy loss reconstruction if the muon spectrometer measurement is coupled to the energy loss reconstruction in these studies. In addition, the  $E_{\text{loss}}^{\text{true}} - E_{\text{loss}}^{\text{reco}}$

distributions show that the resolution obtained with the Bayesian Method is better than that obtained using the parameterization or the measurement only.

These studies prove the potential of these two methods. Now their performance is analyzed when they are used as part of the reconstruction software.

### 3.5 Impact of the Energy Loss Corrections in Reconstruction

Energy loss estimates must be validated as part of the muon reconstruction algorithms. Effects such as the resolution of muon reconstruction, biases intrinsic to the track transport or the effects of gaussian assumptions will be coupled to the energy loss reconstruction. However, the studies shown here are still important for understanding the energy loss correction. They also allow for an investigation of which data samples are most sensitive to an incorrect estimation of the energy loss.

In Figure 17, two parameters that characterize the gaussian distributions  $1/p_T^{\text{reco}} - 1/p_T^{\text{true}}$  are shown. In these plots, the label “MS” corresponds to tracks from fits in the muon spectrometer only. The label

Figure 17: Left: Muon reconstruction bias for different algorithms as a function of muon  $p_T$ . Right: Muon reconstruction resolution for different algorithms as a function of muon  $p_T$ . These plots were produced with the Muonboy/STACO algorithms for muon reconstruction [1], but similar performance is obtained with the MOORE/Muid algorithms [2, 7].

“MS+E<sub>loss</sub> correction” refers to tracks reconstructed at the muon spectrometer and transported to the interaction point (IP), applying an energy loss correction (parameterized or hybrid). For Figure 17 the energy loss correction was calculated using the Muonboy parameterization only. The label “MS+ID” refers to tracks reconstructed with the muon spectrometer and the inner detector. To obtain these combined tracks, the energy loss correction needs to be considered in the fit. The distributions are calculated in  $1/p_T$ -space because the muon spectrometer reconstruction and inner detector reconstruction have gaussian fluctuations in  $1/p_T$ . These plots refer to muons reconstructed in the barrel ( $|\eta| < 1.0$ ) of the muon spectrometer. In the left plot, the bias in the reconstruction is shown, defined as the mean of the distribution

$$\frac{\delta p_T^{-1}}{p_T^{-1}} = p_T^{\text{true,IP}} \left( \frac{1}{p_T^{\text{reco}}} - \frac{1}{p_T^{\text{true,IP}}} \right), \quad (4)$$

with  $p_T^{\text{true,IP}}$  being the true  $p_T$  of the muon at the IP. Clearly, in the absence of an energy loss correction, this reconstruction can be highly biased. Such a bias also causes a degradation in the resolution. The application of an energy loss correction reduces this bias and improves the resolution. Further bias reduction and resolution improvement is obtained by using the inner detector together with the muon spectrometer to reconstruct the muon track. However, the combination of inner detector tracks and muon spectrometer tracks is only possible if a proper energy loss correction exists.

Figure 18 shows the invariant mass resolution ( $M_{\text{inv}}^{\text{reco}} - M_{\text{inv}}^{\text{true}}$ ) for  $Z \rightarrow \mu\mu$  and  $Z'(1000 \text{ GeV}) \rightarrow \mu\mu$  samples. The events include a generation cut that requires the  $p_T$  of both decay muons to be above 7 GeV

Figure 18: Left: Reconstruction resolution of the  $Z$  peak for different algorithms. Right: Reconstruction resolution of the  $Z'$  peak for a  $Z' \rightarrow \mu\mu$  of mass 1 TeV for different algorithms. These plots were produced with the MOORE/Muid algorithms for muon reconstruction [2, 7], but similar performance is obtained with the Muonboy/STACO algorithms [1].

for  $Z$  decays and above 20 GeV for  $Z'$  decays. Inner detector and muon spectrometer tracks were required for both reconstructed muons. The effect of the energy loss correction is most significant in the  $Z$ -mass reconstruction. If the energy loss is not included a shift of about 7 GeV in the mass peak and a significant deterioration in the resolution are visible. These effects are much less pronounced in the reconstruction of the  $Z'$  peak. This happens because the more energetic muons from the  $Z'$  lose a smaller fraction of their total energy as they pass through the calorimeters.

An additional improvement in the  $Z$  and  $Z'$  resolution is possible if the energy loss correction uses the calorimeter measurement [20]. This is demonstrated in Figure 19, where a comparison is shown

Figure 19: Left: Reconstruction resolution of the  $Z$  peak for an algorithm using muon spectrometer standalone tracks and the parameterized energy loss correction (filled histogram) and an algorithm using a combination of a parameterization and the calorimeter measurement for the energy loss correction (empty histogram). Right: Reconstruction resolution of the  $Z'$  peak for a  $Z' \rightarrow \mu\mu$  of mass 1 TeV for the same algorithms.

for the muon spectrometer reconstruction with energy loss correction with and without the calorimeter measurement. The same samples as for Figure 18 were used. A few events are recovered from the tails and populate the peak region. This results in  $\approx 8\%$  resolution improvement when the inner detector hits are not used. If the inner detector hits are used the resolution improves by  $\approx 4\%$ , showing that

the combined fit is less sensitive to the energy loss correction. These plots were produced with the MOORE/Muid algorithms for muon reconstruction using the Hybrid Method (see Section 3.4). A similar performance is expected using the Bayesian Method, implemented in the ATLAS tracking.

## 4 Tagging of Muons in the Calorimeters

In this section the different calorimeter-based muon identification algorithms are described. Section 4.1 provides a detailed description of the algorithm that is currently part of the standard reconstruction; and Section 4.2 illustrates its performance in different physics samples.

These algorithms have been developed with the main goal of complementing the muon spectrometer in two ways: recovering muons with low transverse momentum ( $p_T = 2\text{--}5$  GeV), and in the regions of limited spectrometer acceptance (especially in the  $\eta \sim 0$  region). For completeness, algorithms used for commissioning or triggering are also discussed.

There are two types of calorimeter-based muon tagging algorithms. Their main difference lies in how they initiate the muon search. The calorimeter-seed algorithms search for muons looking at the measured energy. Cells with energy depositions inside some energy range are used as seeds. The lower limit of this range is known as the *initiation* threshold. The cluster of cells used to identify the muon is then built up by adding cells around the seed cell whose energy is above a second lower threshold, so called *continuation* threshold. At the end of the clustering, the  $\eta$  and  $\phi$  directions of the reconstructed cluster can be used to match a track in the inner detector. There are two algorithms that correspond to this description:

- LArMuID is based on a topological clustering algorithm used by ALEPH [21]. A topological clustering algorithm groups neighboring cells whose energy is above a given threshold. Therefore, the resulting clusters have a variable number of cells. This algorithm was used to find muons using the electromagnetic calorimeter data during the test beam and the cosmic commissioning data analysis. It builds the cluster from a seed cell in the middle sampling of the electromagnetic calorimeter. Then, it creates the cluster adding another cell (if any) adjacent in  $\phi$  above the continuation threshold. Due to the accordion structure of the electromagnetic calorimeters there are no more than two adjacent cells in  $\phi$  that can share the muon signal, thus the clusters consist of at most two cells. The efficiency was measured with a muon beam during the combined test beam as the fraction of events with a reconstructed muon cluster. The efficiency and the probability to generate a fake muon from noise fluctuations were evaluated as a function of both thresholds. The clustering algorithm inherently biases the energy reconstruction, so the lower the thresholds the better the estimation of the reconstructed energy for the muon. The spectrum of energies collected has been compared to and shown agreement with GEANT4.
- TileMuId is simple and fast and is used for triggering purposes. Its clustering methods are similar to those of LArMuID. This algorithm, however, runs by default as part of the reconstruction software. It starts with a search for a “candidate” muon in the cells belonging to the last TileCal sampling, where the muon gives the clearest signature, due to the screening effect of the two previous samplings. If the measured energy is between a lower and an upper threshold, it uses the  $\eta$  and  $\phi$  coordinates of the cell to look for another cell with energy within the same thresholds in the central sampling. If both searches are successful it looks for a third cell with energy within the thresholds in the first sampling. When cells with energies within the thresholds are found in all three samplings, the candidate is confirmed to be a muon. Performance studies of TileMuId can be found in [22].

There are two track-seed algorithms that extrapolate inner detector tracks through the calorimeter

identifying those matching the energy deposition pattern of a muon. The track-seed algorithms use no tracking information from the muon spectrometer. The first track-seed algorithm, `CaloMuonTag`, will be described in detail in the next section.

The second track-seed algorithm, `CaloMuonLikelihoodTool`, builds a likelihood ratio to discriminate muons from pions. The likelihood discriminant is built out of different energy ratios in order to capture the global features of the energy depositions. The discrimination power of these ratios varies both as a function of the momentum of the particles considered, and as a function of  $\eta$ . Therefore three bins in  $\eta$  (barrel, crack, end-cap) and three bins in momentum (0-10 GeV, 10-50 GeV, 50-100 GeV) are used, and a different set of ratios is selected for each of the 9 regions. The likelihood ratio for the muon candidate is then defined as

$$\mathcal{L}(x_1, \dots, x_N) = \prod_{i=1}^N \frac{P_i^\mu(x_i)}{P_i^\mu(x_i) + P_i^\pi(x_i)}. \quad (5)$$

Where  $P_i^\mu$  and  $P_i^\pi$ ,  $i = 1, \dots, N$  are the pdf for the energy ratios. The performance of this algorithm is still being studied, however, the first results show that it is comparable to the performance of `CaloMuonTag` discussed in Section 4.2.

#### 4.1 CaloMuonTag

`CaloMuonTag` extrapolates inner detector tracks through the calorimeters, collecting the energy in the cell closest to the extrapolated track for each traversed sampling. The muon can deposit energy in more than one cell in the hadronic calorimeter, but the probability of this happening is rather low, as illustrated in Figure 20. For the purpose of this algorithm, it is enough to assume that all the energy deposited by the muon is localized in the central cell. This also minimizes the electronic noise, which is particularly large in the HEC.

Figure 20: Energy found in the cell traversed by the extrapolated track (solid line) and the surrounding cells (dashed line) in the TileCal (left) and in the HEC (right). Distributions obtained for momentum 100 GeV muons.

A track preselection is made to reduce the number of fakes in the output of the algorithms. In addition, this preselection reduces the time needed by the algorithm to run on events with high track multiplicity. The following cuts in  $p_T$ , and transverse isolation energy ( $E_T^{\text{iso}}$ ) inside a cone of 0.45 are applied:

- $p_T > 2$  GeV and  $E_T^{\text{iso}} < 10$  GeV for tracks pointing to the barrel ( $\eta < 1.6$ ).
- $p_T > 3$  GeV and  $E_T^{\text{iso}} < 8$  GeV for tracks pointing to the end-cap.

Tracks are rejected if any of the collected energies are above veto values defined for each sampling. As most fakes are seeded by low- $p_T$  tracks, more stringent cuts can be set for low- $p_T$  ( $< 10$  GeV) track candidates. These cuts can be relaxed for track candidates of higher  $p_T$ .

Once calorimeter cells along the muon trajectory have been identified, the algorithm determines the lower threshold energy cut that should be used for the tagging as a function of  $\eta$ :

- $E_{\text{th}} = \frac{E_0^{\text{barrel}}}{\sin^2 \theta}$  for  $|\eta| < 1.7$ ,
- $E_{\text{th}} = \frac{E_0^{\text{end-cap}}}{(1 - \sin \theta)^2}$  for  $|\eta| > 1.7$ ,

where  $\theta$  is the polar angle. The values of  $E_{\text{th}}$  from these two equations roughly follow the shape of the measured energy distributions, which increases with the path length of the muon in the cell.

Energy depositions in the last sampling of the calorimeters give the most reliable muon signals. However, due to the gap between the TileCal barrel and extended barrel modules, and the transition region between the TileCal and the end-cap (HEC) calorimeters, it is necessary to look in the two previous samplings to obtain a good efficiency throughout  $\eta$ . For this reason, if the energy in the last sampling, or one of the two previous samplings depending on the  $\eta$  of the track, is above the threshold cut,  $E_{\text{th}}$ , the track is tagged as a muon. A different tag is given depending on which sampling passes the threshold cut.

## 4.2 Performance

In this section the performance of CaloMuonTag is analyzed. The performance of CaloMuonTag is studied in some relevant physics samples:

- $pp \rightarrow J/\psi \rightarrow \mu\mu$ . A direct production of a  $J/\psi$  decaying to two muons with the following cuts at generation level: one muon with  $p_T > 6$  GeV and the other with  $p_T > 4$  GeV.
- $H \rightarrow ZZ^* \rightarrow 4\ell$ . A Higgs generated with an invariant mass of 130 GeV is forced to decay into two  $Z$ 's (one of them offshell) that decay leptonically. Only events with four muons are used for reconstructing the Higgs peak, but all events are used for the efficiency/fake rate calculation.
- $t\bar{t}$ . A sample of pair produced top quarks with all decay channels allowed.
- $Zbb \rightarrow 4\ell$ . A  $Z$  is produced in association with 2  $b$  quarks, and is forced to decay into two charged leptons. The  $b$  quarks are also forced to decay into electrons or muons.

All samples were generated with pile-up with a safety factor of 5, i.e. five times nominal value expected at a luminosity of  $10^{33} \text{ cm}^{-2} \text{ s}^{-1}$ . Except for the  $pp \rightarrow J/\psi \rightarrow \mu\mu$  sample, where a safety factor of 2 was used.

Figure 21 shows the performance of the calorimeter muon tagger algorithm on selected samples. The vertical axis on the left shows the efficiency (top distributions). The vertical axis on the right (in red) shows the fake rate (the number of misidentified tracks per event), represented by the shaded distribution at the bottom of the plots. The efficiency (fake rate) is defined as the fraction of muons that are found by the algorithm and (not) matched with a true MC muon. Muons from minimum-bias interactions were not included in the efficiency calculation.

For the  $t\bar{t}$  ( $Zbb \rightarrow 4\ell$ ) sample, the algorithm performs well in identifying isolated muons from  $W$ 's ( $Z$ 's). However, due to the isolation and veto cuts applied to reduce the number of fakes, the efficiency for non-isolated muons from  $b$  quarks is very poor, affecting the overall efficiency.

To reduce the fake rate due to the low- $p_T$  tracks in the end-caps, some efficiency in that region needs to be sacrificed. The “peaks” in the fake rate in  $\eta$  match the regions where the acceptance of the last

Figure 21: Efficiency (and fakes per event, right axis in red and shaded histograms) vs  $\eta$  for different samples. Top left:  $pp \rightarrow J/\psi \rightarrow \mu\mu$ . Top right:  $H(130) \rightarrow ZZ^* \rightarrow 4\ell$ . Bottom left:  $t\bar{t}$ . Bottom right:  $Zbb \rightarrow 4\ell$ .

calorimeter sampling is limited, and the two previous samplings are used for muon identification. Due to the higher electronic noise, CaloMuonTag presents a higher fake rate in the HEC than in the TileCal. The results for these samples, and for dijet samples generated with different  $p_T$  transfers at the hard scattering interaction are summarized in Table 1.

	$J/\psi \rightarrow \mu\mu$	$H \rightarrow 4\ell$	$t\bar{t}$	$Zbb \rightarrow 4\ell$	1120-2240	560-1120	280-560	70-140	17-35
Eff.	0.80	0.86	0.54	0.69	-	-	-	-	-
f/e	0.05	0.09	0.16	0.14	0.11	0.12	0.12	0.13	0.12

Table 1: Summary of the efficiencies and fakes per event (f/e) for different physics processes and dijet samples (top numbers show the ranges of  $p_T$  transfers at the hard scattering interaction, in GeV).

Finally, Figures 22 and 23 are used to evaluate the performance improvement when using calorimeter muons to reconstruct the Higgs and the  $J/\psi$  mass. The plots on the left show the invariant mass reconstructed with muons from a combined muon reconstruction algorithm, which makes use of both inner detector and muon spectrometer tracks. The plots on the right show the invariant mass including muons tagged by CaloMuonTag with momenta reconstructed by the inner detector.

To obtain the plots in Figure 22 the same set of cuts were used as in the  $H(130) \rightarrow ZZ^* \rightarrow 4\ell$  stud-

Figure 22: Reconstructed Higgs peak in the  $H \rightarrow 4\ell$  invariant mass reconstruction for the standard combined muons (left) and for combined muons together with inner detector muons tagged by CaloMuonTag in the  $\eta$  region  $|\eta| < 0.1$  (right).

ies [19]. The increase on the number of reconstructed events was achieved by adding an extra muon found by the CaloMuonTag algorithm during the muon preselection. The extra muon was requested to be found in the last sampling of the TileCal and within the  $|\eta| < 0.1$  region. No loss in mass resolution or shift in the mean of the mass peak are observed between the two selected muon samples. The acceptance gap around  $|\eta| < 0.1$  represents 4% of the  $|\eta| < 2.5$  region covered by the combined muon reconstruction. Since, four muons are reconstructed in this analysis, the total efficiency loss due to the gap is 16%. This results shows that calorimeter identification can recover almost all of the lost events (14.9%).

For the plots shown in Figure 23 the muons used to reconstruct the invariant mass peak were matched

Figure 23: Reconstructed  $J/\psi$  peak in the  $J/\psi \rightarrow \mu\mu$  invariant mass reconstruction for standard combined muons (left) and for combined muons together with inner detector muons tagged by CaloMuonTag in the  $\eta$  region  $|\eta| < 0.1$  (right).

to the Monte Carlo truth. In this case, all muons identified by the calorimeter were added to the combined reconstruction muons. Again, no loss in mass resolution or shift in the mean of the mass peak are observed between the two selected muon samples.

CaloMuonTag shows very good efficiency and acceptable fake rate for a high- $p_T$  analysis like  $H \rightarrow ZZ^* \rightarrow 4\mu$ . An additional 15% of events were reconstructed when muons identified by CaloMuonTag were added to the muons found by the standard reconstruction algorithm. In low- $p_T$  analyses, such as  $J/\psi \rightarrow 2\mu$ , tighter selection cuts need to be applied to keep an acceptable fake rate. This reduces the efficiency of the tagging algorithms. However, an additional 15% of events were reconstructed when

muons from CaloMuonTag were also used.

## 5 Conclusion

This document reviews the current status of the understanding of muon energy loss in the ATLAS calorimeters. Although energy losses and their distribution along the muon track have a very small impact on muon reconstruction inside the muon system, they play an important role in the transport of a reconstructed muon track to the beam pipe. During this backtracking, the muon momentum can be corrected using the energy measured in the calorimeter cells traversed. This procedure is justified for muons that have a catastrophic energy loss. In most cases, the muon momentum can be corrected using a parameterization of energy loss, estimated from the reconstructed momentum and the amount and the nature of the material traversed by the reconstructed trajectory. Techniques that attempt to combine the measurement with the parameterization to improve the energy loss estimate have been developed and validated. A performance improvement is achieved in some important analyses through the use of these techniques.

Muon tagging algorithms that use calorimeter measurements and track information have been presented. These algorithms have been developed with the main goal of complementing the muon spectrometer in two ways: recovering muons with very low transverse momentum, and in the regions of limited spectrometer acceptance, especially in the  $\eta \sim 0$  region. The performance of the calorimeter muon tagger algorithm in a few relevant data samples has been shown.

# In-Situ Determination of the Performance of the Muon Spectrometer

## Abstract

The ATLAS muon spectrometer consists of three layers of precision drift-tube chambers in a toroidal magnetic with a field integral between 2.5 and 6 Tm. Muon tracks are reconstructed with 97% efficiency and a momentum resolution between 3% and 4% for  $10 \text{ GeV} < p_T < 500 \text{ GeV}$  and better than 10% for transverse momenta up to 1 TeV. In this note, the performance of a perfectly calibrated and aligned muon spectrometer will be reviewed and the impact of deteriorations of the magnetic field, the calibration and misalignment of the muon chambers on the performance will be discussed. The main part of the note describes how the performance of the muon spectrometer can be determined using dimuon decays of  $Z$  bosons and  $J/\psi$  mesons.

## 1 Introduction

Muons with a transverse momentum<sup>1</sup>  $p_T$  greater than 3 GeV are detected in the ATLAS muon spectrometer, which is designed to measure muon momenta with a resolution between 3% and 4% for a range of transverse momenta of  $10 \text{ GeV} < p_T < 500 \text{ GeV}$  and better than 10% for  $p_T$ 's up to 1 TeV. The muon spectrometer consists of a system of superconducting air-core toroid coils producing a magnetic field with a field integral between 2.5 and 6 Tm [1]. Three layers of chambers are used to precisely measure muon momenta from the deflection of the muon tracks in the magnetic field (see Figure 1). Three layers of trigger resistive-plate chambers (RPC) in the barrel and three layers of fast thin-gap chambers (TGC) in the end caps of the muon spectrometer are used for the muon trigger. The trigger chambers measure the muon tracks in two orthogonal projections with a spatial resolution of about 1 cm. The precision measurement of the muon trajectory is performed by three layers of monitored drift-tube (MDT) chambers in almost the entire muon spectrometer and by cathode-strip chambers (CSC) in the innermost layer of the end caps at  $|\eta| > 2.2$ . The precision muon chambers provide track points with  $35 \mu\text{m}$  resolution in the bending plane of the magnetic field. The goal of a momentum resolution better than 10% up to 1 TeV scale requires the knowledge of the chamber positions with an accuracy better than  $30 \mu\text{m}$  in addition to the high spatial resolution of the chambers. This is achieved by a system of optical alignment monitoring sensors [1].

In the first part of this note, we review the performance of a perfectly calibrated and aligned muon spectrometer and discuss the dependence of the performance on the knowledge of the following quantities: the magnetic field, the calibration of the chambers, the alignment of the chambers, and the accuracy of the determination of the energy loss of the muons in the calorimeters. In the second and main part, we describe how the performance of the muon spectrometer can be determined by means of dimuon decays of  $Z$  bosons and  $J/\psi$  mesons.

## 2 Performance of a perfect and deteriorated spectrometer

### 2.1 Muon reconstruction

The muon spectrometer measures the momenta of charged particles at the entrance of the muon spectrometer. The energies lost by the muons on the passage through the calorimeters have to be added to the

---

<sup>1</sup>The transverse momentum is defined as the components of momentum in the transverse plane.

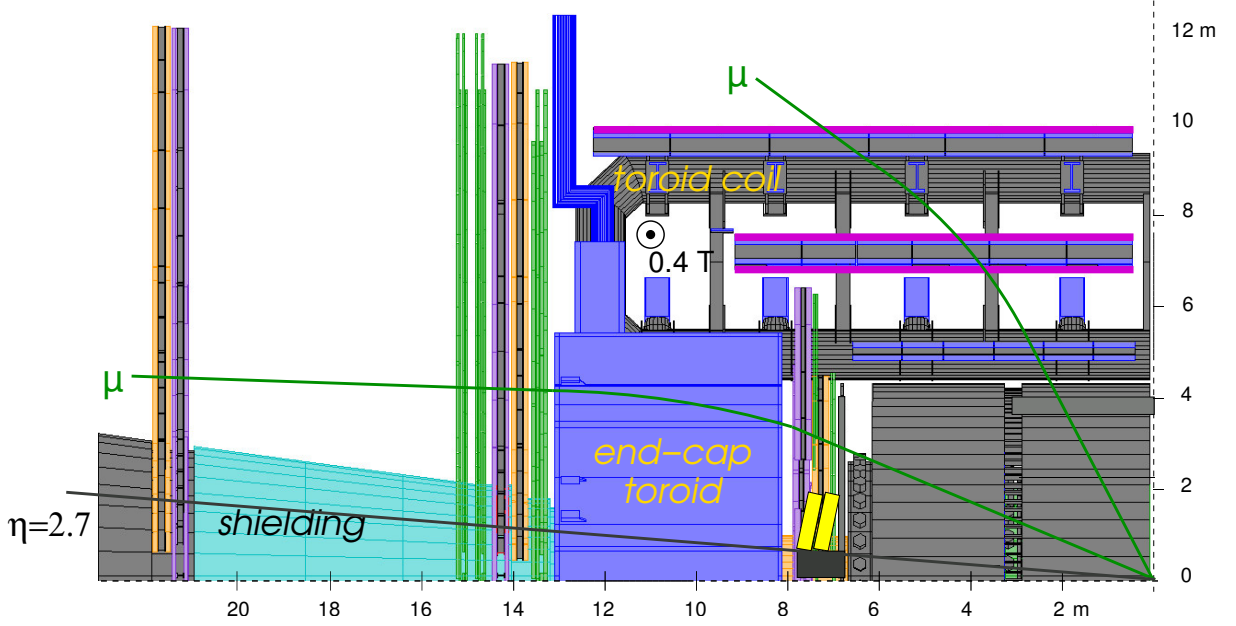

Figure 1: Sketch of a quadrant of the ATLAS muon spectrometer.

energy measured at the entrance of the muon spectrometer in order to obtain the muon momentum at the primary vertex. This reconstruction strategy is called *stand-alone* muon reconstruction. In order to correct for the energy loss, the expected average energy loss is used as a first estimation; in a second step the energy deposition measured in the calorimeters is used to account for the large energy losses of highly energetic muons due to bremsstrahlung and direct  $e^+e^-$  pair production. One speaks of *combined* muon reconstruction when the momentum measurement of the inner detector is combined with the stand-alone reconstruction. In this note, muon momenta will always be given at the  $pp$  interaction point.

The muon reconstruction is described in detail in [2, 3]. The focus of this note is the measurement of the performance of the stand-alone reconstruction from real data.

## 2.2 Definitions

The performance of the muon spectrometer is characterized in terms of *efficiency* and *momentum resolution*. In the analysis of simulated data, let  $\eta_{rec}$  and  $\eta_{truth}$  denote the pseudorapidities and  $\phi_{rec}$  and  $\phi_{truth}$  denote the azimuthal angles of the reconstructed and generated muons. The distance  $\Delta R = \sqrt{(\eta_{rec} - \eta_{truth})^2 + (\phi_{rec} - \phi_{truth})^2}$  of a reconstructed and generated muon is shown for a Monte Carlo sample with muons of  $p_T = 50$  GeV at the  $pp$  interaction point in Figure 2. More than 99.7% of all reconstructed muons have a distance  $\Delta R < 0.05$ . We therefore define the muon reconstruction *efficiency* as the fraction of generated muons which can be matched to a reconstructed muon within a cone of  $\Delta R < 0.05$ .

The momentum resolution is measured by comparing the deviation of the reconstructed inverse transverse momentum from the generated inverse transverse momentum:

$$\rho = \frac{\frac{1}{p_{T,truth}} - \frac{1}{p_{T,rec}}}{\frac{1}{p_{T,truth}}} \quad (1)$$

$\rho$  would be normally distributed for a muon spectrometer uniform in  $\eta$  and  $\phi$ . The momentum resolution is not independent of  $\eta$  and  $\phi$  due to the nonuniformity of the magnetic field and the nonuniformity of the

Figure 2: Distribution of distance  $\Delta R$  of reconstructed from generated muons in a 50 GeV single muon Monte Carlo sample.

material distribution in  $\eta$  and  $\phi$ . This leads to non-Gaussian tails in the  $p$  distribution when integrated over  $\eta$  and  $\phi$ , as illustrated in Figure 3. In order to minimize the effect of tails, the momentum resolution is determined in the following way throughout this note: In the first step, a Gaussian  $g_0$  is fitted to the distribution. In the next step  $i$  a Gaussian  $g_i$  is fitted to the data between the  $x_{m,i-1} \pm 2\sigma_{i-1}$ , where  $\sigma_{i-1}$  is the fitted width of  $g_{i-1}$  and  $x_{m,i-1}$  its fitted mean. The iterative procedure is terminated when the fit relative change of the fit parameters from one to the next iteration is less than 0.1%. The standard deviation of the final fit curve is taken as a measure for the *momentum resolution*. The mean of final fit is referred to as the *momentum scale*, which is a measure for systematic shifts of measured muon momenta with respect to the correct values.

### 2.3 Performance of a perfect muon spectrometer

We briefly review the performance of a perfectly calibrated and aligned muon spectrometer. We refer to [1] and [2] for a more detailed discussion of the performance.

Figure 4(a) shows the reconstruction efficiency for muons with  $p_T=50$  GeV as a function of  $\eta$  and  $\phi$ . The efficiency is close to 100% in most of the  $\eta$ - $\phi$  plane. It drops significantly in the acceptance gaps of the muon spectrometer. The inefficiency near  $|\eta| = 0$  is caused by the gap for services of the calorimeters and the inner tracking detector. The inefficiency near  $|\eta| = 1.2$  will disappear after the installation of additional muon chambers in the transition region between the barrel and the end caps which will not be present in the initial phase of the LHC operation. The inefficiencies at  $\phi \approx 1.2$  and  $\phi \approx 2.2$  for  $|\eta| < 1.2$  are related to acceptance gaps in the feet region of the muon spectrometer.

The stand-alone reconstruction efficiency is presented as function of  $p_T$  in Figure 4(b). It rises from 0 to its plateau value of 95% between  $p_T = 3$  GeV and 10 GeV.

The  $p_T$ -resolution is independent of  $\phi$  apart from the feet region where it is degraded due to the material introduced by the support structure of the detector. The resolution also depends on pseudorapidity. It is almost constant in the barrel part of the spectrometer ( $|\eta| < 1.05$ ). It is up to three times worse in the transition region between the barrel and the end caps for  $1.05 < |\eta| < 1.7$  mainly due to the

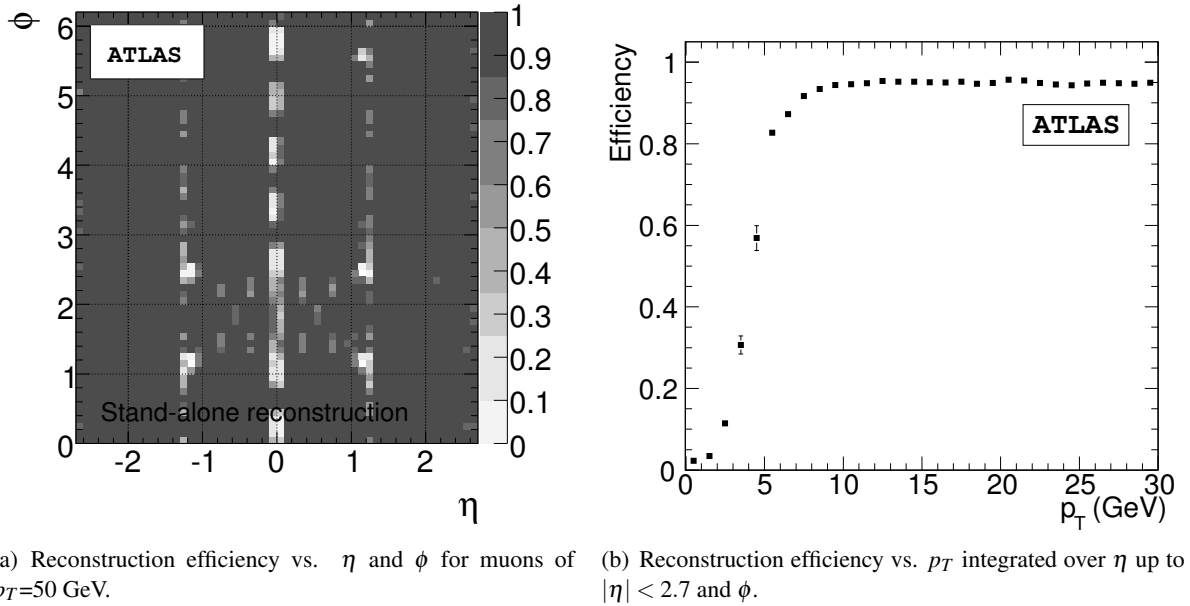

Figure 3: Illustration of the iterative fit of normal distributions to the fractional deviation of the reconstructed inverse momentum from the generated inverse momentum.  $g_0$  is the fitted Gaussian of iteration step 0.  $g_4$  is the fitted Gaussian of final iteration step 4.

(a) Reconstruction efficiency vs.  $\eta$  and  $\phi$  for muons of  $p_T=50$  GeV.

(b) Reconstruction efficiency vs.  $p_T$  integrated over  $\eta$  up to  $|\eta| < 2.7$  and  $\phi$ .

Figure 4: Efficiencies of the reconstruction of tracks in the muon spectrometer.

small integral of the magnetic field in this region. The momentum resolution becomes uniform again for  $|\eta| > 1.7$ .

Figure 5: Stand-alone momentum resolution integrated over  $\eta$  and  $\phi$  as a function of  $p_T$  for the barrel (5(a)) and the end-cap region (5(b)).

The stand-alone momentum resolution varies with  $p_T$  (see Figure 5). The momentum resolution in the barrel is dominated by fluctuations of the energy loss in the calorimeters for  $p_T < 10$  GeV where it is about 5% at  $p_T = 6$  GeV. It is best, 2.6% (4%) in the barrel (end cap), for  $p_T \approx 50$  GeV where it is dominated by multiple scattering in the muon spectrometer. The momentum resolution at high momenta is limited by the spatial resolution and the alignment of the precision chambers and approaches 10% at  $p_T = 1$  TeV.

## 2.4 Deterioration of the performance

The performance of the stand-alone muon reconstruction is affected by the limited knowledge of the magnetic field in the muon spectrometer, the limited knowledge of the material distribution along the muon trajectory required for the calculation of the energy loss, the calibration of the position measurements by the monitored drift-tube chambers, and the alignment of the muon chambers.

The magnetic field will be known with a relative accuracy better than  $5 \times 10^{-3}$  based on the measurements of 1840 magnetic field sensors which are mounted on the muon chambers. As a consequence the relative impact on the momentum resolution is less than 3% [1].

Studies for the technical design report of the muon spectrometer [4], which have been confirmed by studies in the context of this note, show that the space-drift-time relationship  $r(t)$  of the MDT chambers must be determined with  $20 \mu\text{m}$  accuracy in order to give a negligible contribution to the momentum resolution up to  $p_T = 1$  TeV. A strategy to calibrate  $r(t)$  with muon tracks with the required accuracy has been worked out and is described in detail in [5].

The muon chambers are installed with a positioning accuracy of 1 mm in the muon spectrometer with respect to global fiducials in the ATLAS cavern. The studies for the technical design report, however, showed that the muon chambers must be aligned with an accuracy better than  $30 \mu\text{m}$  in the bending plane. A bias of  $30 \mu\text{m}$  on the sagitta of a 1 TeV muon corresponds to a systematic shift of the measured momentum of 60 GeV. The alignment of the muon spectrometer is based on a system of optical alignment

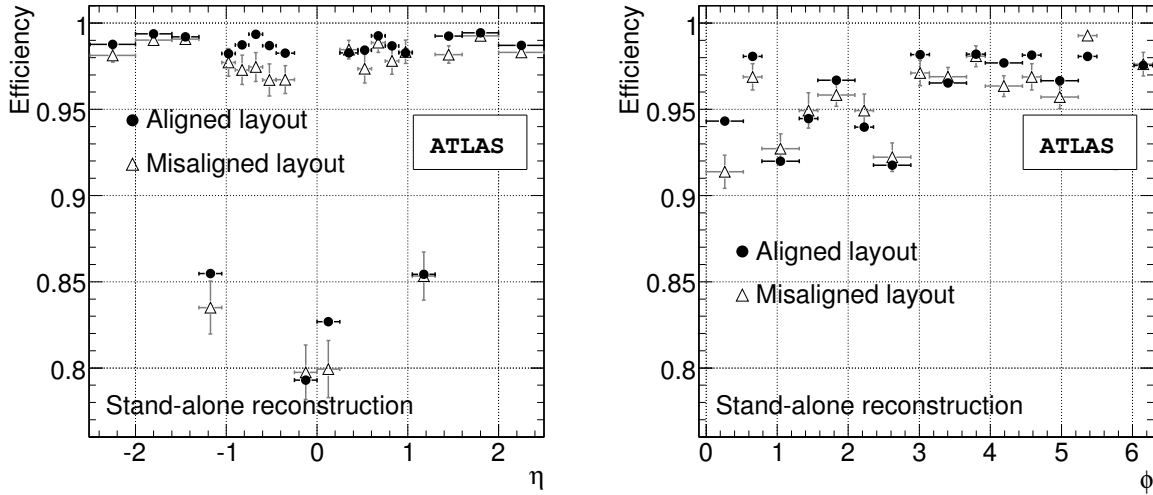

sensors monitoring relative movements of the chambers on the level of a few micrometers. Muon tracks are used for the absolute calibration of the optical sensor with  $30\ \mu\text{m}$  accuracy. The optical system does not cover the whole muon spectrometer. The positions of the end caps with respect to the barrel must be measured with muon tracks traversing the overlap between the barrel and the end-cap part of the spectrometer. There are also chambers in the transition region between the barrel and end caps whose positions are not monitored by the optical system. These chambers will be aligned with the rest of the muon spectrometer by muon tracks. The alignment of the muon spectrometer is discussed in [6].

The expectation of the muon energy loss in the calorimeters can be checked by comparing the muon momentum as measured by the inner detector and the muon momentum at the entrance of the muon spectrometer, for instance. We shall not discuss the measurement of the muon energy loss in this article and refer the reader to [7].

The initial misalignment will be the dominant source of performance degradation. We shall show in the next section that  $Z \rightarrow \mu^+\mu^-$  will lead to a clearly visible resonance peak in the dimuon mass distribution even in the case of the initial misalignment. It will therefore be possible to measure the muon performance of a misaligned muon spectrometer with  $Z \rightarrow \mu^+\mu^-$  events.

### Impact of misalignment on the performance

In order to study the impact of the initial misalignment of the muon spectrometer on the performance, the simulated data were reconstructed with a different geometry from the one used in the simulation. In the reconstruction geometry, the chambers were randomly shifted from the nominal positions with Gaussian distribution centred at 0 and a standard deviation of 1 mm and rotated randomly with Gaussian distribution centred at 0 and a standard deviation of 1 mrad. Deformations of the chambers which are monitored by an optical system mounted on the chambers were not considered in our studies.

(a) Efficiency vs.  $\eta$  integrated over  $\phi$  for  $p_T=50\text{ GeV}$ .

(b) Efficiency vs.  $\phi$  integrated over  $\eta$  for  $p_T=50\text{ GeV}$ .

Figure 6: Comparison of reconstruction efficiency for an aligned muon spectrometer and a misaligned muon spectrometer with a average positioning uncertainty of 1 mm for a simulated single muon sample.

Figure 6 illustrates the comparison of the stand-alone track reconstruction efficiency for 50 GeV muons in the aligned and the misaligned case. Only a small decrease in the reconstruction efficiency can be observed for muons with a momentum of 50 GeV, a momentum typical for muons originating from  $W$

or  $Z$  bosons. The relatively small decrease in the reconstruction efficiency is mainly due to the fact that the used definition of efficiency is based on a simple  $\eta$  and  $\phi$  matching and does not take into account the measured transverse momentum of the muons. The reconstruction efficiency could be increased in the misaligned case by applying softer cuts in the pattern recognition stage of the track reconstruction.

Figure 7(a) and 7(b) show the impact of a misaligned muon spectrometer on the fractional transverse momentum resolution; the resolution is highly degraded. The overall observed fractional muon spectrometer resolution  $\sigma_{tot}$  can be expressed as the quadratic sum of the intrinsic fractional  $p_T$ -resolution at the ideal geometry ( $\sigma_{ideal}$ ) and the fractional resolution due to the misaligned geometry ( $\sigma_{Alignment}$ ).

$$\sigma_{tot} = \sqrt{\sigma_{Alignment}^2 + \sigma_{ideal}^2}$$

This leads to  $\sigma_{Alignment} \approx 0.14$  for muons with  $p_T \approx 50$  GeV as expected from the relationship between sagitta and momentum. The effect on the momentum scale is relatively small for the overall muon spectrometer, since random misalignments cancel to a certain extent. In physics signatures, such as the decay of a  $Z$  boson into two muons, the impact on the average momentum scale is even less, since a misaligned geometry has the opposite effect for opposite charged muons to first order.

Figure 7: Comparison of the fractional  $p_T$ -resolution for an aligned muon spectrometer and a misaligned muon spectrometer.

The impact of initial misalignment of the muon spectrometer on the  $Z$  resonance is shown in Figure 8. It is expected that the mean of the invariant mass distribution does not change significantly, since the momentum scale of the reconstructed muon  $p_T$  is hardly affected by misalignment. On the other hand a large broadening of the distribution due to the degradation of the  $p_T$ -resolution of the muons is expected, which is shown in Figure 8. The dependence of the reconstructed width of the  $Z$  boson mass distribution on the size of the misalignment is shown in Figure 9.  $\sigma_m^{scale}$  is a scaling factor applied to the initial misalignment of 1 mm and 1 mrad. The observed dependence is the basis for the determination of the muon spectrometer resolution with data, which is discussed in section 4. A more detailed discussion of misalignment impacts on the muon spectrometer performance can be found in [8].

Figure 9: Width of the Z resonance peak including the natural width of the Z vs. misalignment parameter  $\sigma_m^{scale}$ .

### 3 Measurement of the reconstruction efficiency from $pp$ collision data

The simulation of the ATLAS detector is still under development and is not expected to reproduce the actual performance of the detector in all details at the beginning of the LHC operation. Therefore it is necessary to determine all efficiencies with data in order not to rely on the simulation.

#### 3.1 Reconstruction efficiency from dimuon decays of the $Z$ boson

##### 3.1.1 Tag-and-probe method

The so-called "tag-and-probe" method can be used to determine the muon spectrometer reconstruction efficiencies from  $pp$  collision data. Muons from  $Z$  decays will be detected by the inner tracking detector and the muon spectrometer in the common acceptance range of  $|\eta| < 2.5$ . The measurements of the inner detector and the muon spectrometer are independent, though not necessarily uncorrelated. We require two reconstructed tracks in the inner detector, at least one associated track in the muon spectrometer, and the invariant mass of the two inner-detector tracks to be close to the mass of the  $Z$  boson. The last requirement ensures that the reconstructed tracks are the tracks of the decay muons of the  $Z$  boson. Moreover, the two inner tracks are required to be isolated to reject possible OCD background. The inner track which could be associated to the track in the muon spectrometer is therefore a muon and is called the *tag muon*. It is also required that the tag muon fired the 20 GeV single-muon trigger in order to ensure that the event is recorded. This selection ensures that a  $Z \rightarrow \mu^+ \mu^-$  decay has been detected. The second inner track must then be a muon, too, which is called the *probe muon* (see Figure 10). In the analysis of dimuon events from  $pp$  collisions, the probe muon plays the role of the generated muon in the determination of the efficiency with simulated data.

The tag-and-probe technique is not restricted to the measurement of the stand-alone reconstruction efficiency. It can, for instance, be used to measure the muon reconstruction efficiency of the inner detector or the trigger efficiency [9].

Figure 10: Schematic illustration of the tag and probe method.

Our studies show that the acceptance gaps of the muon trigger which are reflected in uncovered  $\eta$ - $\phi$  regions of the tag muon do not create uncovered  $\eta$ - $\phi$  regions of the probe muon. The tag-and-probe method therefore allows us to determine the efficiency over the full  $\eta$  and  $\phi$  coverage of the inner detector.

Some systematic uncertainties of the tag-and-probe method must be considered. Muons from  $Z \rightarrow \mu^+\mu^-$  decays usually fly in opposite directions in the plane transverse to the proton beam axis. Hence inefficiencies which are symmetric in  $\Delta\phi \approx \pi$  may not be detected with this method.

The topology of  $pp \rightarrow Z/\gamma^* \rightarrow \mu^+\mu^-$  events is characterized by two highly energetic and isolated muons in the final state. A significant QCD-background contribution is expected due to the huge cross section of QCD processes. Moreover, the decay of a  $W^\pm$  boson into one highly energetic muon and a neutrino plus an additional muon from a QCD jet and the process  $Z \rightarrow \tau^+\tau^- \rightarrow \mu^+\bar{\nu}_\tau\nu_\mu\mu^-\nu_\tau\bar{\nu}_\mu$  were studied as possible background processes in our analysis.

Because of the high collision energy of the LHC, the production of top quark pairs has a cross section of the order of the signal cross section. Top quarks mostly decay into a  $W$  boson and bottom quark. The  $W$  boson and the bottom quark can decay into muons or electrons, which also might fake the signal process.

The cross section of QCD processes is far too large to be simulated within a full Monte Carlo simulation of the ATLAS detector. Hence it is assumed that the dominant contribution from highly energetic muons is due to the decay of  $b$ -mesons. A more detailed discussion of the selection of  $pp \rightarrow Z \rightarrow \mu^+\mu^-$  events and the background processes which must be considered can be found in [9].

### 3.1.2 Selection of candidate tracks

Figure 11 shows the invariant dimuon mass and the transverse momenta of the selected muon track candidates for the signal and the chosen background processes.

The following cuts have been applied to get a clean track selection. Tracks of opposite charge and a difference in their  $\phi$  coordinates greater than 2.0 rad are selected. The rapidity of the tracks is limited to a rapidity coverage of the inner detector of  $|\eta| < 2.5$ . Each of the selected muon candidate tracks is required to have  $p_T > 20$  GeV. The invariant mass  $M_{\mu\mu}$  of the two muon candidate tracks must agree with the  $Z$  mass within  $\pm 10$  GeV, i.e.  $|M_{\mu\mu} - 91.2 \text{ GeV}| < 10 \text{ GeV}$ . The following isolation cuts are applied to the selected tracks:

- number of reconstructed tracks in the inner detector within a hollow cone around the candidate muon:  $N_{r_1 < r < r_2}^{\text{ID Tracks}} < 5$
- sum of the  $p_T$ 's of reconstructed tracks in the inner detector within a hollow cone around the candidate muon:  $\sum_{r_1 < r < r_2} p_T^{\text{ID Tracks}} < 8 \text{ GeV}$
- sum of reconstructed energy in the cells of the calorimeter within a hollow cone around the candidate muon:  $\sum_{r_1 < r < r_2} E_T < 6 \text{ GeV}$
- energy of a possible reconstructed jet within a hollow cone around the candidate muon:  $E_{r < r_2}^{\text{Jet Energy}} < 15 \text{ GeV}$

These isolation variables are defined within a hollow cone in the  $\eta$ – and  $\phi$ –plane of the reconstructed muon track,

$$r_1 < \sqrt{(\eta_\mu - \eta_{ic})^2 + (\phi_\mu - \phi_{ic})^2} < r_2 \quad (2)$$

where  $r_1$  and  $r_2$  are the inner and the outer radius of the cone. The index  $\mu$  stands for the reconstructed muon track while the index  $ic$  labels the isolation criteria. The smaller radius is set to  $r_1 = 0.05$  and is introduced to exclude the candidate muon track from the calculations of the isolation quantities. The specific value of the outer radius  $r_2$  has only a minor effect on the signal and background separation, as long it is large enough to contain a significant amount of data for the definition of isolation variables,

(a) Invariant mass of Z candidates.

(b) Transverse momentum distribution.

 (c) Number of reconstructed tracks within a cone of  $\Delta R = 0.5$  around the candidate track.

 (d) Sum of transverse momenta of all tracks within a cone of  $\Delta R = 0.5$  around the candidate track.

Figure 11: Reconstructed quantities for Z candidate events only using inner detector tracks with a transverse momentum above 6 GeV and no further cuts for signal and background processes.

i.e.  $r_2 > 0.3$ . Our choice of  $r_2 = 0.5$  is the same as used in the measurement of the cross section of the process  $pp \rightarrow Z \rightarrow \mu^+ \mu^-$  (see [9]). The isolation criteria listed here are optimized for events without pile-up of inelastic  $pp$  collisions in a selected event. Pile-up of inelastic  $pp$  collisions is expected for the operation of the LHC at a luminosity of  $10^{33} \text{ cm}^{-2} \text{ s}^{-1}$  and will lead to more energy in a cone around the muons. It was checked that the efficiency of our event selection is reduced by less than 5% in the presence of pile-up and that the purity of our selected samples is not affected by the presence of pile-up.

The distributions of the first two isolation variables for signal and background processes normalized to their cross sections are presented in Figure 11(c) and 11(d) in absence of pile-up. The selection of isolated high- $p_T$  muons allows for a substantial suppression of the background.

Figure 12: Cut-flow diagram for probe muon tracks: (0) opposite charge requirement, (1) invariant mass requirement, (2) kinematic cuts, (3) isolation requirements, (4) electron veto, (5) found at least one track in the muon spectrometer.

The cut-flow diagram for probe muons is shown in Figure 12. The QCD background can be rejected with isolation cuts. More problematic in this selection is the  $W \rightarrow \mu\nu$  background, and those  $t\bar{t}$ -events in which at least one  $W$  boson decays into a muon and a neutrino. These processes produce one highly energetic isolated muon track which passes all selection cuts for a tag muon. A further track in the inner detector which passes the other cuts and is not a muon will decrease the measured efficiency. Such a track is most likely caused by an electron, since it is expected that electrons also appear as isolated tracks in the inner detector. Therefore it is required that no reconstructed electromagnetic jet in the electromagnetic calorimeter can be matched to an inner track as an additional selection requirement. This applies especially for probe tracks stemming from a  $t\bar{t}$ -event. Here, again, one has to distinguish between inner tracks, which result from the decay of the bottom quark or simple QCD-interactions and those, which result from the decay of the  $W$  boson. The first case is suppressed by the isolation requirement and can be neglected. The second case can lead to a highly energetic isolated electron, stemming from the decay of the second  $W$  boson. These electrons are expected to be vetoed. The cut-flow diagram also shows that the probe muon candidates from the background processes can also be associated to a muon spectrometer track and hence have no negative effect on the efficiency determination.

An overview of the remaining background expected from Monte Carlo is shown in Table 1; there we have assumed at least three events surviving the cuts as a systematic uncertainty in order not to

Table 1: Fractional background contribution in % based on Monte Carlo prediction including estimated systematic and statistical uncertainties.

$b\bar{b} \rightarrow \mu\mu$	$W^\pm \rightarrow \mu^\pm \nu$	$Z/\gamma^* \rightarrow \tau\tau$	$t\bar{t} \rightarrow W^+bW^-b$	Overall
$\approx 0 + 0.03$	$\approx 0 + 0.06$	$\approx 0$	$\approx 0.02 \pm 0.01$	$0.02 \pm 0.1$

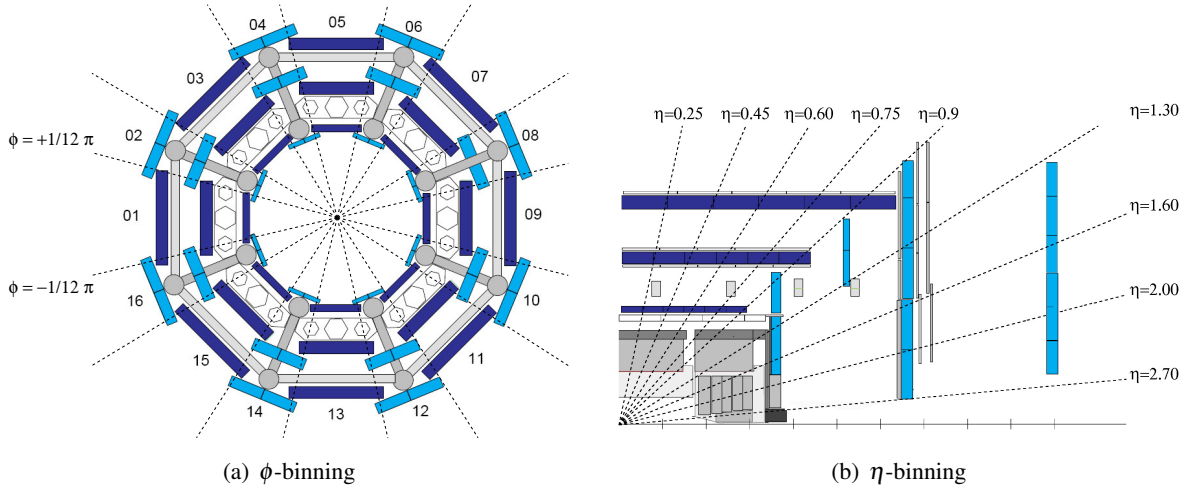

underestimate the background contribution. After all selection cuts, the purity of our sample is high: less than 0.1% of the selected dimuon events are from background processes.

Our results are stable against variations of the track matching distance  $\Delta R$  from 0.05 to 0.3. The larger track matching cut of  $\Delta R=0.3$  takes account for possible misalignment effects in the first phase of LHC. The robustness of our results against the  $\Delta R$  matching cut indicates that our selected data sample will allow an efficiency determination which is not significantly affected by background processes even with a possible misalignment of the muon spectrometer.

### 3.1.3 Determination of the stand-alone reconstruction efficiency

The stand-alone reconstruction efficiency depends on  $p_T$ ,  $\eta$  and  $\phi$  of the muons. Hence, one should determine the efficiency in appropriate bins in these quantities. The lower value of the  $p_T$ -binning is given by the selection cut of 20 GeV. The highest value is set to 70 GeV and 10 bins are used to ensure high enough statistics within each bin. For larger statistics also values above 100 GeV can be considered.

A natural binning in  $\eta$  and  $\phi$  is given by the geometry of the muon spectrometer. The muon spectrometer consists of 16 sectors in the  $\phi$  plane, small and large MDT chambers sequentially ordered as illustrated in Figure 13(a). Therefore 16 bins in  $\phi$  are used. The same geometrical argument applies to the  $\eta$ -plane of the detector. Three MDT-chambers which are projective to the interaction point define one tower. Twenty towers are defined in  $\eta$  which are the basis for the chosen binning (Figure 13(b)). In total 320 regions are defined in the  $\eta - \phi$  plane.

 Figure 13: Illustration of the chosen  $\phi$  and  $\eta$ -binning of the muon spectrometer

It is important to note that the dominant effect of losing reconstruction efficiency is the acceptance gap due to the absence of MDT chambers. Hence it is a pure geometrical effect mainly in the  $\eta$ -direction. Therefore different physics samples with different  $\eta$ - and to a certain extent also different  $\phi$ - and  $p_T$ -

Table 2: Overall reconstruction efficiencies for different physics processes. Efficiencies with respect to the Monte Carlo truth information are quoted for the sample of events that pass the single muon trigger.

Sample	$\Delta R = 0.05$	$\Delta R = 0.075$	$\Delta R = 0.15$
$Z \rightarrow \mu^+ \mu^-$	0.952	0.956	0.958
$W^\pm \rightarrow \mu^\pm \nu$	0.953	0.958	0.960
$t\bar{t} \rightarrow W^+ W^- b\bar{b}$	0.943	0.948	0.950
$b\bar{b} \rightarrow \mu^+ \mu^-$	0.930	0.944	0.952

distributions will lead to different overall reconstruction efficiencies. An overview of the overall reconstruction efficiencies for different physics samples and track matching distances is shown in Table 2. Hence the in-situ determined efficiencies must be applied in an appropriate binning for different physics samples.

The comparison of the efficiencies determined with Monte Carlo truth information and the tag-and-probe method is shown in Figure 14 for  $\eta$  and  $p_T$ , assuming an aligned muon spectrometer. A track matching distance of  $\Delta R < 0.075$  was chosen. The efficiencies determined in both ways coincide within their statistical uncertainty for an integrated luminosity of  $100 \text{ pb}^{-1}$ . This proves that possible correlations between tag and probe muons are small and can be neglected to a good extent.

Figure 14: Comparison of the muon reconstruction efficiency of the muon spectrometer vs.  $\eta$  and  $p_T$  determined by the tag and probe method and via the Monte Carlo truth information.

The statistical error on the reconstruction efficiency  $\varepsilon$  can be calculated (for large  $N$ ) by

$$\Delta\varepsilon = \sqrt{\frac{\varepsilon(1-\varepsilon)}{N}}, \quad (3)$$

where  $N$  is the number of tag muons. Note that both muons can, and will, be chosen as tag muons in most cases, as the muon spectrometer is expected to have a reconstruction efficiency of 95% on

average. Figure 15 shows the distribution of the in-situ determined efficiencies for all 320 regions. The overall reconstruction efficiency can be determined to a high statistical precision even for relatively low integrated luminosities. A statistical precision of 1% of the overall muon spectrometer reconstruction efficiency can be reached with less than  $1 \text{ pb}^{-1}$ . Figure 16 illustrates the statistical uncertainty averaged over all 320 regions versus the integrated luminosity.

Figure 15: Distribution of muon reconstruction efficiency of the 320 muon spectrometer regions.

Figure 16: Average statistical error of reconstruction efficiency of the 320 regions vs. integrated luminosity.

A possible correlation between tag and probe muons could be caused by the trigger. The probability of reconstructing a muon is significantly higher if it was triggered, as shown in Figure 17. Hence, it might be suspected that this correlation implies also a correlation in real data, since data events must contain at least one muon which has been triggered. This is not a problem as long as the trigger requirement is only applied on the tag muon.

In Section 3.1.1 it was already mentioned that the tag and probe approach has problems in detecting inefficiencies which have a  $\phi \approx \pi$  symmetry. Dividing the data sample in two parts differing in the angle  $\Delta\Phi$  could overcome this problem. One part contains reconstructed tag and probe muons with  $\Delta\Phi < 2.8 \text{ rad}$  the second sample with  $\Delta\Phi > 2.8 \text{ rad}$ . The chosen value of 2.8 rad leads to roughly equally sized samples. Applying the tag and probe method on both sub-samples will lead to different efficiency distributions in case of  $\phi$ -symmetric inefficiencies. Monte Carlo studies showed that for the presently simulated detector layout we expect only small differences (Fig. 18).

Table 3 summarizes statistical and systematic uncertainties of the in-situ determined stand-alone reconstruction efficiency for two different integrated luminosities. The difference in  $|\epsilon_{in-situ} - \epsilon_{true}|$  is calculated via

$$|\epsilon_{in-situ} - \epsilon_{true}| = \sum_{i=1}^N \frac{1}{N} |\epsilon_{in-situ}^i - \epsilon_{true}^i| \quad (4)$$

where the index  $i$  runs over all bins in  $\eta$ -direction. This is treated as primary source of systematic uncertainty. One should note that the given systematic error has a strong statistical component from the Monte Carlo statistics which is reflected in the large decrease of the systematic uncertainty in Table 3.

Figure 17: Reconstruction efficiency of the muon spectrometer for muon tracks which have been triggered and muon tracks which have not been triggered.

Figure 18: Comparison of muon reconstruction efficiencies determined via tag and probe approach for two sets of muons differing by  $\Delta\phi$ .

Table 3: Estimated uncertainties of in-situ determined muon spectrometer reconstruction efficiencies for muons in a  $p_T$ -range between 20 GeV and 70 GeV and within an  $\eta$ -range smaller than 2.5 from a  $Z \rightarrow \mu\mu$  decay.

$\int \mathcal{L}$	Statistical Uncertainty	$ \epsilon_{in-situ} - \epsilon_{true} $	Background Contribution	Overall Systematic
100 pb <sup>-1</sup>	0.08%	0.9%	0.02%	$\approx 1\%$
1 fb <sup>-1</sup>	0.03%	0.1%	0.02%	$\approx 0.1\%$

We take the difference between the efficiency obtained for the misaligned layout and the efficiency obtained for the aligned layout as a conservative estimate of the precision which can be achieved with the tag-and-probe method in case of small unresolved misalignments. The difference in both efficiencies for the different  $\Delta\phi$ -sample is comparable within its statistical uncertainties. The background contribution is only estimated by the Monte Carlo prediction and treated as a systematic uncertainty.

The Gaussian sum of the two systematic uncertainties, namely  $|\epsilon_{in-situ} - \epsilon_{true}|$  and the background contribution, is defined as the overall systematic uncertainty.

The given uncertainty estimation assumes that nearly all MDT chambers work and  $\epsilon_{true} \approx 96\%$ . A lower value of  $\epsilon_{true}$  will lead to an increase of the statistical uncertainty via Equation (3) and also to a higher systematic uncertainty. For real data a conservative estimate of the systematic uncertainty would be the difference of the Monte Carlo prediction for the efficiency and the efficiency determined with collision data. Moreover, it should be noted that the given uncertainties apply for muons in a  $p_T$ -range between 20 GeV and 60 GeV and within an  $\eta$ -range smaller than 2.5.

### 3.1.4 Alternative approach

The tag-and-probe analysis presented above uses isolation cuts to reject background events and assumes that a negligible background contribution remains. In this section, we explore the possibility of determining the reconstruction efficiency from collision data without isolation cuts and determine the background contribution directly in data. We apply only cuts on the transverse momenta, e.g.  $p_T > 10$  GeV. This leads to a dominant background contribution in the lower invariant dimuon-mass region.

In this approach, a tag muon is defined as a muon spectrometer and inner detector combined muon track, with  $p_T > 10$  GeV. A probe muon is defined as any inner detector track, also with  $p_T > 10$  GeV. An invariant mass is then calculated from every combinatoric tag and probe pair with opposite charges. The size of this sample is denoted as  $N$  in the following (Figure 19(b)). Finally, we select a subsample requiring that the probe muon also be a combined muon track. The size of this sample is denoted as  $n$  (Figure 19(a)).

(a) At least one of the muons is matched to a muon spectrometer track.

(b) Both muons are matched to muon spectrometer tracks.

Figure 19: Expected invariant Masses  $M_{\mu\mu}$  resulting from two inner tracks where both muons must be matched to a muon spectrometer track (a) or at least one of the muons must be matched to a muon spectrometer tracks (b).

The track-finding efficiency of the muon spectrometer,  $\varepsilon$ , is then defined as  $n/N$ . Missing tracks in the muon spectrometer will result in  $n < N$  and thus efficiency loss. The main difference from the approach presented in Section 3.1 is that no isolation cuts are used for the background rejection but instead the background is directly estimated from data via side band subtraction. In this approach an exponential function is fitted to the invariant mass region between  $\sim 40$  GeV to  $\sim 60$  GeV, where it is assumed that the background contribution is dominating. The exponential function is then extrapolated to the invariant mass region between  $\sim 81$  GeV to  $\sim 101$  GeV and used for subtraction of the background in this region. The remaining number of events between  $\sim 81$  GeV to  $\sim 101$  GeV define  $n$  and  $N$ , respectively. In this way, the background contribution is accounted for implicitly in data and no further assumptions on the Monte Carlo predictions are made. The disadvantage of this procedure are the systematic uncertainties of the fitting procedure and the choice of the fitting function. One possible improvement with higher statistics of the background sample would be that the Monte Carlo prediction of the shape of the background distribution could be used to obtain a better fit function than the pure exponential for the side

band subtraction.

The systematic uncertainty of this method is again estimated by the residual difference of the in-situ determined efficiency and the true efficiency. For a simulated data sample corresponding to an integrated luminosity of  $\int L dt = 100 \text{ pb}^{-1}$  it is expected to determine the efficiency with this approach up to a precision of

$$\Delta\epsilon = \pm 0.05(\text{sys.}) \quad (5)$$

The relative large systematic uncertainty arises mainly from the limited available statistics of background Monte Carlo samples which has a direct impact on goodness of applied fit. Hence, further improvements are likely to be achieved in future studies.

### 3.2 Determination of the reconstruction efficiency with $J/\Psi$ events

The reconstruction efficiency for muons with transverse momenta less than 20 GeV is not determined from  $Z \rightarrow \mu^+ \mu^-$  events due to the cuts on the transverse momenta of the muons. Muons from  $J/\psi \rightarrow \mu^+ \mu^-$  decays populate the momentum range below 20 GeV. We explored the possibility of using the tag-and-probe method on  $J/\psi \rightarrow \mu^+ \mu^-$  events for the measurement of the reconstruction efficiency at low transverse momenta. The method works well on signal events. Yet the huge QCD background contaminates the selected dimuon data sets so much that a reliable efficiency measurement becomes very difficult. Studies using muon isolation techniques have started. The muon reconstruction efficiency of low- $p_T$  muons must therefore be extracted from Monte Carlo simulations and not be determined easily from data.

## 4 Measurement of the momentum resolution and momentum scale

The muon momentum measurement will be affected by the limited knowledge of the magnetic field, the uncertainty in the energy loss of the muons, and the alignment of the muon spectrometer as discussed in Section 2.4.

The analysis of the measurements of the optical alignment sensors and the collision data with the switched-off toroid coils will provide the position of the muon chambers with an accuracy better than  $100 \text{ } \mu\text{m}$  at the start-up of the LHC [1]. A systematic error of  $100 \text{ } \mu\text{m}$  on the sagitta corresponds to an additional systematic error in the muon momentum of about  $0.1 \text{ TeV}^{-1} \cdot p^2$  which amounts to 250 MeV for  $p=50 \text{ GeV}$ .

Muons with energies below 100 GeV lose on average about 3 GeV of their energy on their passage through the calorimeters almost independently of their energy. The material distribution of the ATLAS detector is modelled in the detector simulation with an accuracy better than a few percent [1]. A 5% uncertainty in the amount of the material traversed by the muons would reflect in a 5% uncertainty of the energy loss, that is an uncertainty of the average energy loss of  $\pm 150 \text{ MeV}$ .

The uncertainty in the bending power of the toroidal field will lead to a momentum uncertainty which is significantly smaller than the energy loss uncertainty and the impact of the misalignment on the momentum measurement. It can therefore be neglected with respect to energy loss uncertainties and the misalignment of the spectrometer.

A bias in the measured muon momentum translates into a bias in the measurement of the dimuon mass in  $Z \rightarrow \mu^+ \mu^-$  decays. An  $\eta$ ,  $\phi$ , and momentum dependent bias will also broaden the dimuon mass peak. The shape of the dimuon invariant mass distribution for  $Z \rightarrow \mu^+ \mu^-$  decays can therefore be used to measure the accuracy of the momentum measurement with collision data.

As the momentum bias caused by misalignment is of the same magnitude, but of opposite sign for  $\mu^+$  and  $\mu^-$  leptons while the energy loss uncertainty has the same sign and magnitude for  $\mu^+$  and  $\mu^-$

leptons, it is possible to disentangle the effect of misalignment and the effect of energy loss errors on the reconstructed  $Z$  mass. The sensitivities of the dimuon invariant mass spectrum to misalignment and errors in the energy-loss correction were therefore studied separately to get a first insight.

#### 4.1 Determination of the energy-loss uncertainty with $Z \rightarrow \mu^+ \mu^-$ events

We begin with the determination of the energy-loss uncertainty with  $Z \rightarrow \mu^+ \mu^-$  events. We assume that the detector is aligned and that the magnetic field is known with the expected accuracy such that its impact on the momentum scale can be neglected. We allow for an error in the energy-loss and, therefore, correct the reconstructed muon energy in each of the 320 spectrometer towers by a tower-dependent constant  $\delta E_{rec,tower}$ :

$$E_{rec,tower} \rightarrow E_{rec,tower} + \delta E_{rec,tower}. \quad (6)$$

We determine the 400 constants  $\delta E_{rec,tower}$  by minimizing

$$\chi^2 = \sum_{\text{dimuon pairs } k} \frac{[(p_{corr,+,k} + p_{corr,-,k})^2 - M_Z^2]^2}{\sigma_k^2} \quad (7)$$

where  $p_{corr,\pm,k}$  denotes the corrected measured  $\mu^\pm$  momentum and  $\sigma_k$  the expected dimuon mass resolution. To estimate the sensitivity to the energy-loss correction, we applied this fit to 40,000 simulated  $Z \rightarrow \mu^+ \mu^-$  events (corresponding to an integrated luminosity of  $50 \text{ pb}^{-1}$ ). The fit gives  $\delta E_{rec,tower}$  with a bias of 100 MeV and a statistical error of the same size. Studies to improve the check of the energy-loss correction with collision data are ongoing.

#### 4.2 Determination of the momentum scale and resolution for a misaligned spectrometer

In a second step, we assume that the energy-loss correction is right and consider the misalignment of the muon spectrometer as the only source of a deterioration of the momentum measurement.

If the Monte Carlo simulation describes the detector correctly, it also predicts the shape of the reconstructed dimuon mass spectrum for  $Z \rightarrow \mu^+ \mu^-$  events correctly. The misalignment of the muon chambers causes a deviation of the measured from the predicted shape of the invariant dimuon mass spectrum. In order to match the Monte Carlo prediction with the experimental measurement, the reconstructed simulated muon momenta must be smeared and shifted. The following procedure was adopted in our analysis: A random number  $\delta p$  normally distributed around 0 with standard deviation  $\sigma_{res}$  was added to the reconstructed simulated muon momenta  $p_{rec,MC}$  and multiplied by a scale factor  $\alpha$ :

$$p_{corr} = \alpha(p_{rec,MC} - \delta p). \quad (8)$$

The inclusion of  $\delta p$  corrects for an underestimation of the momentum resolution. The scale factor  $\alpha$  takes care of systematic shifts between the reconstructed momenta in the experiment and the simulation.  $\alpha$  and  $\sigma_{res}$  are determined by a fit of the corrected simulated invariant dimuon mass spectrum to the experimentally measured spectrum.

To test this approach, the existing  $Z \rightarrow \mu^+ \mu^-$  Monte Carlo data set was divided into two subsamples of equal size corresponding to an integrated luminosity of  $50 \text{ pb}^{-1}$ . The one sample serves as Monte Carlo reference for an aligned muon spectrometer, the other plays the role of the experimental data set. Two scenarios were investigated:

1. The Monte Carlo reference sample and the experimental sample were simulated and reconstructed with the same (aligned) geometry.  $\sigma_{res}$  was fixed to 0 in the analysis of this scenario. Separate scale factors  $\alpha_B$  and  $\alpha_E$  were applied to muon in the barrel ( $|\eta| < 1$ ) and the end-cap region ( $1 \leq |\eta| < 2.7$ ).

2. The Monte Carlo reference sample was simulated and reconstructed with the same (aligned) geometry. But the experimental sample was reconstructed with a different geometry misaligned as described in Section 2.4. In this scenario, two scale factors  $\alpha_B$  and  $\alpha_E$  for the barrel and end-cap parts of the muon spectrometer and a global standard deviation  $\sigma_{res}$  were used as fit parameters.

 Table 4: Fit results for the scale and resolution parameters for an integrated luminosity of  $50 \text{ pb}^{-1}$ .

Layout	$1 - \alpha_B$	$1 - \alpha_E$	$\sigma_{res}$
Aligned	$(4 \pm 14)10^{-4}$	$(1 \pm 13)10^{-4}$	–
Misaligned	$(6 \pm 2)10^{-3}$	$(5 \pm 2)10^{-3}$	$(11.6 \pm 0.3) \%$

The results of the tests are summarized in Table 4. In the ideal case in which the reference and the experimental sample are statistically independent, but equivalent otherwise, the fit gives factors  $\alpha_B$  and  $\alpha_E$  equal to 1 within the statistical errors as expected. In the second scenario, the uncorrected misalignment in the experimental sample leads to a systematic shift of the reconstructed momenta, hence  $\alpha_B$  and  $\alpha_E$  differ from 1 slightly, but significantly, and a large degradation of the momentum resolution from 3.5% to 12% is observed which is consistent with the degradation presented in Section 6. A large  $Z \rightarrow \mu^+ \mu^-$  sample would clearly allow for a finer segmentation than the division in barrel and end-cap parts for the scale factors and lead to smaller values of  $\sigma_{res}$ .

 Figure 20: Dependence of  $\langle p_{corr} - p_{rec,MC} \rangle / p_{rec,MC}$  on  $\eta$  integrated over  $p_T$  and  $\phi$  for  $Z \rightarrow \mu^+ \mu^-$  events in the second scenario of a misaligned detector.

The mean value of  $1 + \frac{p_{corr} - p_{rec,MC}}{p_{rec,MC}}$  is presented in Figure 20 as a function of  $\eta$  for the second scenario. The mean values are spread around 1 with a standard deviation of 0.3%. The maximum deviation from 1 is less than 1%. This results indicates that the Z-mass distribution permits the detection of imperfections in the momentum reconstruction. Studies which use a more refined parametrization of the momentum correction and take into account energy-loss and alignment corrections at the same time are in progress.

We conclude from the studies in this section that it should be possible to control the muon momentum and energy scale on the level of 0.5 GeV for 50 GeV muons with 40,000  $Z \rightarrow \mu^+ \mu^-$  events corresponding

to an integrated luminosity of  $50 \text{ pb}^{-1}$ .

## 5 Conclusions

The performance of the ATLAS muon spectrometer can be predicted by Monte Carlo simulations. The performance of the spectrometer will, however, differ from the prediction due to the initial misalignment of the muon chambers and imperfections in the corrections of the muon energy-loss. It is therefore important to measure the performance with collision data.

We showed in the present article that it is possible to measure the muon reconstruction efficiency with  $Z \rightarrow \mu^+ \mu^-$  events with an accuracy better than 1% with an integrated luminosity of  $100 \text{ pb}^{-1}$ . Selection cuts and the  $p_T$  spectrum of the  $Z$  decay muons limit the momentum measurement to range of  $20 \text{ GeV} < p_T < 70 \text{ GeV}$ . The efficiency measurement can be extended to higher momenta with increased luminosity when the tails of the  $p_T$  spectrum get populated.

We explored the possibility of measuring the efficiency at low transverse momenta with  $J/\psi \rightarrow \mu^+ \mu^-$  events. Our studies show that a reliable efficiency measurement will be difficult due to large irreducible QCD background.

We finally addressed the question of how the momentum and energy scale can be measured with  $Z \rightarrow \mu^+ \mu^-$ . According to our feasibility study it will be possible to control the energy-loss correction on the level of 100 MeV and the momentum scale on the level of 1% for an integrated luminosity of about  $100 \text{ pb}^{-1}$ . More detailed studies are needed to obtain a better estimate of the achievable precision.

# Reconstruction and Identification of Hadronic $\tau$ Decays

## Abstract

In this note the overall performance of the ATLAS detector is discussed for the identification of and measurements with hadronic decays of  $\tau$  leptons in a wide dynamic range of transverse energies, spanning from 10-15 GeV up to at least 500 GeV. In general, hadronically decaying  $\tau$  leptons are reconstructed by matching narrow calorimetric clusters with a small number of tracks. Two complementary approaches, a calorimeter-seeded and a track-seeded algorithm, have been developed to efficiently reconstruct these decays while providing the necessary large rejection against jets from QCD processes. The performance of these algorithms in terms of efficiency and rejection against jets is discussed. In addition, the prospects for the determination of fake  $\tau$  rates as well as the extraction of  $\tau$  lepton signals from  $W$  and  $Z$  boson decays and from  $t\bar{t}$  events in early ATLAS data corresponding to an integrated luminosity of  $100 \text{ pb}^{-1}$  are discussed.

## 1 Introduction

Tau leptons, and particularly their hadronic decays, will play an important role at the LHC. They will provide an excellent probe in searches for new phenomena: the Standard Model Higgs boson at low masses, the MSSM Higgs boson or Supersymmetry (SUSY). Therefore, understanding their selection efficiencies and the cross-sections at which they will be produced is essential for discovering new physics.

Tau leptons are massive particles with a measurable lifetime undergoing electroweak interactions only. The production and the decay of  $\tau$  leptons are well separated in time and space ( $\Gamma_\tau/m_\tau \sim 10^{-11}$ ), providing potential for unbiased measurements of the polarisation, spin correlations, and the parity of the resonances decaying into  $\tau$  leptons. The excellent knowledge of  $\tau$  decay modes from low energy experiments indeed makes this an ideal signature for the observations of new physics.

The interesting transverse momentum range of  $\tau$  leptons spans from below 10 GeV up to at least 500 GeV. Experiments at the LHC will thus have to identify them in a wide momentum range. The low energy range should be optimized for analyses related to  $W$  and  $Z$  boson observability with  $\tau$  decays and also to Higgs boson searches and SUSY cascade decays. The higher energy range is mostly of interest in searches for heavy Higgs bosons in MSSM models and for extra heavy  $W$  and  $Z$  gauge bosons. For illustration, Fig. 1 shows the transverse energy spectrum of the visible decay products of  $\tau$  leptons from different processes of interest normalized to the predicted cross-section with which they will be produced at the LHC and to an integrated luminosity of  $10 \text{ fb}^{-1}$ .

The reconstruction of  $\tau$  leptons is usually understood as a reconstruction of the hadronic decay modes, since it would be difficult to distinguish leptonic modes from primary electrons and muons. Despite a strong physics motivation for exploring data with  $\tau$  leptons in the final state, their reconstruction at hadron colliders remains a very difficult task in terms of distinguishing interesting events from background processes dominated by QCD multi-jet production. Another related challenge is providing efficient triggering for these events while keeping trigger rates at manageable levels.

The availability of various decay modes makes  $\tau$  leptons a rich but not totally unique signature. Hadronically decaying  $\tau$  leptons<sup>1</sup> are distinguished from QCD jets on the basis of low track multiplicities contained in a narrow cone, characteristics of the track system and the shapes of the calorimetric showers. Isolation from the rest of the event is required both in the inner detector and the calorimeter. From this

---

<sup>1</sup>We will often use notation  $\tau_{had}$  in this note when discussing objects reconstructed from the visible part of the hadronic decay products of a  $\tau$  lepton.

Figure 1: The visible transverse energy of  $\tau$  leptons from different physics processes: top quark decays, W/Z production, Standard Model vector boson fusion Higgs boson production for  $m_H = 120$  GeV with  $H \rightarrow \tau\tau$ , for  $\tau$  leptons from low energy Supersymmetry with a light stau (SU1 sample), heavy  $Z'$  bosons, and heavy Higgs bosons from  $bbH$  production in the MSSM with  $\tan\beta = 20(45)$  for masses of 400 GeV (800 GeV).

information, a set of identification variables is built, to which either a traditional cut-based selection or multi-variate discrimination techniques are applied.

The inner detector provides information on the charged hadronic track or the collimated multi-track system reconstructed in isolation from the rest of the event. These tracks should neither match track segments in the muon spectrometer nor reveal features characteristic of an electron track (e.g. high threshold hits in the Transition Radiation Tracker). In the case of a multi-track system, they should be well collimated in  $(\eta, \phi)$  space and the invariant mass of the system should be below the  $\tau$  lepton mass. The charge of the decaying  $\tau$  lepton can be directly determined from the charge(s) of its decay product(s).

Calorimetry provides information on the energy deposit from the visible decay products (i.e. all decay products excluding neutrinos). Hadronically decaying  $\tau$  leptons are well collimated (with an opening angle limited by the ratio  $m_\tau/E_\tau$ ) leading to a relatively narrow shower in the electromagnetic (EM) calorimeter with, for single-prong decays with one or few  $\pi^0$ 's, a significant pure electromagnetic component. On average in this case about 55% of the energy is carried by  $\pi^0$ 's present among the decay products.

The calorimeter and tracking information should match, with narrow calorimeter cluster being found close to the track(s) impact point in the calorimeter. Furthermore, the invariant mass of the cluster should be small and the cluster should be isolated from the rest of the event.

The algorithms for the reconstruction of hadronically decaying  $\tau$  leptons are considered higher level reconstruction as they use components provided by algorithms specific to different subdetectors like track reconstruction in the inner detector or topological clustering of the energy deposits in the calorimeter. At present, two complementary algorithms have been implemented into the ATLAS offline reconstruction software.

- The calorimetry-based algorithm starts from clusters reconstructed in the hadronic and electromagnetic calorimeters and builds the identification variables based on information from the tracker and the calorimeter.
- The track-based algorithm starts from seeds built from few (low multiplicity) high quality tracks collimated around the leading one. The energy is calculated with an energy-flow algorithm based only on tracks and the energy in the electromagnetic calorimeter. All identification variables are built using information from the tracker and the calorimeter.

A short overview of the features of  $\tau$  lepton decays is included in Section 2. In Section 3 selected topics on the performance of the detector directly relevant to the reconstruction and identification of the hadronically decaying  $\tau$  leptons are discussed. Offline reconstruction algorithms and performance results are described in Section 4. In the remaining part of the note strategies for analyses using  $\tau$  leptons with the first 100 pb<sup>-1</sup> of data are presented.

## 2 Topology of $\tau$ leptons in LHC collisions

The transverse momentum range of interest spans from below 10 GeV up to 500 GeV.  $\tau$  leptons decay hadronically in 64.8% of all cases, while in  $\sim 17.8\%$  (17.4%) of the cases they decay to an electron (muon) [1]. From the detection point of view, hadronic modes are divided by the number of charged  $\pi$ s among the decay products into single-prong (one charged  $\pi$ ) and three-prong (three charged  $\pi$ s) decays. The small fraction (0.1%) of five-prong decays is usually too hard to detect in a jet environment. The  $\tau \rightarrow \pi^\pm \nu$  mode contributes 22.4% to single-prong hadronic decays and the  $\tau \rightarrow n\pi^0 \pi^\pm \nu$  modes 73.5%. For three-prong decays, the  $\tau \rightarrow 3\pi^\pm \nu$  decay contributes 61.6%, and the  $\tau \rightarrow n\pi^0 3\pi^\pm \nu$  mode only 33.7%. In general, one- and three-prong modes are dominated by final states consisting of  $\pi^\pm$  and  $\pi^0$ . There is a small percentage of decays containing  $K^\pm$  which nevertheless can be identified using the same technique as for states with  $\pi^\pm$  from the ATLAS detector point of view. A small percentage of states with  $K_S^0$  cannot be easily classified as belonging to either the single-prong or three-prongs categories as the number of registered prongs depends on the actual  $K_S^0$  interaction within the detector. Unless specific studies are done, other multi-prong hadronic modes can be safely neglected.

The lifetime of the  $\tau$  lepton ( $c\tau = 87.11\mu m$ ) in principle allows for the reconstruction of its decay vertex in the case of three-prong decays. The flight path in the detector increases with the Lorentz boost of the  $\tau$  lepton, but at the same time the angular separation of the decay products decreases. A resulting transverse impact parameter of the  $\tau$  decay products can be used to distinguish them from objects originating from the production vertex.

The incorporation of spin effects in  $\tau$  lepton decays is often of importance. This was done within the framework of the ATLAS Monte Carlo simulation and events were generated using PYTHIA [2] interfaced with TAUOLA [3]. The generation process has correctly included full spin correlations in production and decays of the  $\tau$  leptons. Tau leptons from the decay of gauge bosons, Higgs bosons or in SUSY cascade decays will carry information on the polarisation of the decaying resonance and in the case of pair production also some information on the spin correlations. Tau leptons from  $W \rightarrow \tau \nu$  and  $H^\pm \rightarrow \tau \nu$  will be 100% longitudinally polarised, with  $P_\tau = +1.0$  and  $P_\tau = -1.0$  respectively, resulting in different distributions of the charged to total visible energy for single-prong decays in the center-of-mass system of the decaying resonance. At the LHC this effect can be used to suppress  $W \rightarrow \tau \nu$  background and to increase the  $H^\pm \rightarrow \tau \nu$  observability [4]. The  $\tau$  polarisation could also be used as a tool to discriminate between MSSM versus Extra Dimension scenarios [5]. The longitudinal polarisation of  $\tau$  leptons from neutral Higgs boson decays will be democratic with 50% probability, thus  $\tau$  leptons from Higgs boson decays are effectively not polarized. The polarisation of  $\tau$  leptons from Z boson decays will be a more complicated function of the center-of-mass energy of the system and the angle of the decay products [6]. In the cleaner environment of the ILC and also perhaps at the sLHC, building variables sensitive to the longitudinal and transverse spin correlations may lead to a CP measurement of the Higgs boson [7, 8].

## 3 Performance of the ATLAS detector for $\tau$ identification

Hadronic  $\tau$  decays can be efficiently reconstructed and identified using information from the inner detector and from the calorimeter. Reconstruction is done only for the visible part of the decay products,

however, for specific analyses like  $H \rightarrow \tau\tau$  the complete invariant mass of the  $\tau\tau$  system may be reconstructed using the collinear approximation [9] (neutrino momenta parallel to that of the visible decay products). A few selected topics related to the performance of the detector are discussed below before turning to the reconstruction algorithms.

### 3.1 Tracking and vertexing

The reconstruction of tracks from charged pion decays is an important ingredient of the  $\tau_{had}$  reconstruction algorithms. The track-based algorithm is seeded by one or more good quality tracks which allow for the calculation of the  $\tau_{had}$  energy with the so called energy-flow scheme. Both the calo-based and the track-based algorithm determine the charge of the  $\tau_{had}$  candidate by summing up the charge(s) of the tracks reconstructed in the  $\tau_{had}$  core region<sup>2</sup>. The tracking information is further used to identify hadronically decaying  $\tau$  leptons and to discriminate them against the background from hadronic jets by considering the track multiplicity, the impact parameter and the transverse flight path in the case of multi-track candidates. The track selection should therefore ensure high efficiency and quality of the reconstructed tracks over a broad momentum range from 1 GeV to a few hundred GeV.

#### 3.1.1 Reconstruction efficiency and track quality

The efficiency for track reconstruction in  $\tau$  decays is defined as the probability for a given charged  $\pi$  from a  $\tau$  decay to be reconstructed as a track. With respect to the reference tracking performance of the detector established for single muons in the low  $p_T$  range a degradation due to hadronic interactions (a charged  $\pi$  interacting with the material of the inner detector) is expected. In the higher  $p_T$  range a degradation is caused by the strong collimation of the multi-track system for three-prong decays.

Good quality tracks reconstructed with  $p_T$  as low as 1 GeV are required by the track-based algorithm, while the calorimeter-based algorithm accepts any track with  $p_T > 2$  GeV. A standard quality selection has been defined in Ref. [10]. However, for the reconstruction of  $\tau$  leptons a somewhat stricter selection has been applied. Good quality tracks are required to satisfy  $\chi^2/\text{n.d.f} < 1.7$ , to have a number of pixel and SCT hits  $\geq 8$  and transverse impact parameters  $d_0 < 1\text{mm}$ . For the leading track in addition the number of low threshold TRT hits has to be larger than 10 in a pseudorapidity  $\eta$  range up to 1.9, while for the second or third track the presence of a B-Layer hit and ratio of the of high-to-low threshold hits of smaller than 0.2 are required. Both requirements were added to minimize the number of accepted tracks from conversions. A dedicated veto against electron tracks being used as leading tracks is not applied at the reconstruction level. This will be taken care of separately as part of the identification procedure.

Figure 2 shows the reconstruction efficiency for  $p_T = 1 - 50$  GeV using the standard quality selection as defined in Ref. [10]. Adding the additional quality criteria as described above, the overall efficiency for reconstructing good quality tracks from  $\tau$  lepton hadronic decays is reduced to 82 – 83%. The reconstruction efficiency is slightly higher for tracks from single prong decays compared to three-prong decays, where tracks could be very collimated particularly for boosted  $\tau$  leptons.

#### 3.1.2 Charge misidentification

The charge of the  $\tau$  lepton is calculated as the sum of the charges of the reconstructed tracks. For the leading track, which is required (e.g. by the track-based algorithm) to have a transverse momentum<sup>3</sup> larger than 9 GeV, charge mis-identification is limited to  $\sim 0.2\%$  using the quality cuts described above.

<sup>2</sup>The core region for the track-based (calo-based) algorithm is understood here as  $\Delta R < 0.2(0.3)$  cone in  $(\eta, \phi)$  around the reconstructed direction of the visible decay products.

<sup>3</sup>The threshold  $p_T > 9$  GeV on the leading track was used for results presented here, while it was lowered to 6 GeV in the more recent software releases.

Figure 2: Reconstruction efficiency for tracks from charged  $\pi$ s for one- and three-prong hadronic  $\tau$  decays from  $W \rightarrow \tau\nu$  and  $Z \rightarrow \tau\tau$  signal samples as a function of the transverse momentum of the track (left) and of the pseudorapidity for three different ranges of track  $p_T$  (right).

The overall charge mis-identification probability for the hadronically decaying  $\tau$  lepton is however dominated by combinatorial effects: single-prong decays may migrate to the three-prong category due to photon conversions or the presence of additional tracks from the underlying event. A three-prong decay might be reconstructed as a single-prong decay due to inefficiencies of the track reconstruction and selection. This overall charge mis-identification is estimated to be below  $\sim 3.6\%$  without requiring additional quality cuts. In fact, the  $\tau$  charge misidentification is dominated by a combination of effects, but the contributions from the charge misidentification of the individual tracks should not be neglected.

Table 1 shows the percentage of contamination for one- and three-prong candidates using the aforementioned quality criteria for tracks in the core region. For the roughly 3.9% contamination of the single-track candidates from three-prong decays, about 85% are due to hadronic interactions. A 3.8% contamination of three-track candidates from one-prong decays is observed with 70% of them being due to conversions. The percentage of the overall charge misidentification is also shown. Requiring at least one B-Layer hit reduces the charge misidentification both in the case of electron tracks from conversions and in the case of hadronic interactions at low radii. However, this happens at the expense of an additional loss in efficiency in particular for three-prong decays.

### 3.1.3 Tracks from conversions

Photons from  $\pi^0$  decays might convert in the material of the inner detector and then contribute additional tracks to the core or isolation region of the  $\tau_{had}$  candidate. This could result in one-prongs being reconstructed as three-prong candidates, in an inefficiency of the reconstruction and identification criteria and in a degradation of the energy resolution as calculated from the energy-flow algorithm.

A large fraction of reconstructed  $\tau_{had}$  candidates are accompanied by conversions. In 1.5% of the cases a conversion electron is reconstructed as the leading track of the one-prong candidate, while 5.7% of the three-prong candidates contain one reconstructed track coming from a conversion electron. In Table 1 the effects of charge misidentification and contamination from photon conversions are quantified.

### 3.1.4 Impact parameter

The mean proper lifetime of the  $\tau$  lepton is about 0.29 ps. Although the lifetime of the  $\tau$  lepton is about five times shorter than that of the  $b$ -quark, the transverse impact parameters of its decay products are still useful for  $\tau$  identification. The impact parameters,  $d_0$  and  $z_0 \sin(\theta)$ , have been studied for one-prong candidates reconstructed by the track-based algorithm. The transverse impact parameter  $d_0$  is defined

Table 1: Percentage of one- and three prong  $\tau$  lepton hadronic decays within reconstructed one-, two- and three-prong  $\tau_{had}$  candidates by the track-based algorithm, matched to true  $\tau$  decays. Tracks in a cone of  $\Delta R = 0.2$  around the leading good quality track are considered. A transverse momentum of  $p_T > 9$  GeV is required for the leading track. An estimate for electron contamination and charge misidentification is given in addition. Separately specified are results for a subsample where no hadronic secondary interaction of primary charged  $\pi$  was recorded inside the inner detector volume. Events from  $Z \rightarrow \tau\tau$  and  $W \rightarrow \tau\nu$  samples were used.

Seeds for track-based $\tau_{had}$ -candidates	Reconstructed as single-prong	Reconstructed as three-prong	Reconstructed as two-prong
Electron contamination (from conversion)	1.5%	5.7%	2.9%
$\tau \rightarrow \pi^\pm n\pi^0\nu$	96.1%	3.8%	23.8%
$\tau \rightarrow 3\pi^\pm n\pi^0\nu$	3.9 %	96.2%	76.2%
Charge misid. (no had. interact.)	1.7%	3.6%	
	0.4%	2.1%	

Figure 3: Transverse (left) and longitudinal (right) impact parameter resolution as a function of  $|\eta|$  from a one-prong  $Z \rightarrow \tau\tau$  sample. The open (full) circles are from  $\tau \rightarrow \pi(\pi^0)\nu$  ( $\tau \rightarrow \mu\nu\bar{\nu}$ ) events.

as the smallest distance in the transverse plane between the track and the reconstructed primary vertex. The impact parameter  $z_0$  is given by the distance in  $z$ -direction between the reconstructed primary vertex and the point of closest approach in the transverse plane of the track multiplied by  $\sin(\theta)$  to obtain the component transverse to the track direction. Tracks assigned to the  $\tau_{had}$  candidate are not used in the primary vertex fit.

In Fig. 3 the resolution of the transverse (left) and longitudinal (right) impact parameters are shown as a function of  $|\eta|$ . The resolution for final state muons and pions from  $\tau \rightarrow \mu\nu\bar{\nu}$  and  $\tau \rightarrow \pi(\pi^0)\nu$  decays are similar: about  $13 \mu\text{m}$  for  $|\eta| < 1.0$  and about  $50 \mu\text{m}$  for  $|\eta| > 1.0$  for the transverse and longitudinal impact parameters, respectively. No degradation related to hadronic interactions for  $\tau \rightarrow \pi\nu$  decays is observed. This has been verified by studying events with elastic interaction in the Inner Detector (hadronic interaction), defined as events where the outgoing  $\pi^\pm$  carries more than 90 % of the transverse energy of the incoming  $\pi^\pm$ . This observation is consistent with that presented in Ref. [11].

In Fig. 4 distributions of the significances of the impact parameters are presented. The significance is defined as the impact parameters divided by its estimated error. The distribution shows a moderate discrimination power between one-prong candidates reconstructed from hadronic  $\tau$  decays and fake one-prong candidates. Due to the limited resolution of the longitudinal impact parameter, the separation

Figure 4: Significances of the impact parameters  $d_0$  (left) and  $z_0 \sin(\theta)$  (right) for 1-prong  $\tau_{had}$  candidates reconstructed by the track-based algorithm. Distributions are shown for  $\tau_{had}$  candidates reconstructed from  $\tau$  decays and for fake candidates which do not originate from the decays of  $b$ - or  $c$ -hadrons.

between the two classes is less significant in that case.

### 3.1.5 Secondary vertex reconstruction and transverse flight path

The significant lifetime of the  $\tau$  lepton ( $c\tau = 87.11\mu\text{m}$ ) allows the reconstruction of its decay vertex for three-prong decays. Currently, five vertex fitting algorithms [12–14] are implemented in the ATLAS reconstruction framework. Among these the adaptive vertex fitter [13], an iterative re-weighted fit which down-weights tracks according to their weighted distance to the vertex, was found to give the optimal performance.

To estimate its performance, secondary vertex fits were performed using tracks associated with  $\tau_{had}$  candidates from  $Z \rightarrow \tau\tau$  and  $W \rightarrow \tau\nu$  events. The quality criteria applied in the track-based reconstruction were required to be met by the tracks. The  $\tau_{had}$  candidates associated with a true hadronic  $\tau$  decay were divided into two classes. Candidates with three tracks successfully matched to true particles coming from the same true three-prong hadronic  $\tau$  decays were used as a reference. These candidates are denoted hereafter as fully-matched. The second class is composed of the remaining candidates with at least two tracks of which at least one is matched to a true particle coming from a hadronic  $\tau$  decay. These candidates are denoted hereafter as partially matched.

The resolution of the secondary vertex position varies strongly if measured in the perpendicular or parallel direction with respect the momentum of  $\tau_{had}$  candidate. The resolution on the position of the secondary vertex calculated in the plane perpendicular to the momentum of the  $\tau_{had}$  candidate is expected to be better than in the parallel direction due to the collimation of tracks. To estimate the resolution in the transverse plane, the residuals of the vertex position in the direction perpendicular to both momentum of a  $\tau_{had}$  candidate and the beam axis were calculated. The distributions were approximated by a double Gaussian fit. For fully matched three-prong  $\tau_{had}$  candidates there is no significant difference between the distributions obtained with different fitters. The distributions of residuals of the secondary vertex position obtained with the adaptive fitter, parallel and perpendicular to the direction of flight of the  $\tau_{had}$  candidate are presented in Fig. 5. Shown in Table 2 are the resolution<sup>4</sup>, the mean values of the fit and 68.3 % and 95.0 % coverages<sup>5</sup> for the fully matched, partially matched and combined samples. As expected, the transverse resolution ( $\sigma \sim 10 \mu\text{m}$ ) is far more accurate than the parallel one ( $\sigma \sim 600 \mu\text{m}$ ). The non-Gaussian tails are significant in both cases, but far more important in the case of the parallel component. A precise reconstruction of the transverse flight path is therefore possible, which is important for further

<sup>4</sup>In the case of a double Gaussian fit, the width of the central Gaussian will be quoted as the resolution hereafter.

<sup>5</sup>The coverage is the half-width of a symmetric interval covering a given percentage of the distribution.

Figure 5: Residuals of the secondary vertex position parallel and perpendicular to the direction of flight of the  $\tau_{had}$  candidate using the adaptive vertex fitter. Fully (solid) and partially (open) matched three-prong  $\tau_{had}$  candidates reconstructed with the track-based algorithm from  $Z \rightarrow \tau\tau$  and  $W \rightarrow \tau\nu$  processes are used.

Table 2: Resolution and mean of the distribution of residuals of the secondary vertex position in the directions parallel and transverse to that of the reconstructed momentum vector of the  $\tau_{had}$  candidate as obtained from the adaptive vertex fitter. Candidates with up to three associated tracks reconstructed by the track-based algorithm were used. The resolution quoted is the  $\sigma$  of the core Gaussian of a double Gaussian fit in the range  $[-4\text{mm}, 4\text{mm}]$  in the parallel direction and  $[-50\mu\text{m}, 50\mu\text{m}]$  in the transverse direction. The 68.3% and 95% coverages are also quoted.

	Resolution	Mean	68.3%	95%
Parallel				
Fully matched 3-prong	$0.593 \pm 0.008\text{ mm}$	$0.006 \pm 0.006\text{ mm}$	1.27 mm	5.33 mm
Partially matched	$0.703 \pm 0.030\text{ mm}$	$-0.035 \pm 0.020\text{ mm}$	3.83 mm	> 15 mm
Combined	$0.613 \pm 0.008\text{ mm}$	$0.004 \pm 0.006\text{ mm}$	1.89 mm	11.37 mm
Transverse				
Fully matched 3-prong	$10.1 \pm 0.2\mu\text{m}$	$0.2 \pm 0.1\mu\text{m}$	$14.4\mu\text{m}$	$36.9\mu\text{m}$
Partially matched	$11.3 \pm 0.5\mu\text{m}$	$-0.1 \pm 0.2\mu\text{m}$	$20.9\mu\text{m}$	$72.2\mu\text{m}$
Combined	$10.5 \pm 0.2\mu\text{m}$	$0.1 \pm 0.1\mu\text{m}$	$16.4\mu\text{m}$	$48.1\mu\text{m}$

rejection of the QCD background. It may also be possible to obtain a competitive measurement of the  $\tau$  lifetime, which requires a measurement of the flight path and momentum of the  $\tau$  lepton.

Shown in Fig. 6 is the resolution on the transverse flight path as a function of the transverse momentum and the pseudorapidity of the  $\tau_{had}$  candidates. The resolution was obtained from a Gaussian fit to a central interval covering 80% of distributions of residuals of a transverse flight path for the adaptive vertex fitter for fully matched three-prong candidates. In addition the 68.3% and 95% coverages of distributions of residuals are presented.

Distributions of the significance of the transverse flight path, for different classes of three-prong candidates are shown in Fig. 7. This distribution might be used to discriminate between true  $\tau_{had}$  candidates and fake candidates from light jets. The discrimination in the case of  $b$ - and  $c$ - jets seems however to be difficult.

An efficient rejection of tracks coming from photon conversions, decays of long-lived particles and

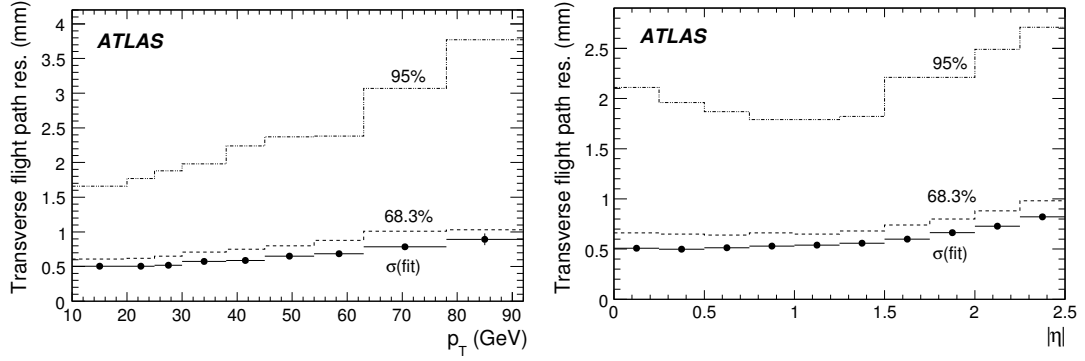

Figure 6: Resolution on the transverse flight path reconstructed with the adaptive vertex fit for fully matched three-prong  $\tau_{had}$  candidates as a function of the transverse momentum (left) and the pseudorapidity (right). Standard deviations of Gaussians fitted to central intervals covering 80% of the residual distributions are shown (black points). In addition the 68.3 % and 95 % coverages of the distributions of residuals of the secondary vertex position are shown (dashed and dot-dashed lines).

Figure 7: Significance of the transverse flight path for fully matched and partially matched three-prong and for fake candidates with and without hadrons containing b or c quarks (the contribution from semileptonic decays of b/c jets into  $\tau$  leptons was not subtracted).

Table 3: Single prong candidates: fractions with zero, one and two or more reconstructed  $\pi^0$  subclusters.

decay mode	no $\pi^0$ subclusters	1 $\pi^0$ subcluster	$\geq 2$ $\pi^0$ subclusters
all $\tau \rightarrow \text{had}\nu$	32%	35%	33%
$\tau \rightarrow \pi\nu$	65%	20%	15%
$\tau \rightarrow \rho\nu$	15%	50%	35%
$\tau \rightarrow a_1(\rightarrow 2\pi^0\pi)\nu$	9%	34%	57%

hadronic interactions in the material reduce the number of one-prong candidates wrongly reconstructed as two- or three-prong candidates and improve the separation between correctly reconstructed three-prong candidates and candidates from light jets. It is a subject of further studies currently in progress.

### 3.2 Reconstruction of $\pi^0$ subclusters

The high granularity of the electromagnetic calorimeter in ATLAS allows for the identification of isolated subclusters from  $\pi^0$ s inside the core region of the reconstructed  $\tau$  lepton hadronic decays.

Studies have been performed based on the topological clustering algorithm [15] with only the middle layer of the calorimeter used for finding primary maxima, and the strip layer used for finding the secondary maxima. The clustering was performed based on cells in a region  $\Delta R < 0.4$  around the direction of the leading track satisfying  $p_T > 9$  GeV and only subclusters with center within  $\Delta R < 0.2$  were taken. A subtraction procedure was applied first to reduce the impact from energy deposits of nearby  $\pi^\pm$ 's and of energy double-counting when adding the latter (track +  $\pi^0$  clusters) to reconstruct the visible  $\tau_{had}$  energy. Namely, before clustering procedure, cells being closest to the impact point of the track ( $\Delta R < 0.0375$ ) were removed. The subtraction was stopped when the subtracted energy exceeded 70% of the track momentum. In the case of coincidence of large energy deposits in the hadronic calorimeter (above 40% of the track momentum) and in the presampler+strip layer close to the track, indicating superposition of  $\pi^0$  and  $\pi^\pm$  showers, cells were subtracted only from the middle layer up to the point where the transverse energy of the remaining cells exceeded  $2.5 \cdot E_T$  collected in the presampler+strip layer (always counted in  $\Delta R < 0.0375$  from the track impact point).

Reconstructed subclusters were required to have  $E_T > 1$  GeV and be separated by  $\Delta R > 0.0375$  from the impact point of the track in the middle layer. In addition, subclusters were accepted if their reconstructed energy in the strip+presampler layers exceeded 10% of their total energy. These requirements efficiently removed about 50% of satellite clusters from charged  $\pi$ s in the case of  $\tau \rightarrow \pi\nu$  decays. Table 3 summarizes the results in terms of the fraction of one-prong candidates reconstructed with a given multiplicity of  $\pi^0$  subclusters.

Reconstructing the track and  $\pi^0$  subclusters for single-prong decays allows for the definition of the energy and visible mass of the hadronic  $\tau$  decays from the vector sum of both components. The procedure was evaluated for one-prong decays from  $W \rightarrow \tau\nu$  events, i.e. for  $\tau$  leptons with visible transverse momenta below 50 GeV. Figure 8 shows the response and resolution obtained by this algorithm for reconstructing the visible energy in decays of type  $\tau \rightarrow \rho\nu$  from  $W \rightarrow \tau\nu$  events in case at least one  $\pi^0$  subcluster is reconstructed. A Gaussian fit to the core region of the distribution yields a resolution of 4.6% with an effective shift of  $-2.4\%$ , dominated by the calibration of the electromagnetic calorimeter not being optimal for the  $\pi^0$  subcluster reconstruction.

As a final benchmark for the quality of the  $\pi^0$  cluster reconstruction discussed above, the invariant mass of  $\tau \rightarrow \rho\nu \rightarrow \pi^0\pi\nu$  decays is reconstructed from the track +  $\pi^0$  subcluster system which is more difficult than the reconstruction of the transverse energy only since the resolution is dominated by the precision of the reconstruction of the angle between the charged and the neutral pion. Figure 8 (right)

Figure 8: The energy response obtained for the visible energy from  $\tau \rightarrow \rho \nu$  events using candidates with one  $\pi^0$  subcluster (left). The invariant mass of the visible decay products for hadronic single-prong  $\tau \rightarrow \rho \nu$ ,  $\tau \rightarrow a_1(\rightarrow 2\pi^0\pi)\nu$ , and  $\tau \rightarrow \pi\nu$  decays using candidates from  $W \rightarrow \tau\nu$  events with at least one  $\pi^0$  subcluster reconstructed (right).

Figure 9: The efficiency of the electron veto algorithm for  $W \rightarrow \tau\nu$  (rectangles) and  $W \rightarrow e\nu$  (triangles) events as a function of  $|\eta|$  and  $p_T$  of the leading track.

shows the reconstructed visible mass for  $\tau \rightarrow \rho \nu$ ,  $\tau \rightarrow a_1(\rightarrow 2\pi^0\pi)\nu$ , and  $\tau \rightarrow \pi\nu$  decays. The relative contributions are proportional to the branching fractions convoluted with the experimental efficiencies of the algorithm applied to inclusive hadronic decays of the  $\tau$  lepton. If more than one  $\pi^0$  subcluster is reconstructed the energy weighted barycenter of the cluster system is taken.

### 3.2.1 Combined veto on electron tracks

An efficient rejection of tracks originating from isolated electrons is important for rejecting backgrounds for example from  $W \rightarrow e\nu$  and  $Z \rightarrow ee$  events. One possibility would be to reject tracks that have been identified as good electron candidates by the standard electron reconstruction algorithm. With the so called tight selection this algorithm is found to reject  $\sim 85\%$  of all electrons from  $W \rightarrow e\nu$  events with a loss of efficiency for true hadronic  $\tau$  decays with  $p_T^{\text{track}} > 9$  GeV of less than 1%.

To achieve a more stringent selection, a dedicated algorithm to veto electrons has been developed aiming at a higher rejection rate while, at the same time, retaining a high fraction of hadronic  $\tau$  decays. It is based on the following variables:

- The energy deposited in the hadronic part of the calorimeter ( $E^{\text{HCAL}}$ ).
- The energy not associated with a charged track in the strip compartment of the electromagnetic

Table 4: Efficiency for hadronically decaying  $\tau$  leptons and true electrons from  $W \rightarrow \tau\nu$  for passing the electron veto algorithm. The numbers given are normalized to true electrons with  $p_T > 9$  GeV and  $|\eta| < 2.5$  (vs. true e) and to reconstructed one-prong or three-prong candidates with the leading track being matched to a  $\pi$  from  $W \rightarrow \tau\nu$  events (vs. reconstructed  $\tau_{had}$ ). The probability that an electron from  $W \rightarrow e\nu$  events with  $p_T > 9$  GeV and  $|\eta| < 2.5$  is reconstructed as one-prong (three-prong) candidate is  $\sim 70\%$  ( $\sim 0.7\%$ ). In addition the performance of the standard algorithm for electron reconstruction [16] is shown. The statistical uncertainty on the numbers presented here is at the level of  $0.1 - 0.5\%$ .

Candidates	Reconstructed as single-prong	Reconstructed as three-prong	Overall
Electron-veto algorithm			
$\tau$ from $W \rightarrow \tau\nu$ (vs reconstructed $\tau_{had}$ )	94.1%	96.2%	94.9%
Electron from $W \rightarrow e\nu$ (vs true e)	1.5%	$< 0.1\%$	1.6%
Standard algorithm (tight selection)			
$\tau$ from $W \rightarrow \tau\nu$ (vs reconstructed $\tau_{had}$ )	99.9%	99.9%	99.9%
Electron from $W \rightarrow e\nu$ (vs true e)	15.6%	0.4%	16.4%
Standard algorithm (medium selection)			
$\tau$ from $W \rightarrow \tau\nu$ (vs reconstructed $\tau_{had}$ )	90.6%	95.1%	92.1%
Electron from $W \rightarrow e\nu$ (vs true e)	4.2%	0.2%	4.6%

part of the calorimeter ( $E_{max}^{strip}$ ).

- The ratio in the transverse plane of the associated energy in the electromagnetic calorimeter and the track momentum ( $E_T/p_T$ ).
- The ratio of the number of high threshold to low threshold hits (including outliers) in the TRT ( $N_{HT}/N_{LT}$ ).

The first two variables are used to divide tracks into categories in which discrimination is provided by fixed cuts on the remaining two variables.

The algorithm yields a rejection factor of 60 against electrons from  $W \rightarrow e\nu$  events at the expense of losing 5% of the signal from  $W \rightarrow \tau\nu$  events. The efficiency of the algorithm <sup>6</sup> as a function of  $|\eta|$  and  $p_T$  is shown in Fig. 9 and its performance is summarized in Table 4. For completeness results from the standard electron reconstruction algorithm are also shown. The dedicated electron-veto described here gives much better efficiency for rejecting isolated electrons from W decay than the standard electron reconstruction algorithm for comparable loss in accepting true hadronic  $\tau$  decays.

## 4 Offline algorithms for $\tau$ reconstruction

Two complementary algorithms for the reconstruction of hadronic  $\tau$  decays have been implemented in the ATLAS offline reconstruction software. Each algorithm is discussed separately below and their performance is compared.

<sup>6</sup>For hadronic decays of  $\tau$  leptons the efficiency is defined w.r.t. the reconstructed  $\tau_{had}$  candidates and for electrons w.r.t. to all electrons inside  $|\eta| \leq 2.5$  with  $p_T > 9$  GeV.

Figure 10: The ratio of the reconstructed ( $E_T$ ) and the true ( $E_T^{\tau-vis}$ ) transverse energy of the hadronic  $\tau$  decay products is shown as a function of the visible true transverse energy  $E_T^{\tau-vis}$  (left), calculated in  $|\eta| < 2.5$  and  $|\eta|$  (right) for taus from  $Z \rightarrow \tau\tau$  (triangles) and  $A \rightarrow \tau\tau$  with  $m_A = 800$  GeV (squares) decays. The ordinate value is the mean and the error bars correspond to the sigma of the Gaussian fit performed in the range  $0.8 < E_T/E_T^{\tau-vis} < 1.2$ . The results are obtained after applying the loose likelihood selection, see below.

#### 4.1 The calorimeter-based algorithm

In this approach [17], hadronically decaying  $\tau$  candidates are reconstructed using calorimeter clusters as seeds. They are obtained from a sliding window clustering algorithm applied to so called calorimeter towers which are formed from cells of all calorimeter layers on a grid of size  $\Delta\eta \times \Delta\phi = 0.1 \times 2\pi/64$ . The energy and position are calculated from the clusters, while all cells with the full granularity of the corresponding calorimeters are used to calculate the quantities involved in  $\tau$  identification as described in the following. Only clusters with a transverse energy  $E_T > 15$  GeV are used. The probability for a true  $\tau$  to be reconstructed as a cluster increases from 20% to 68% over the visible  $\tau$  transverse energy range from 15 to 20 GeV and saturates at 98% for  $E_T > 30$  GeV.

All cells within  $\Delta R < 0.4$  around the barycenter of the cluster are then calibrated with an H1-style calibration [18]. The cell weights are a function of the cell energy density,  $\eta$  and the calorimeter region. These weights have been optimized for jets [18] and only approximately for hadronic  $\tau$  decays. The mean and sigma of a Gaussian fit to the ratio of the reconstructed and the generated energy of the visible  $\tau$  decay products,  $E_T^{\tau-vis}$ , in the range from 0.8 to 1.2 is shown in Fig. 10 as a function of  $E_T^{\tau-vis}$  and  $\eta$ . The resolution is of the order of 10% and an offset in the range from +5 to -7% is observed in the  $\tau$  energy range from 20 to 50 GeV, while at larger energies the offset is of the order of -3 to -5%.

Several quantities that exploit the  $\tau$  lepton properties have been combined in a likelihood function to discriminate hadronic  $\tau$  decays from fake candidates originating from QCD jets. These quantities are described in the following:

- **The electromagnetic radius  $R_{em}$ :**

To exploit the smaller transverse shower profile in  $\tau$  decays, the electromagnetic radius  $R_{em}$  is used, defined as

$$R_{em} = \frac{\sum_{i=1}^n E_{T,i} \sqrt{(\eta_i - \eta_{cluster})^2 + (\phi_i - \phi_{cluster})^2}}{\sum_{i=1}^n E_{T,i}}, \quad (1)$$

where  $i$  runs over all cell in the electromagnetic calorimeter in a cluster with  $\Delta R < 0.4$ . The quantities  $\eta_i$ ,  $\phi_i$ , and  $E_{T,i}$  denote their position and transverse energy in cell  $i$ . Cells may have different sizes depending on the layer and their  $\eta$  value. The size varies from  $\Delta\eta \times \Delta\phi = 0.003 \times$

0.1 in the  $\eta$ -strip region of the barrel to  $0.025 \times 0.025$  for the second calorimeter layer. This leads to a dependence of the performance on  $\eta$ . This variable shows good discrimination power at low  $E_T$  but becomes less effective at higher  $E_T$ .

- **Isolation in the calorimeter:**

Clusters built from hadronic  $\tau$  decays are well collimated and therefore rather tight isolation criteria can be used. Here a ring of  $0.1 < \Delta R < 0.2$  was chosen as the isolation region and the quantity

$$\Delta E_T^{12} = \frac{\sum_i E_{T,i}}{\sum_j E_{T,j}}, \quad (2)$$

is calculated, where the indices  $i$  and  $j$  run over all electromagnetic calorimeter cells in a cone around the cluster axis with  $0.1 < \Delta R < 0.2$  and  $\Delta R < 0.4$ , respectively, and  $E_{T,i}$  and  $E_{T,j}$  denote the transverse cell energies.

Like  $R_{em}$ , the  $\Delta E_T^{12}$  distribution shows an  $E_T$  dependence and becomes narrower with increasing  $E_T$ . This variable also depends on the event type and is expected to be less effective for events with higher hadronic activity, like e.g.  $t\bar{t}$  events.

- **Charge of the  $\tau$  candidate:**

The charge of a  $\tau$  candidate is defined as the sum over the charge(s) of the associated track(s). The misidentification of the charge on the level of a few percent shows almost no  $E_T$  dependence.

- **Number of associated tracks:**

The number of tracks,  $N_{tr}$ , associated with a given cluster within  $\Delta R < 0.3$ . The tracks are required to have  $p_T > 2$  GeV and no specific requirements on the quality of the track reconstruction is made. A significant fraction of events with zero, two, and even four tracks is observed for true hadronic  $\tau$  decays.

- **Number of hits in the  $\eta$  strip layer:**

The number of hits in  $\eta$  direction in the finely segmented strip detector,  $N_{strip}$ , in the first layer of the electromagnetic barrel calorimeter is also used in the likelihood discrimination. Cells in the  $\eta$  strip layer within  $\Delta R < 0.4$  around the cluster axis are counted as hits if the energy deposited exceeds 200 MeV. In contrast to jets, a significant fraction of  $\tau$  leptons deposit nearly no energy in the  $\eta$  strip layer ( $\tau \rightarrow \pi\nu$  decays) and the number of corresponding hits is small.

- **Transverse energy width in the  $\eta$  strip layer**

The transverse energy width  $\Delta\eta$  is defined as

$$\Delta\eta = \sqrt{\frac{\sum_{i=1}^n E_{Ti}^{strip} (\eta_i - \eta_{cluster})^2}{\sum_{i=1}^n E_{Ti}^{strip}}}. \quad (3)$$

where the sum runs over all strip cells in a cone with  $\Delta R < 0.4$  around the cluster axis and  $E_{Ti}^{strip}$  is the corresponding strip transverse energy. Like  $R_{em}$  it is a powerful discriminator at low  $E_T$  but loses discrimination power with increasing  $E_T$  for higher collimated high  $E_T$  jets.

- **Lifetime signed pseudo impact parameter significance:**

At present only a 2-dimensional impact parameter, also called the pseudo impact parameter, is used. It is defined as the distance from the beam axis to the point of closest approach of the track

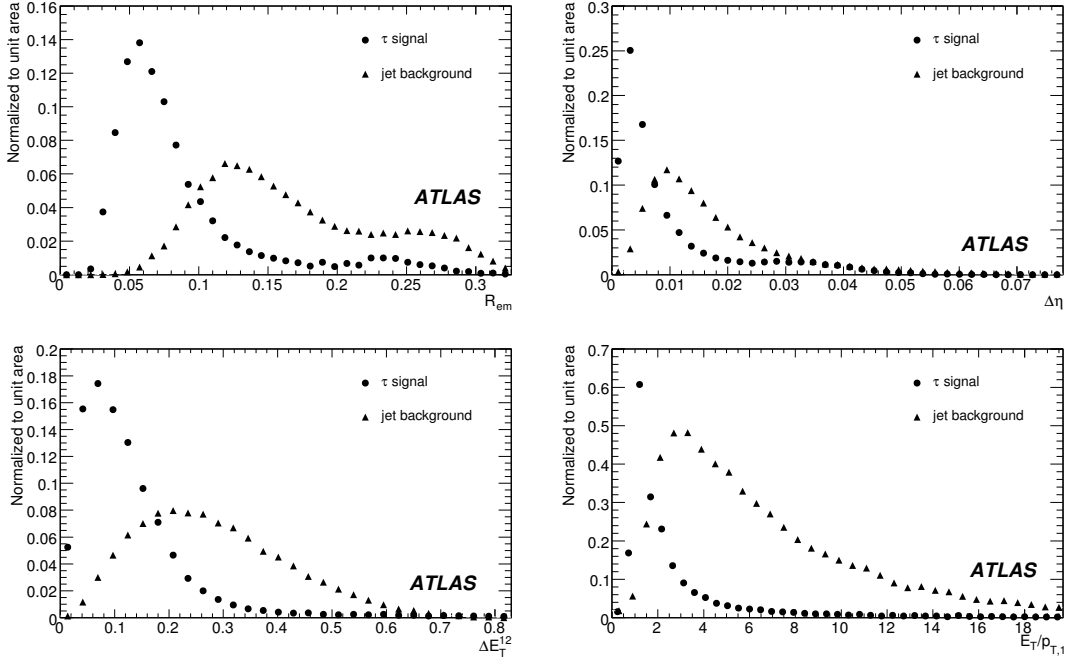

Figure 11: The distributions of a few discriminating variables (electromagnetic radius, energy isolation, transverse energy width in the  $\eta$  strip layer and  $E_T$  over  $p_{T1}$  of the leading track) used in the calorimeter-based tau identification for true tau decays and jets with visible transverse cluster energies  $E_T$  in the range from 40 to 60 GeV and track multiplicities between 1 and 3.

in the plane perpendicular to the beam axis. From this information and from the jet axis, a quantity denoted as lifetime signed pseudo impact parameter significance, defined as  $\text{sig}_{d_0} = d_0 / \sigma_{d_0}^2$  where  $\sigma$  is the impact parameter resolution, is calculated.

- **$E_T$  over  $p_T$  of the leading track:  $E_T / p_{T1}$  :**

For  $\tau$  decays a large fraction of the energy is expected to be carried by the leading track and the ratio of the cluster energy  $E_T$  to the momentum of the leading track  $p_{T1}$  is expected to be large, close to 1. This provides another discrimination against QCD jets, which are expected to have a more uniform distribution of  $p_T$  among the tracks. They are also expected to have more additional neutral particles. Values above one are also expected from  $\tau$  decay modes involving additional  $\pi^0$ s and for three-prong decays. The  $E_T$  dependence is rather modest for  $\tau$  decays but more pronounced for QCD jets, which tend to become more signal like with higher  $E_T$ .

In Fig. 11 the distributions of a few discriminating variables are shown for signal and backgrounds for transverse cluster energies  $E_T$  in the range between 40 and 60 GeV and for candidates with 1 or 3 tracks.

For the calorimeter-based algorithm the  $\tau$  identification is based on a one-dimensional likelihood ratio constructed from three discrete variables ( $N_{\text{tr}}$ ,  $N_{\text{strip}}$  and the charge of the  $\tau$  lepton) and five continuous variables ( $R_{\text{em}}$ ,  $\Delta E_T^{12}$ ,  $\Delta\eta$ ,  $\text{sig}_{d_0}$ , and  $E_T / p_{T1}$ ). For the discrete variables the ratios are directly taken from the reference histograms. For the continuous variables fits of appropriate functions to each variable for all  $E_T$  bins have been performed. The distribution of the likelihood for taus and jets are shown in Fig. 12. Despite any limitation from using only one-dimensional distributions it shows a good separation power.

Figure 12: Left: The log likelihood (LLH) distribution for  $\tau$  leptons (solid) and jets from QCD production (dashed). The likelihood is applied after a preselection on the number of associated tracks, i.e. requiring  $1 \leq N_{tr} \leq 3$ . (Candidates with  $LLH < -10$  had variables outside the boundaries of histograms used when obtaining the PDFs for the likelihood calculation). Right: Efficiency for  $\tau$  leptons and rejection against jets for different  $E_T$  ranges, achieved with the likelihood selection.

It should be noted that the  $\tau$  identification efficiency chosen to keep enough signal events and to achieve the necessary rejection against background depends on the physics channel. Despite the use of  $E_T$  bins the likelihood discrimination shows a residual  $E_T$  dependence. Therefore, a fixed cut on the likelihood value neither will result in a generally flat efficiency, nor will it be optimal.

## 4.2 The track-based algorithm

In this approach [19], the visible part of the hadronically decaying  $\tau$  lepton is seen as a very well collimated object consisting of charged and neutral pions, with the charged component being the leading one, *i.e.* reproducing well the direction of the visible decay products and having significant transverse momentum. This assumption is followed by the requirement of a low multiplicity of tracks reconstructed in the region considered the core of the  $\tau_{had}$  candidate, and the requirement of only minimal energy deposit in the isolation region around the core. The energy-scale of the object and the calorimetric variables used in the identification are built following this picture. For most of the analyses only one-track and three-track candidates should be used. Including candidates with two tracks helps to recover a large fraction of lost three-prong candidates, however it also significantly increases the background from QCD events, in particular for  $\tau$  leptons with visible transverse momentum below 30 GeV. Candidates with track multiplicities larger than three should be used for monitoring the level of fake candidates only.

The reconstruction step consists of identifying and qualifying a leading hadronic track<sup>7</sup> which becomes a seed for building the  $\tau$  candidate. Then up to six additional tracks are allowed in the core region. The  $(\eta, \phi)$  position of the candidate is taken from the direction of the track at the vertex or the track- $p_T$  weighted bary-center in the case of multi-track candidates and the energy of the candidate is calculated from the energy flow method. In addition charge  $\pm 1$  or 0 is required in the case of multi-prong candidates. The identification step consists of calculating calorimetric and tracking quantities and then providing a decision either based on selection with cuts or a discriminating variable based on multi-variate techniques.

<sup>7</sup>The threshold  $p_T > 9$  GeV on the leading track was used for results presented here, while it was lowered to 6 GeV in the more recent software releases.

#### 4.2.1 The energy - flow approach

The energy scale of the hadronic  $\tau_{had}$  candidate is defined using an energy flow algorithm. The energy deposit in cells is divided into categories.

- The pure electromagnetic energy,  $E_T^{emcl}$ :  
The energy is seeded by an isolated electromagnetic cluster which is isolated from the good quality tracks and which has no substantial hadronic leakage. The energy is collected in a narrow window around the seed. Only presampler, strip and middle layers are used.
- The charged electromagnetic energy,  $E_T^{chrgEM}$ ,  $E_T^{chrgHAD}$ :  
The energy is seeded by the impact point of the track(s) in each layer and the energy is collected in a narrow window around it.
- The neutral electromagnetic energy,  $E_T^{neuEM}$ :  
The energy is seeded by the  $(\eta, \phi)$  of the track at the vertex and in each layer the closest cell is searched for. The energy is collected from not yet used cells in a cone of  $\Delta R = 0.2$  with respect to the cell closest to the impact point. Only presampler, strip and middle layers are used.

In the energy-flow approach the charged energy deposits  $E_T^{chrgEM} + E_T^{chrgHAD}$  are replaced by the track(s) momenta (no hadronic neutrals) in order to define the energy scale of the  $\tau_{had}$ . The contribution from  $\pi^0$ 's is included in  $E_T^{emcl}$  and  $E_T^{neuEM}$ ; the effects of  $\pi^0$  and  $\pi^\pm$  depositing energy in the same calorimeter cells or charged energy leakage outside a narrow cone around the track are corrected by adding two terms:  $\sum res E_T^{chrgEM}$  and  $res E_T^{neuEM}$ . The complete definition for the energy scale  $E_T^{eflow}$  reads as follows:

$$E_T^{eflow} = E_T^{emcl} + E_T^{neuEM} + \sum p_T^{track} + \sum res E_T^{chrgEMtrk} + res E_T^{neuEM}. \quad (4)$$

The fractional energy response, calculated as  $(E_{rec} - E_{truth})/E_{truth}$ , for one and three prong candidates is shown in Fig. 13.

The evident advantage from using the above approach for defining the energy scale comes from the fact that while performing well for true hadronic decays of  $\tau$  leptons, it significantly underestimates the nominal energy of fake  $\tau_{had}$ s from jets. This effect is rather obvious since a cone of  $\Delta R = 0.2$  is too narrow to efficiently collect the energy of a QCD jet (particularly with low transverse momentum) and also since a large fraction of the neutral hadronic component is largely omitted in the definition itself (as the energy deposit in the hadronic calorimeter does not contribute to the energy calculations). This leads to a faster falling background spectrum as a function of  $E_T$  compared to that using calibrated calorimetric clusters as implemented in the calorimeter-based algorithm (Section 4.1). This method leads however to more non-Gaussian tails in the fractional energy response than the more conventional energy estimates from calorimetry only.

#### 4.2.2 Identification with calorimetric and tracking variables

Several calorimetric and tracking variables are used to discriminate a narrow, low track multiplicity  $\tau_{had}$  cluster from a hadronic cluster originating from quarks or gluons. If not stated otherwise, the calorimetric and tracking identification quantities are calculated from cells/tracks within a core cone of  $\Delta R = 0.2$  around the seed. The isolation criteria used here are checked in an isolation cone  $\Delta R = 0.2 - 0.4$ . Please note, that although some definitions are very similar for the calorimeter-based and track-based algorithms, in case of the latter the narrower core cone is often used for the calculation of calorimetric quantities and a more explicit distinction between core and isolation cone is made.

Not all discriminating quantities discussed in Section 3 have been already implemented in the identification procedure. In particular transverse impact parameter, transverse flight path and categorizing

Figure 13: The fractional energy response for single-prong (left) and three-prong (right) true  $\tau_{had}$  candidates reconstructed with the track-based algorithm. Events from a  $W \rightarrow \tau \nu$  sample are shown.

single-prong candidates using  $\pi^0$  subclusters have been added only in the current releases of the reconstruction software. Therefore they are not used for the results presented below.

#### • Tracking quantities

- The variance  $W_{tracks}^\tau$  (for multi-prong candidates only), defined as

$$W_{tracks}^\tau = \frac{\sum (\Delta\eta^{\tau, track})^2 \cdot p_T^{track}}{\sum p_T^{track}} - \frac{(\sum \Delta\eta^{\tau, track} \cdot p_T^{track})^2}{(\sum p_T^{track})^2}. \quad (5)$$

- The invariant mass of the tracks system (for multi-track candidates),  $m_{trk3p}$ ,
- The number of tracks in the isolation cone.

#### • Calorimetric quantities

- The electromagnetic radius of the  $\tau_{had}$  candidate,  $R_{em}^\tau$ , as defined in Eq. (1) for the calorimeter-based algorithm, but calculated from cells around the seed belonging to the first three samplings of the electromagnetic calorimeter only (presampler, strips and middle layer).
- The number of  $\eta$  strips,  $N_{strips}^\tau$ , with energy deposits above a certain threshold.
- The width of the energy deposit in the strips, as defined in Eq. (3) for the calorimeter based algorithm but calculated in the core cone only.
- The fraction of the transverse energy,  $fracE_T^{R12}$ , deposited in a cone of radius  $0.1 < \Delta R < 0.2$  with respect to the total energy in a cone of  $\Delta R = 0.2$ . Cells belonging to all layers of the calorimeter are used:

$$fracE_T^{R12} = \frac{\sum E_T^{cell}(R^{\tau, cell} < 0.2) - \sum E_T^{cell}(R^{\tau, cell} < 0.1)}{\sum E_T^{cell}(R^{\tau, cell} < 0.2)}. \quad (6)$$

- The transverse energy,  $E_T^{core}$ , at the EM scale deposited inside the core cone.
- The transverse energy,  $E_T^{isol}$  and  $E_T^{isolHAD}$ , at the EM scale, deposited inside the isolation cone.

#### • Tracking and calorimetric quantities

- The ratio of transverse energy deposited in the hadronic calorimeter in the core region (at the EM scale),  $E_T^{chrgHAD}$ , with respect to the sum of the transverse momenta of the tracks.

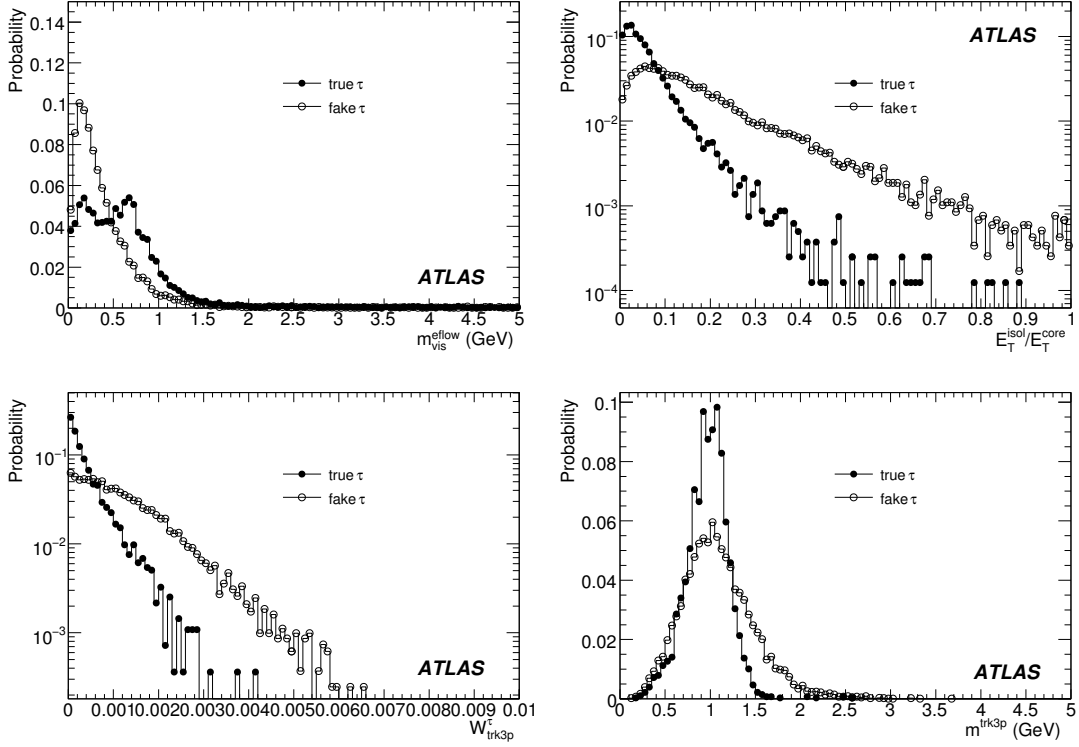

Figure 14: The distributions for signal and backgrounds for the visible mass  $m_{vis}^{eflow}$  and ratio of the transverse energy in the isolation and core region  $E_T^{isol}/E_T^{core}$  for single-prong candidates, and variance  $W_{tracks}^\tau$  and invariant mass of the track system  $m_{trk3p}$  for three-prong candidates. Distributions are shown for the candidates in the transverse energy range  $E_T = 20 - 40$  GeV.

- The visible mass  $m_{vis}^{eflow}$  calculated from cells used for the energy-flow calculation and tracks. In case of multi-prong candidates, where this mass is smaller than that calculated from the four-momenta of the tracks, the invariant mass of the track system is taken instead.

In Fig. 14 as an example the distributions for signal and backgrounds for the  $m_{vis}^{eflow}$ , the ratio  $E_T^{isol}/E_T^{core}$  for single-prong candidates, the variance  $W_{tracks}^\tau$  and the invariant mass  $m_{trk3p}$  for three-prong candidates are shown. Note that the  $m_{vis}^{eflow}$  distribution shows a double peak structure coming from  $\tau \rightarrow \pi^\pm \nu$  and  $\tau \rightarrow \rho(a1) \nu$  decays. The separation for candidates with and without  $\pi^0$  clusters was not done for the distribution shown.

#### 4.2.3 Overall efficiency and rejection

The identification step is done by calculating discriminants using basic cut methods, cut methods optimized by the TMVA package [20], multi-variate analyses based on neural network technique, and from PDRS discrimination [21].

The rejection power expected from the identification step only is quite modest, given that a quite good rejection is already achieved in the reconstruction step. The overall performance is summarized in Table 5. For an efficiency of about 30% with respect to all hadronic decays in the energy range 10 – 30 GeV, rejection rates of 200/360 for one-prong/three-prong hadronic  $\tau$  decays can be achieved with the cut based selection and of 500/700 with multi-variate selection techniques.

Table 5: Efficiencies and rejection rates for different discrimination techniques for the track-based algorithm for fixed efficiencies. The efficiencies are normalized to all hadronic  $\tau$  decays. The rejection rates are calculated with respect to jets reconstructed from true particles in the Monte Carlo. Events from  $Z \rightarrow \tau\tau$  signal samples and QCD dijets were used. The errors given are statistical only.

Selection	Efficiency	Rejection cuts	Rejection TMVA cuts	Rejection NN	Rejection PDRS
$E_T = 10\text{-}30$ GeV					
one-prong	0.33	$225 \pm 10$	$435 \pm 30$	$510 \pm 40$	$460 \pm 40$
three-prong	0.28	$360 \pm 25$	$470 \pm 40$	$740 \pm 70$	$670 \pm 60$
$E_T = 30\text{-}60$ GeV					
one-prong	0.42	$140 \pm 10$	$170 \pm 10$	$440 \pm 40$	$320 \pm 30$
three-prong	0.45	$60 \pm 2$	$90 \pm 10$	$160 \pm 10$	$130 \pm 10$

Table 6: Rejection against jets from Monte Carlo true particles for a 30% efficiency and separately for the one-prong (1p) and three-prong (3p) candidates. The efficiencies are normalized to true hadronic  $\tau$  decays. For the signal  $Z \rightarrow \tau\tau$  events and events from  $bbH, H \rightarrow \tau\tau$  with  $m_H = 800$  GeV were used; for the background QCD dijet-samples were used. The errors given are statistical only.

Algorithm	$E_T = 10\text{-}30$ GeV	$E_T = 30\text{-}60$ GeV	$E_T = 60\text{-}100$ GeV	$E_T > 100$ GeV
Track-based (neural network)	1p: $740 \pm 70$ 3p: $590 \pm 50$	1p: $1030 \pm 160$ 3p: $590 \pm 70$		
Calo-based (likelihood)		1p: $1130 \pm 50$ 3p: $187 \pm 3$	1p: $2240 \pm 140$ 3p: $310 \pm 7$	1p: $4370 \pm 280$ 3p: $423 \pm 8$

### 4.3 Comparison of the two algorithms

Figure 15 shows the expected performance of the two algorithms, illustrated as curves describing the jet rejection versus the efficiency, separately for one and three-prong hadronic  $\tau$ -decays and for different ranges of the visible transverse energy. The jet rejections are computed with respect to jets reconstructed from true particles in the Monte Carlo. The rejections obtained are between a factor of two and ten higher for one-prong decays than for three-prong decays, depending on the algorithm and on the transverse energy range considered. For an efficiency of 30% for one-prong decays, the rejection against jets is typically between 500 and 5000, as illustrated more quantitatively and as a function of the visible transverse energy in Table 6.

Figure 16 shows the normalized track-multiplicity spectra for hadronic  $\tau$  candidates with visible transverse energies above 20 GeV, from  $Z \rightarrow \tau\tau$  decays and from jets, as reconstructed by the track-based algorithm. The distributions are shown after the reconstruction step, after a cut-based identification algorithm and finally after applying a neural network discrimination. The track multiplicity in the jet sample is quite different from that in the signal sample, independently from the cuts applied.

At the same time, Figure 16 indicates that the purity of one-prong and three-prong  $\tau_{had}$  candidates improves in the signal sample since the expected fractions of single versus three prongs are reproduced. For one-prong (three-prong) candidates, the purity improves from 87% (74%) after reconstruction to 91% (86%) after cut-based identification and to 92% (93%) after applying the neural-network discrimination technique.

Figure 16 also shows that using candidates with track multiplicities above three to normalize the

Figure 15: Expected performance for the track-based algorithm with a neural-network selection (left) and the calorimeter-based algorithm with the likelihood selection (right). The rejection rates against jets from Monte-Carlo particles as a function of the efficiency for hadronic  $\tau$  decays for various ranges of the visible transverse energy are shown. For signal events  $Z \rightarrow \tau\tau$  and  $bbH, H \rightarrow \tau\tau$  with  $m_H = 800$  GeV were used, for the background QCD dijet samples were used.

Figure 16: Track multiplicity distributions obtained for hadronic  $\tau$  decays with a visible transverse energy above 20 GeV and below 60 GeV using the track-based  $\tau$  identification algorithm. The distributions are shown after reconstruction, after cut-based identification and finally after applying the neural network (NN) discrimination technique for an efficiency of 30% for the signal (left) and the background (right).

Figure 17: Track multiplicity distributions obtained for hadronic  $\tau_{had}$ -decays with visible transverse energy above 20 GeV and below 60 GeV using the calorimeter-based  $\tau$  identification. The distributions are shown after reconstruction and after applying the likelihood discrimination technique (medium selection) for the signal (left) and the background (right).

QCD background will allow a reasonably precise calibration of the performance using real data, provided the rejection against QCD jets is proven to be sufficient to extract a clean signal in the one-prong and three-prong categories. The sensitivity of such a method can be enhanced by also studying the track multiplicity outside the narrow cone used for  $\tau$ -identification and combining this information with that presented in Fig. 16.

The corresponding spectra for the calorimeter-based algorithm are shown in Figure 17 after reconstruction and after applying the likelihood discriminant. The optimization of the likelihood results in a lower efficiency for accepting three-prong decays which biases the track multiplicity spectra. One should note that candidates with 1-3 tracks are accepted as good  $\tau_{had}$  candidates.

The application of these  $\tau$  identification algorithms to extract  $\tau$  signatures from physics processes and to reject the large backgrounds from QCD processes is discussed in Section 6.

## 5 Fake-rates from QCD di-jet samples

This study demonstrates a simple and generic method to determine the  $\tau_{had}$  fake rate from jets in early data. Since fake rates are expected to be in the range of  $10^{-3}$  to few  $10^{-2}$  for low  $p_T$   $\tau$  leptons, and since the expected rate of QCD jets far exceeds the rate of hadronically decaying  $\tau$  leptons, a precise measurement of fake rates is expected to be crucial for many analyses, and also for a further optimization of the  $\tau_{had}$  identification algorithms. In the following, the method and the results are described and statistical and systematic uncertainties are discussed.

The method proposed here uses a very clean sample of QCD jets, with no significant contamination from true  $\tau$  leptons. This is achieved by selecting dijet events with two jets having similar  $p_T$  and being back-to-back in  $\phi$  (see Fig. 18). One of the two jets is randomly chosen as the so-called ‘tag jet’, for which a cut on the number of tracks ( $n_{Trk} \geq 4$  for  $p_T \leq 50$  GeV + 1 track for each additional 50 GeV interval in  $p_T$ ) ensures that it is not a true hadronic  $\tau_{had}$  decay. If this cut is fulfilled, the other jet, called ‘probe jet’, can be used to measure the fake rate from QCD jets<sup>8</sup>. This is performed both for the calorimeter-based and the track-based  $\tau_{had}$  reconstruction algorithm, with identification according to the medium likelihood selection and cut discriminant, respectively. Note also that, in order to avoid a direct dependence on the trigger, the probe jet should be required to not have caused the event to be triggered.

<sup>8</sup>The fake rate is determined as the number of probe jets identified as  $\tau_{had}$  divided by the number of probe jets.

Figure 18: Example of selections on a MC dijet sample, generated with  $70 \leq p_T \leq 140$  GeV. The two jets have to fulfill  $\Delta\phi \geq (\pi - 0.3)$  in order to be back to back in  $\phi$  (left) and have similar  $p_T$  values (right).

Table 7: The  $\tau_{had}$  fake rate from QCD jets and its statistical uncertainty for the available Monte Carlo statistics and for expected  $100 \text{ pb}^{-1}$  of data in bins of  $p_T$  for both  $\tau_{had}$  reconstruction algorithms.

$p_T$ range (GeV)	Calorimeter-based algorithm		Track-based algorithm	
	MC stat. (%)	Expected stat. error for $100 \text{ pb}^{-1}$ (%)	MC stat. (%)	Expected stat. error for $100 \text{ pb}^{-1}$ (%)
15-40	$2.3 \pm 0.3$	$\pm 0.02$	$2.5 \pm 0.5$	$\pm 0.02$
40-80	$5.2 \pm 2.2$	$\pm 0.01$	$6.7 \pm 2.2$	$\pm 0.01$
80-120	$0.5 \pm 0.2$	$\pm 0.001$	$1.8 \pm 0.6$	$\pm 0.002$
120-160	$0.2 \pm 0.2$	$\pm 0.002$	$1.4 \pm 0.6$	$\pm 0.004$

This method, which achieves low statistical uncertainties even for small datasets, only relies on the dijet and tag jet selection to acquire a clean QCD jet sample and it does not depend, to first order, on the number of true  $\tau$  leptons present in the sample nor on the  $\tau_{had}$  efficiencies. Also, the selection can be easily adapted to select probe jets in an environment similar to the one of any given physics analysis using  $\tau_{had}$  candidates.

To perform these studies, Monte Carlo dijet samples (generated in various  $p_T$  ranges) and samples containing true  $\tau$  leptons ( $Z \rightarrow \tau\tau$ ,  $W \rightarrow \tau\nu$ ) were used. Proper weighting of the samples, including trigger prescales for running at  $\mathcal{L} = 10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ , has been applied. To cross-check the method, it has been verified that there is very good agreement between the values obtained with all selected jets and those coming from jets matched to Monte Carlo particles jets only, which indicates a very high jet purity.

The numerical results of the fake rate determination using the available Monte Carlo statistics for the two algorithms can be found in Table 7. Systematic uncertainties (discussed below) are not included. Note that the uncertainty in the range  $40 < p_T < 80$  GeV, for both algorithms using available Monte Carlo statistics, is dominated by one dijet event (with large weight) in one of the Monte Carlo samples. More interesting are the expected statistical uncertainties in data, which are at the percent or sub-percent level for  $100 \text{ pb}^{-1}$ , and even for  $10 \text{ pb}^{-1}$  of integrated luminosity. This demonstrates the relevance of this method for very early data.

Given the statistical precision of the fake rate results, this measurement of the systematics of other measurements is going to be limited by its own systematic uncertainties. In the following, an outline of the necessary systematic studies is given, including results where possible.

The presence of true hadronically decaying  $\tau$  leptons in the selected Monte Carlo sample is not

statistically significant enough to alter the results within their uncertainties. When more statistics are available, tighter cuts on the tag side can be applied in order to remove more efficiently these types of events.

A slight tendency was observed for the jet samples with lower hard scattering transverse momenta, to show higher fake rates. This can be explained by the fact that the jet characteristics depend on the degree of parton showering. Also, jets from gluons are wider and on average have higher tracks multiplicity than jets from quarks. Then, the fake rate of gluon-jets should be smaller than that of quark-jets. Data triggered with the jet-triggers, that has more gluon-jets than quark-jets, and with single photon triggers, where the quark-jets very likely will be dominant, can be used to understand this effect. However, this type of systematic uncertainty will be small as long as the distributions of observable quantities (such as the number of tracks and the jet isolation) of the probe jets studied for the fake rate is comparable with the properties of the jets faking hadronically decaying  $\tau$  leptons in the physics analysis.

In case there is a physical correlation between the properties of the tag and the probe jet, the selection of the tag jet would directly influence the properties of the probe jet, and hence distort the results. As an example of a possible observable correlation, the number of tracks per jet was studied and it has been found that the correlations were in the sub-percent range. Hence it is concluded that given the current knowledge from Monte Carlo, this source of uncertainty can be neglected. For data, this can be revisited.

## 6 Tau leptons in Standard Model processes

The goals for early  $\tau$  physics in ATLAS include acquiring a sample of  $\tau$  leptons from data with a purity as high possible so that the  $\tau_{had}$  identification efficiency can be measured and the simulation can be tuned. Collecting data with an integrated luminosity of  $100 \text{ pb}^{-1}$  at an instantaneous luminosity of  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  will provide a unique opportunity to access and understand statistically significant  $\tau$  samples from Standard Model processes at relatively low transverse momenta. Processes, like the production of W and Z bosons and top quark pairs with their huge cross section will lead to samples of a few hundred to a few thousand identified hadronic  $\tau$  decays. Hadronically decaying  $\tau$  leptons will then become a well understood probe for discovery physics like searches for Higgs bosons, SUSY, or unexpected phenomena. Below we present feasibility studies for analyses which can be envisaged with an integrated luminosity of  $100 \text{ pb}^{-1}$ .

### 6.1 The $W \rightarrow \tau \nu$ inclusive production

The  $W \rightarrow \tau \nu$  signal will be produced with  $\sigma \times BR = 1.7 \cdot 10^4 \text{ pb}$ , and will be dominated by events with low  $p_T$  of the W-boson resulting in soft  $\tau$  leptons with low missing transverse energy. The expected cross-section of the dominant background from hadronic jets is  $\sim 10^{10} \text{ pb}$  (calculated for hard-scattering  $p_T^{hard} > 8 \text{ GeV}$ ), about 6 orders of magnitude larger than the signal production.

The analysis is very sensitive to the performance of the hadronic  $\tau$ -trigger [22]. These events will have to be triggered with a  $\tau + E_T^{miss}$  trigger, with a configuration adequate to fit into the allowed budget for trigger rates. Given the fact that the physics motivation is to get signal events with  $\tau_{had}$  candidates at low transverse momenta, the present base-line configuration for this analysis is to use  $\tau 20i + EFxE30^9$ , with the  $E_T^{miss}$  trigger applied only at the Event Filter level. The present trigger optimization gives an overall  $\sim 70\%$  trigger efficiency with respect to off-line analysis.

The signal will be extracted requiring one identified hadronic  $\tau$  decay with transverse energy  $E_T = 20 - 60 \text{ GeV}$  and observing the characteristic track multiplicity spectrum of identified hadronic  $\tau$  decays. In the present study the track-based algorithm was used with the medium identification, corresponding

<sup>9</sup>In this notation,  $\tau 20i + EFxE30$  denotes a trigger which requires at least one  $\tau_{had}$  candidate with a transverse energy above 20 GeV and “EFxE30” is short for  $E_T^{miss} > 30 \text{ GeV}$  at the Event Filter level.

to rejection of 700-1000 for the single- and 600 for the three-prong  $\tau$  selection against jets and 30% efficiency for true hadronic  $\tau_{had}$  decays (see Table 6). The overwhelming background from QCD events will be further suppressed by vetoing events with an additional isolated electrons or muons and by increasing the threshold on  $E_T^{miss}$ . An additional handle is to select only events with the topological configuration of the  $\tau_{had}$ ,  $E_T^{miss}$  or additional jets optimal for suppressing events with large fake  $E_T^{miss}$ , *i.e.* excluding those where the  $E_T^{miss}$  direction is close to the direction of the identified  $\tau_{had}$  or an additional jets (see Ref. [23]).

The QCD background has been estimated with a mixture of full and fast simulation, taking into account the necessary corrections for the different slopes in the  $E_T^{miss}$  distribution in the full and fast simulations. It should be noted also that predictions for this overwhelming background are subject to large uncertainties.

An important background is also expected from  $W \rightarrow e\nu$  events, where an electron passes the hadronic  $\tau$ -trigger selection criteria. This channel, with an initial production cross-section of the same order as the signal, but contributing almost exclusively to the single-prong mode, will exceed the signal rates by some factor, before a dedicated electron veto is applied to the single-prong candidates. With the expected performance of such an algorithm, as discussed in Section 3.2.1, this background can be efficiently suppressed, also providing a control channel for the topology of the hadronic part of the  $W \rightarrow \tau\nu$  events passing the trigger and offline selections. Backgrounds from  $Z \rightarrow \tau\tau$ ,  $t\bar{t}$ ,  $Z \rightarrow ee$ ,  $W \rightarrow \mu\nu$  events were also considered and it was estimated that they will be suppressed with the offline selection below a few percent of the signal.

Table 8 summarises the expected event yield at the various stages of the selection. With an  $E_T^{miss}$  threshold of 50 GeV, the expected signal-to-background ratio is 1:1 and about 3240 signal events would be observed. Increasing the threshold to 60 GeV would reduce the number of accepted signal events to 1550 but increase the signal-to-background ratio to 3:1. Figure 19 shows the expected track multiplicity spectrum after the final selection. The optimisation of this selection can be performed using control samples, *i.e.*  $W \rightarrow e\nu$  events extracted from the same filter stream, hence modeling of the W-recoil part of the event will be possible directly from the data. The final optimisation of the chosen efficiency/rejection and offline threshold on  $E_T^{miss}$  will have to be tuned with data, given the large uncertainties on Monte Carlo predictions for the background from hadronic jets. The control on the QCD background normalization will be possible with fake  $\tau_{had}$  with track multiplicity above 3, *i.e.* in the signal-free region.

Table 8: Expected number of events in  $100 \text{ pb}^{-1}$  of data for signal and background after subsequent steps of the selection. The track-based algorithm has been used for  $\tau_{had}$  reconstruction. The QCD background has been estimated combining fast and full simulation. Given are the expected number of events of track multiplicity one to three, *i.e.* contributing to signal region only.

Selection	$W \rightarrow \tau\nu$	$W \rightarrow e\nu$	$W \rightarrow \mu\nu$	QCD dijet	$t\bar{t}$ , $Z \rightarrow ee$ , $Z \rightarrow \tau\tau$
Trigger $\tau 20i + \text{EFxE30}$	$8.8 \cdot 10^4$	$6.1 \cdot 10^5$	$3.2 \cdot 10^4$	$4.8 \cdot 10^8$	$3.0 \cdot 10^5$
Identified $\tau + E_T^{miss} > 30 \text{ GeV}$	$2.0 \cdot 10^4$	2600	200	$3.0 \cdot 10^6$	1600
$E_T^{miss} > 50 \text{ GeV}$	4200	530	90	$5.0 \cdot 10^4$	550

Require jet $p_T > 15 \text{ GeV}$	3240	450	60	3200	80
Increase to $E_T^{miss} > 60 \text{ GeV}$	1550	150	25	500	30

Figure 19: The track multiplicity spectrum of accepted  $\tau_{had}$  candidates after selection as described in the text with thresholds respectively  $E_T^{miss} > 50$  GeV (left) and  $E_T^{miss} > 60$  GeV (right). The expected event numbers are given for an integrated luminosity of  $100 \text{ pb}^{-1}$ .

## 6.2 The $Z \rightarrow \tau\tau$ inclusive production

The inclusive  $Z \rightarrow \tau\tau$  process will provide a ten times lower rate compared to  $W \rightarrow \tau\nu$ , but will have more robust prospects for analysis. It will be possible to cross-check channels with  $e \tau_{had}$  and  $\mu \tau_{had}$  final states to control the background, comparing the number of events observed in the same-sign and opposite-sign samples. Moreover, events will be primarily triggered with lepton triggers providing an unbiased sample of hadronic  $\tau$  decays which could also serve to understand efficiencies of the hadronic  $\tau$ -trigger. The measured cross-section for the  $Z \rightarrow \tau\tau$  process will be an excellent check on the  $\tau$  identification efficiencies, while the lepton identification and trigger efficiencies will be measured first from  $Z \rightarrow \ell\ell$  channels. A measurement of the visible mass of the  $\ell \tau_{had}$  system at low background levels will have sensitivity to the energy scale of the reconstructed  $\tau_{had}$ s.

The analysis presented here is designed to select in the first  $100 \text{ pb}^{-1}$  of data a sufficient number of  $Z \rightarrow \tau\tau \rightarrow \ell\nu\nu \tau_{had}\nu$  events with very low background, which then can be used to determine the  $\tau_{had}$  energy scale from the reconstructed  $\ell\tau_{had}$  visible mass and to determine the  $E_T^{miss}$  scale [23] from the reconstructed complete invariant mass of the  $\tau\tau$  pair (including neutrinos). Events, which have been selected by the single electron or single muon trigger stream are analysed and as a first step an isolated lepton (electron or muon) with  $p_T^\ell > 15$  GeV is required. Then, the set of basic selection cuts is applied. It requires a missing transverse energy  $E_T^{miss} > 20$  GeV (to suppress  $Z \rightarrow \ell\ell$  and QCD backgrounds), transverse mass of the lepton and  $E_T^{miss}$  system  $m_T^{\ell, E_T^{miss}} < 30$  GeV (against  $W \rightarrow \ell\nu$  background), total transverse energy deposited in the calorimeter  $\Sigma E_T^{calo} < 400$  GeV (against  $t\bar{t}$  and QCD backgrounds) and finally no identified b-jet (against  $t\bar{t}$  and QCD backgrounds). In the next step, events with an identified  $\tau_{had}$  with  $p_T > 15$  GeV are selected. The track multiplicity of identified  $\tau_{had}$  is required to be one or three. In addition the angular separation between the isolated lepton and  $\tau$  is imposed, requiring  $\Delta\phi(\ell, \tau_{had})$  to be in the ranges between 1.0 - 3.1 or 3.2-5.3.

The analysis was performed using  $\tau_{had}$  reconstructed with the calorimeter-based algorithm and the identification with the likelihood discriminant. The thresholds on the likelihood discriminant were optimized for this analysis and correspond to an overall efficiency of  $\sim 35\%$  with respect to all hadronic  $\tau$  decays. The QCD background has been estimated with a mixture of full and fast simulation which assumes uncorrelated probabilities for a jet to produce an isolated lepton candidate (predominantly leptons from heavy flavor decays with a small contribution from fakes in the electron case) and for the second jet to produce a fake  $\tau_{had}$  candidate.

Table 9 gives the expected number of signal and background events passing the selection criteria for

Figure 20: Left: The reconstructed visible mass of the  $(\ell\tau_{had})$  pair for  $Z \rightarrow \tau\tau$  decays (solid line) and QCD,  $W \rightarrow \ell\nu$ ,  $Z \rightarrow \ell\ell$  backgrounds (dashed line). Right: The reconstructed visible mass of the  $(\ell\tau_{had})$  pair from  $Z \rightarrow \tau\tau$  decays as a function of the  $\tau_{had}$  energy scale (right). The dashed lines correspond to  $\pm 1\sigma$  and  $\pm 3\sigma$  with respect to the reconstructed peak position. The results were obtained with the calorimeter-based algorithm.

Table 9: Expected number of events in  $100 \text{ pb}^{-1}$  of data for signal and background after reconstruction of the  $\tau$  candidate with the calorimeter-based algorithm and after application of the selection cuts for the  $Z \rightarrow \tau\tau$  channel. The QCD background has been estimated combining fast and full simulation.

Selection	$Z \rightarrow \tau\tau$	$W \rightarrow \ell\nu$	QCD dijet	$t\bar{t}$	$Z \rightarrow \ell\ell$
Isolated lepton	$1.5 \cdot 10^4$	$16.7 \cdot 10^5$	$1.1 \cdot 10^7$	$2.6 \cdot 10^4$	$2.2 \cdot 10^5$
$E_T^{miss} > 20 \text{ GeV}$	4750	$14.3 \cdot 10^5$	$3.2 \cdot 10^5$	$2.4 \cdot 10^4$	$1.0 \cdot 10^4$
$m_T^{\ell, E_T^{miss}} < 30 \text{ GeV}$	3200	$2.6 \cdot 10^4$	$1.8 \cdot 10^5$	3650	3200
$\Sigma E_T < 400 \text{ GeV}$	3000	$2.4 \cdot 10^4$	$1.7 \cdot 10^5$	1280	2800
b-jet veto	2780	$2.4 \cdot 10^4$	$2.7 \cdot 10^4$	135	2600
$\tau_{had}$ -id + $\Delta\phi(\ell\tau_{had})$ cuts	$630 \pm 30$	$210 \pm 10$	$74 \pm 11$	$10 \pm 2$	$30 \pm 5$
OS events, $m^{\ell, \tau_{had}} = 37\text{-}75 \text{ GeV}$	$520 \pm 30$	$45 \pm 5$	$29 \pm 5$	$< 5$	$10 \pm 5$

a data sample of  $100 \text{ pb}^{-1}$ . About 520 signal events are expected in the visible mass  $m_{\ell\tau_{had}}$  window between  $37 - 75 \text{ GeV}$ . The expected background levels are 10% from  $W \rightarrow \ell\nu$  events and about 5% background from QCD events. The reconstructed visible mass of the  $\ell\tau_{had}$  pair is shown in Figure 20 for opposite-sign events.

This selection for  $Z \rightarrow \tau\tau$  events will provide access to signal-suppressed and signal-enriched samples. The same-sign events ( $e\tau_{had}$  and  $\mu\tau_{had}$ ) will be essentially signal-free. This will allow a study of  $\tau_{had}$  identification and mistagging efficiencies. The mistagging efficiency will be estimated from the ratio of accepted to all candidates in different categories (one-prong with and without  $\pi^0$  subclusters, multi-prong). Then, this estimate can be used to predict the background component in opposite-sign events and to tune the Monte Carlo predictions for the identification variables. It will allow a confirmation of the overall consistency and an estimate of the relative error on the background predictions in the signal enriched sample. Finally, a measurement of the cross-section for  $Z \rightarrow \tau\tau$  events relative to the  $Z \rightarrow ee, \mu\mu$  channels will provide a cross-checks on the associated efficiencies.

Once the lepton energy scale is determined with the very first data, the selected  $Z \rightarrow \tau\tau$  events can be used to determine the  $\tau_{had}$  energy scale in-situ. Subtracting the estimated background from opposite-sign events, as measured with the same-sign events, will allow for better estimates on the energy scale

Table 10: Expected number of events in  $100 \text{ pb}^{-1}$  of data for  $t\bar{t} \rightarrow W(\ell\nu)W(\tau_{had}, \nu_\tau)b\bar{b}$  signal and background after subsequent steps in the selection. The track-based algorithm has been used for  $\tau_{had}$  reconstruction.

Selection	$t\bar{t}(\ell, \tau_{had})$	$W \rightarrow \ell\nu + 3 \text{ jets}$	single t	$Z \rightarrow \ell\ell + 2 \text{ jets}$
Isolated lepton $p_T > 20 \text{ GeV}$	1300	$3.9 \cdot 10^5$	4300	630
Identified $\tau_{had}$ $p_T > 15 \text{ GeV}$	190	22000	210	120
1st jet $E_T > 50 \text{ GeV}$ , 2nd jet $E_T > 30 \text{ GeV}$	170	4000	170	35
$E_T^{miss} > 25 \text{ GeV}$	150	3400	150	15
$\Sigma E_T > 250 \text{ GeV}$	150	1750	130	10
Opposite-sign events	130	850	54	$< 10$
1 b-jet tag	67	28	20	

from the shape of the distribution of the visible mass. In Fig. 20 the sensitivity of the measured visible  $Z$  boson mass, as obtained from the reconstructed  $\tau$  pairs, on the absolute  $\tau$  energy scale is shown, assuming only signal events. The statistics correspond to  $100 \text{ pb}^{-1}$  of data. Taking into account only the statistical uncertainties, the  $\tau_{had}$  energy scale could be determined with a precision of  $\sim 3\%$ .

### 6.3 The $\tau$ leptons from $t\bar{t}$ production

With a cross-section of  $833 \text{ pb}$  [24], about 16500 events are expected in  $100 \text{ pb}^{-1}$  with a  $W$  boson decaying into a  $\tau$  lepton. Due to the increased center of mass energy available at the LHC the cross section for  $t\bar{t}$  production increases by nearly two orders of magnitude over what is available at the Tevatron. The  $t\bar{t}$  channel is discussed here as an additional source for  $\tau$  leptons from the SM processes, supplementing samples expected from  $W \rightarrow \tau\nu$  and  $Z \rightarrow \tau\tau$  process.

The decay chain  $t\bar{t} \rightarrow W(qq')W(\tau_{had}\nu)b\bar{b}$  requires events triggered using  $\tau + E_T^{miss}$  triggers,  $\tau$  triggers and multi-jets triggers. In the latter case this will lead to an unbiased sample of  $\tau_{had}$  candidates. The event is required to have at least two light quark jets, two  $b$ -tagged jets, and an identified hadronic  $\tau$  decay. If the event has more than two light quark jets, the pair with the invariant mass closest to the nominal mass of the  $W$  bosons is chosen which is then combined with the closest  $b$  jet to constitute the hadronically decaying top quark. With  $100 \text{ pb}^{-1}$  of data about 300  $t\bar{t} \rightarrow W(qq')W(\tau_{had}\nu)b\bar{b}$  signal events with S:B of 20:1 are expected. These events can be used to study the  $\tau_{had}$  reconstruction and identification performance and to commission the  $\tau$  trigger. The  $p_T$  range of identified  $\tau$  leptons will be complementary to that available from the inclusive  $W$  and  $Z$  boson production. A more detailed description of the analysis is included in Ref. [25].

The decay chain  $t\bar{t} \rightarrow W(e\nu_e, \mu\nu_\mu)W(\tau_{had}, \nu_\tau)b\bar{b}$  is also interesting for both its physics potential and the possibility of using this channel to understand  $\tau_{had}$  identification. These events will be triggered with single lepton triggers and the main background will come primarily from  $W(\rightarrow \ell\nu)$ +jets, single top production and from  $Z(\rightarrow \tau\tau)$ +jets production. The analysis requires an isolated lepton and identified  $\tau_{had}$ . To suppress backgrounds from  $W$ +jets and  $Z$ +jets events it requires two additional high  $E_T$  jets, significant energy deposition in the calorimeter  $\Sigma E_T > 250 \text{ GeV}$  and  $E_T^{miss} > 25 \text{ GeV}$ . Additional background suppression can be achieved by requiring that one or two jets are  $b$ -tagged. Table 10 summarizes cut flow of the analysis.

In the first  $100 \text{ pb}^{-1}$  of data,  $54 \pm 4$  signal events in the  $e\tau_{had}$  channel are expected, with a signal-to-background ratio (S:B) 1:10. The use of  $b$ -tagging rejects considerably the dominant  $W + 3 \text{ jets}$  background (see Fig. 21). If at least one tight  $b$ -tag jet is required the expected number of signal events decreases to  $28 \pm 3$  with S:B improving to 1:1. When requiring a jet in the event that passes the tight  $b$

Figure 21: Combined  $b$ -tagging weights using impact parameter and secondary vertex information for the first two leading  $E_T$  jets, both in  $t\bar{t} \rightarrow W(e\nu_e, \mu\nu_\mu)W(\tau_{had}\nu_\tau)b\bar{b}$  and  $W + 3 jets$  background. The  $e\tau$  ( $\mu\tau$ ) channel is shown on the left (right). The cut value of 7 on the  $b$ -tagging weight is indicated with the arrows. An integrated luminosity of  $100 \text{ pb}^{-1}$  of data is assumed.

tagging criteria, the dominant source of background is still  $W(\rightarrow \ell\nu)+jets$ , however the composition of the background changes and single top production starts contributing significantly, with quark or gluon jets faking  $\tau_{had}$  and true  $b$ -jets from  $b$ -quark fragmentation.

## 7 Summary

Two complementary algorithms for the identification of hadronic  $\tau$  decays in the ATLAS experiment have been developed. The first one (calorimeter based) is seeded from a reconstructed cluster in the calorimeter, the second one (track based) relies on seeds built from reconstructed tracks in the inner detector. Several discrimination methods have been established, including a simple cut-based selection as well as multivariate selections based on likelihood, neutral network, and probability range search techniques. Rejection factors against jets from QCD processes of a few hundred up to a few thousand can be achieved for a  $\tau$  efficiency of 30% in the  $p_T$  range between 10 to 60 GeV. In addition, a dedicated algorithm has been developed to reject electrons that pass the  $\tau$  identification criteria. In the low energy range, rejection factors of the order of 50 and higher against electrons from  $W$  and  $Z$  bosons decays are achieved at the expense of a 5% efficiency loss for hadronic  $\tau$  decays.

It has also been estimated that the expected performance in the ATLAS experiment will be adequate to extract  $\tau$  signals in early LHC data from  $W \rightarrow \tau\nu$  and  $Z \rightarrow \tau\tau$  decays. These signals are important to establish and calibrate the  $\tau$  identification performance with early data. The study of dijet events from QCD processes will allow a determination of  $\tau$  fake rates. It is expected that such rates can be measured with a statistical precision at the percent level or better already with data corresponding to an integrated luminosity of  $100 \text{ pb}^{-1}$ .

## **Jets and Missing Transverse Energy**

# Jet Reconstruction Performance

## Abstract

This section summarizes the general aspects of jet reconstruction with the ATLAS detector. General but brief descriptions of the available jet algorithms are provided, together with a discussion of the performance expectations for the various algorithm configurations in different detector regions and for different physics environments. The emphasis is on realistic estimates for the initial jet reconstruction performance, determined in the absence of experimental data. The corresponding expectations for important jet reconstruction parameters like signal linearity and uniformity, the relative energy resolution, and the jet reconstruction efficiency and purity, are presented.

## 1 Introduction

High quality and highly efficient jet reconstruction is an important tool for almost all physics analyses to be performed with the ATLAS experiment at the Large Hadron Collider (LHC) at CERN. The requirements especially for the absolute precision on the jet energy scale often exceed the corresponding achieved performance in previous experiments. Typically, an absolute systematic uncertainty of better than 1% is desirable for precision physics like the measurement of the top quark mass, and the reconstruction of some SUSY final states.

The principal detector for jet reconstruction is the ATLAS calorimeter system, with its basic components depicted in Fig. 1. It provides near hermetic coverage in a pseudorapidity range  $-4.9 < \eta < 4.9$ . The technology choices are well suited for high quality jet reconstruction in the challenging environment of the proton-proton ( $pp$ ) collisions at  $\sqrt{s} = 14$  TeV at the LHC. The electromagnetic liquid ar-

Figure 1: The ATLAS calorimeter system.

gon/lead calorimeters feature an accordion geometry homogeneous in azimuthal coverage for  $|\eta| < 3.2$ . The hadronic calorimeters surrounding them are iron with scintillating tile readout in the central region ( $|\eta| \lesssim 1.7$ ) and parallel plate liquid argon/copper in the endcap region ( $1.7 \lesssim |\eta| \lesssim 3.2$ ). The forward region is covered by liquid argon/copper and liquid argon/tungsten calorimetry with a tubular electrode readout accommodating the high ionization rates expected at LHC at design luminosity. The readout of the calorimeters is highly granular for the electromagnetic devices, with typically three longitudinal segments with varying lateral cell sizes, e.g.  $\Delta\eta \times \Delta\phi = 0.025 \times 0.025$  in the second segment containing the electromagnetic shower maximum. The hadronic calorimeters are coarser, with typically  $\Delta\eta \times \Delta\phi = 0.1 \times 0.1$ , but have also at least three longitudinal segments. The total number of readout cells in the ATLAS calorimeter system is close to 200,000. The total thickness of the ATLAS calorimeter system for hadrons is at least 10 absorption lengths over the whole acceptance region. More details on the calorimeters, and any other detectors in ATLAS, can be found in Ref. [1].

In this note the approaches used by the ATLAS collaboration to achieve the challenging performance goals are discussed. First, the most commonly used jet finders are briefly introduced in Section 2, together with the theoretical and experimental guidelines for the ATLAS implementations. Then, the expectations for the performance of these algorithms using different detector signals are shown in Section 3. As the focus is on the upcoming initial data taking period of ATLAS, some distortions in the detector alignment and material distributions have been included but not corrected in the results presented here. Finally, special challenges to jet reconstruction like forward going jets and jets in minimum bias events are discussed in Section 4, followed by conclusions in Section 5.

## 2 Jet algorithms in ATLAS

In general an attempt is made to provide implementations of all relevant jet finding algorithms in ATLAS. These include fixed sized cone algorithms as well as sequential recombination algorithms and an algorithm based on event shape analysis. This approach is a response to the fact that there is no universal jet finder for the hadronic final state in all topologies of interest. For example, for the measurement of the inclusive QCD jet cross-sections wider jets are typically preferred to capture the hard scattered parton kinematics, including possible small angle gluon radiation, completely. On the other hand, to reconstruct a  $W$  boson decaying into two jets or to find jets in very busy final states like  $t\bar{t}$  production or possible SUSY signatures, narrow jets are preferred.

The common feature of all jet finder implementations in ATLAS is full four-momentum recombination whenever the constituents of a jet change, either through adding a new constituent, or by removing one, or by changing the kinematic contribution of a given constituent to the jet. Also, in the ATLAS reconstruction software framework ATHENA, the same jet finder code can be run on objects like calorimeter signal towers, topological cell clusters in the calorimeters, reconstructed tracks, and generated particles and partons.

In this section the basics of the present default jet algorithms used in ATLAS are discussed after a brief summary of the theoretical and experimental guidelines for jet algorithm implementation. In addition, some features of jet finders not included in the more comprehensive presentation of jet reconstruction performance in Section 3 are shown.

### 2.1 Guidelines for jet reconstruction

The basic guidelines for jet reconstruction in ATLAS have been extracted from Ref. [2]. They also reflect the concept of *jet definition* discussed in Ref. [3], which is an attempt to provide a common understanding between experiments and theory on how a given jet finding strategy should be specified to assure the highest level of comparability between the results from various sources.

### 2.1.1 Theoretical guidelines

The major theoretical guidelines for jet reconstruction are:

**Infrared safety:** The presence of additional soft particles between two particles belonging to the same jet should not affect the recombination of these two particles into a jet. In the same sense, the absence of additional particles between these two should not disturb the correct reconstruction of the jet. Generally, any soft particles not coming from the fragmentation of a hard scattered parton should not effect the number of jets produced.

**Collinear safety:** A jet should be reconstructed independent of the fact that a certain amount of transverse momentum is carried by one particle, or if a particle is split into two collinear particles.

**Order independence:** The same hard scattering should be reconstructed independently at parton-, particle- or detector level.

Note that from the perspective of experimental data the particles mentioned in these guidelines can, to a point, be replaced by four-momentum type objects reconstructed from detector signals, see e.g. Section 2.5 and Section 2.6 below.

### 2.1.2 Experimental guidelines

Additional aspects of jet reconstruction in ATLAS include features also reflected in the design of the detector. They can be divided into three classes.

**Detector technology independence:** The reconstructed jet and its kinematic variables should not depend on the signal source, i.e. all detector specific signal characteristics and inefficiencies must be calibrated out or corrected as much as possible.

**Detector resolution:** contributions from the finite spatial and energy resolution must be at a minimum;

**Detector environment:** effects from the detector environment like electronics noise, signal losses in un-instrumented (inactive) materials and cracks between detectors must be at a minimum;

**Stable signals:** the detector signal reconstruction and calibration must provide a stable input signal to jet reconstruction.

**Environment independence:** The jet reconstruction environment is characterized by the additional activity in the collision event due to multiple interactions and pile-up, the source of the jet, the underlying event activity, and other features of the  $pp$  collisions at LHC.

**Stability:** a jet should be found and reconstructed safely even in the case of changing underlying event activity and changing instantaneous luminosity, thus changing number of multiple interactions;

**Efficiency:** all physically interesting jets from energetic partons must be identified with high efficiency.

**Implementation:** The jet algorithm implementation must be fully specified in that the jet definition, which consists of the jet finder and its configuration together with the choice of kinematic recombination given in Ref. [3], must be complete. Also included must be all selections and, if important for the measured jet, the signal choices. In addition, the implementation of the jet reconstruction must make efficient use of computing resources, i.e. it must be sufficiently fast and avoid excessive memory consumption.

The most commonly used jet finder implementations in ATLAS are a seeded fixed cone finder with split and merge (see below), and a  $k_T$  algorithm [4, 5] implementation, with an initial implementation as described in Ref. [6], but later replaced by a faster implementation similar to the one in the FASTJET package [7]. It is anticipated that for the first experimental collision data all implementations of the FASTJET library ( $k_T$ , anti- $k_T$ , Cambridge flavor  $k_T$  [8]) will be available, as well as the seedless infrared-safe cone algorithm SISCONe [9]. As there are no complete systematic evaluations of these algorithms available for this note, they are excluded from further discussions here.

## 2.2 Fixed cone jet finder in ATLAS

The ATLAS implementation of the iterative seeded fixed-cone jet finder follows the algorithm description of Ref. [2]. First, all input is ordered in decreasing order in transverse momentum  $p_T$ . If the object with the highest  $p_T$  is above the seed threshold, all objects within a cone in pseudorapidity  $\eta$  and azimuth  $\phi$  with  $\Delta R = \sqrt{\Delta\eta^2 + \Delta\phi^2} < R_{\text{cone}}$ , where  $R_{\text{cone}}$  is the fixed cone radius, are combined with the seed. A new direction is calculated from the four-momenta inside the initial cone and a new cone is centered around it. Objects are then (re-)collected in this new cone, and again the direction is updated. This process continues until the direction of the cone does not change anymore after recombination, at which point the cone is considered stable and is called a jet. At this point the next seed is taken from the input list and a new cone jet is formed with the same iterative procedure. This continues until no more seeds are available. The jets found this way can share constituents, and signal objects contributing to the cone at some iteration may be lost again due to the recalculation of the direction at a later iteration.

This algorithm is not infrared safe, which can be (at least) partly recovered by introducing a split and merge step after the jet formation is done. Jets which share constituents with more than a certain fraction  $f_{\text{sm}}$  of the  $p_T$  of the less energetic jet are merged, while they are split if the amount of shared  $p_T$  is below  $f_{\text{sm}}$ , with  $f_{\text{sm}} = 0.5$  in ATLAS. Other important parameters of the ATLAS cone jet finder are a seed threshold of  $p_T > 1$  GeV, and a narrow ( $R_{\text{cone}} = 0.4$ ) and a wide cone jet ( $R_{\text{cone}} = 0.7$ ) option.

From a theoretical standpoint this particular cone jet finder is by design only meaningful to leading order for inclusive jet cross-section measurements and final states like  $W/Z + 1$  jet, but is not meaningful at any order for 3-jet final states,  $W/Z + 2$  jets, and for the measurement of the dijet invariant mass in 2 jets +  $X$  final states [10].

## 2.3 Sequential recombination algorithms

The default implementation of a sequential recombination jet finder in ATLAS is the  $k_T$  algorithm. Here all pairs  $ij$  of input objects (partons, particles, reconstructed detector objects with four-momentum representation) are analyzed with respect to their relative transverse momentum squared, defined by

$$d_{ij} = \min(p_{T,i}^2, p_{T,j}^2) \frac{\Delta R_{ij}^2}{R^2} = \min(p_{T,i}^2, p_{T,j}^2) \frac{\Delta\eta_{ij}^2 + \Delta\phi_{ij}^2}{R^2},$$

and the squared  $p_T$  of object  $i$  relative to the beam  $d_i = p_{T,i}^2$ . The minimum  $d_{\min}$  of all  $d_{ij}$  and  $d_i$  is found. If  $d_{\min}$  is a  $d_{ij}$ , the corresponding objects  $i$  and  $j$  are combined into a new object  $k$  using four-momentum recombination. Both objects  $i$  and  $j$  are removed from the list, and the new object  $k$  is added to it.

If  $d_{\min}$  is a  $d_i$ , the object  $i$  is considered to be a jet by itself and removed from the list. This procedure is repeated for the resulting new sets of  $d_{ij}$  and  $d_i$  until all objects are removed from the list. This means that all original input objects end up to be either part of a jet or to be jets by themselves. Contrary to the cone algorithm described earlier, no objects are shared between jets. The procedure is infrared safe. As it does not use seeds, it is also collinear safe. The distance parameter  $R$ , which is the only free parameter besides the choice of recombination scheme in this inclusive implementation of the  $k_T$  algorithm, allows

Table 1: Default jet finder configurations used in ATLAS.

Algorithm	Main parameter	Clients
Seeded fixed cone	$R_{\text{cone}} = 0.4$	$W \rightarrow jj$ in $t\bar{t}$ , SUSY
(seed $p_T > 1$ GeV)	$R_{\text{cone}} = 0.7$	inclusive jet cross-section, $Z' \rightarrow jj$
$k_T$	$R = 0.4$	$W \rightarrow jj$ in $t\bar{t}$ , SUSY
	$R = 0.6$	inclusive jet cross-section, $Z' \rightarrow jj$

some control on the size of the jets. Default configurations in ATLAS are  $R = 0.4$  for narrow and  $R = 0.6$  for wide jets.

Table 1 summarizes the algorithms and configurations which have been used by ATLAS for basically all pre-collision physics studies. Thus, these are the base for most predictions related to the performance of the hadronic final state reconstruction for all studied physics channels available to date.

## 2.4 Alternative jet finders

As jet finders others than the “default” algorithms and configurations discussed above can be more appropriate for the precision analysis of specific final states, additional jet algorithms are available in ATLAS for application at the analysis stage. Those are the mid-point variant of the fixed cone algorithm originally introduced by CDF in Ref. [2, 11], and the “optimal jet finder” discussed in Ref. [12]. Both algorithms have been studied for ATLAS and in general provide a very similar performance when compared to the default seeded cone and  $k_T$  implementations. This can be seen in Fig. 2 for the mid-point algorithm, which, as already said, is a flavour of the fixed cone algorithm with the modification that the seeds are placed between two particles with significant  $p_T$ , rather than just using an individual particle  $p_T$  as seed directly. Besides a slightly smaller efficiency in the central region, there are no significant differences between the studied jet finders observed in this non-comprehensive investigation with simulated  $t\bar{t}b\bar{b}$  events.

The optimal jet finder is a departure from the traditional approach of reconstructing each jet rather independent from previously reconstructed jets in the same event. Here the basic scheme is to calculate a weight for each particle reflecting the contribution to any jet by minimizing a test function event by event. This function actually includes weights for contributions to transverse momentum not clustered into any jet at all, thus using the overall event shape when reconstructing the jets. Parameters of the algorithm are a jet cone size and a threshold for the test function. A more exclusive mode is available where the number of jets to be reconstructed can be fixed beforehand. In general this jet finder works well in busy final states like full hadronic top-quark decays in  $t\bar{t}$  production. Predictions for the relative top mass resolution, for example, are basically identical for the default  $k_T$  implementation with  $R = 0.6$  and the optimal jet finder for the same jet size.

## 2.5 Calorimeter jets

The most important detectors for jet reconstruction are the ATLAS calorimeters. In this section the input signals and default calibration schemes for calorimeter jets are briefly described.

The ATLAS calorimeter system [13] has about 200,000 individual cells of various sizes and with different readout technologies and electrode geometries. For jet finding it is necessary to first combine these cell signals into larger signal objects with physically meaningful four-momenta. The two concepts available are calorimeter *signal towers* and *topological cell clusters*.

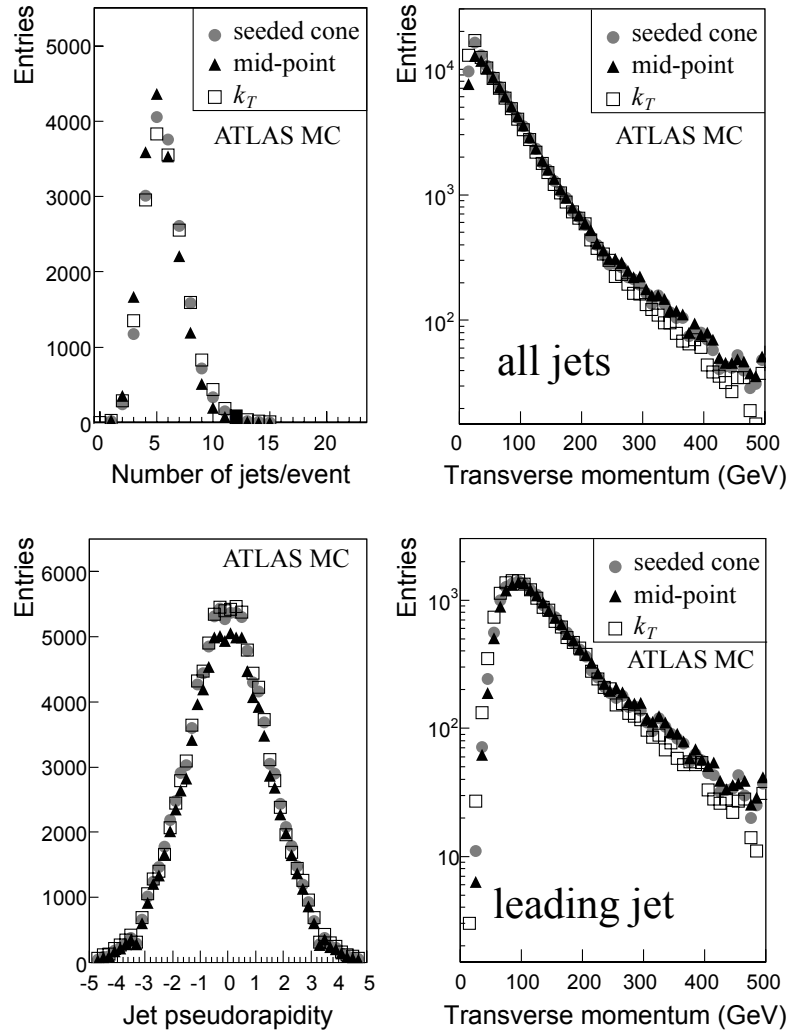

Figure 2: Performance comparison of the ATLAS seeded cone,  $k_T$ , and the mid-point seeded cone for  $t\bar{t}b\bar{b}$  events, as calculated from simulations. Shown are the distributions for jet multiplicity (top left), the  $p_T$  spectrum for all jets (top right), the rapidity distribution (bottom left) and the  $p_T$  spectrum for the leading jets (bottom right).

### 2.5.1 Calorimeter tower signals

In case of the towers, the cells are projected onto a fixed grid in pseudorapidity ( $\eta$ ) and azimuth ( $\phi$ ). The tower bin size is  $\Delta\eta \times \Delta\phi = 0.1 \times 0.1$  in the whole acceptance region of the calorimeters, i.e. in  $|\eta| < 5$  and  $-\pi < \phi < \pi$  with  $100 \times 64 = 6,400$  towers in total. Projective calorimeter cells which completely fit inside a tower contribute their total signal, as reconstructed on a basic electromagnetic energy scale<sup>1</sup>, to the tower signal. Non-projective cells and projective cells larger than the tower bin size contribute a fraction of their signal to several towers, depending on the overlap fraction of the cell area with the towers, see Fig. 3 for illustration.

Figure 3: Calorimeter cell signal contributions to towers on a regular  $\Delta\eta \times \Delta\phi = 0.1 \times 0.1$  grid, for projective and non-projective cells. The signal contribution is expressed as a geometrical weight and is calculated as the ratio of the tower bin area over the projective cell area in  $\eta$  and  $\phi$ .

Thus, the tower signal is the nondiscriminatory sum of possibly weighted cell signals (all cells are included). As the cell signals are on the basic electromagnetic energy scale, the resulting tower signal is on the same scale. No further corrections or calibrations are applied at this stage.

### 2.5.2 Topological cell clusters

The alternative representation of the calorimeter signals for jet reconstruction are topological cell clusters, which are basically an attempt to reconstruct three-dimensional “energy blobs” representing the showers developing for each particle entering the calorimeter. The clustering starts with seed cells with a signal-to-noise ratio, or signal significance  $\Gamma = E_{\text{cell}} / \sigma_{\text{noise, cell}}$ , above a certain threshold  $S$ , i.e.  $|\Gamma| > S = 4$ . All directly neighbouring cells of these seed cells, in all three dimensions, are collected into the cluster. Neighbours of neighbours are considered for those added cells which have  $\Gamma$  above a certain secondary threshold  $N$  ( $|\Gamma| > N = 2$ ). Finally, a ring of guard cells with signal significances above a basic threshold  $|\Gamma| > P = 0$  is added to the cluster. After the initial clusters are formed, they are analyzed for local signal maximums by a splitting algorithm, and split between those maximums if any are found [15].

<sup>1</sup>This is the raw signal from the ATLAS calorimeters. The nomenclature indicates that this scale has been derived from electron signals, but it lacks all corrections applied in high precision electron or photon reconstruction as described in Ref. [14]. It typically includes all electronic corrections and the geometrically motivated corrections for high voltage problems, like inactive electrode sub-gaps and similar.

Figure 4 shows the average number of particles in Monte Carlo generated jets from QCD dijet production together with the number of topological cell clusters in the corresponding simulated calorimeter jets. The figure indicates that the clustering algorithm resolves the particle content of the jet in the pseudorapidity range  $1.5 \lesssim |\eta| \lesssim 2.5$ . The shower overlap between the particles in the jet cannot be resolved as well in the central region  $|\eta| \lesssim 1.5$ , where the calorimeter cell sizes are a bit larger on the scale of the hadronic shower. Here the ratio of number of particles per cluster is approximately 1.6. Similarly, in the forward region  $|\eta| \gtrsim 2.5$  both the increase in shower overlap, due to the decreasing linear distance between jet particles, and the increase of the cell sizes reduce the resolution power of the clustering algorithm for individual particle showers.

Figure 4: Estimates for the average number of particles in seeded fixed size cone jets with  $R_{\text{cone}} = 0.7$  in fully simulated QCD dijet production, shown as function of the pseudorapidity  $\eta$  of the jet. Also shown is the corresponding average number of topological clusters in matching jets found with the same algorithm in the ATLAS calorimeters.

Like towers, clusters are initially formed using the basic electromagnetic energy scale cell signals. These clusters can already be used for jet reconstruction. In addition, clusters can be calibrated to a local hadronic energy scale. This calibration starts with a classification step characterizing clusters as electromagnetic, hadronic, or noise, based on their location and shape. After that, cell signals inside hadronic clusters are weighted with functions depending on cluster location, energy, and the cell signal density. Then, a correction for energy losses in inactive materials close to or inside the cluster is applied. Finally, a correction for signal losses due to the clustering itself (out-of-cluster correction) is applied. Note that all calibrations and corrections for topological clusters are derived from single particle simulations and do not use the jet context.

### 2.5.3 Characteristics of calorimeter input to jet finding

There are attempts in ATLAS to go beyond the high quality reconstruction of the total jet signal with the best possible resolution. Especially the reconstruction of jet structure, including the lateral and longitudinal signal distributions, can be useful to apply jet energy scale corrections jet by jet, or reconstruct the origin of a given jet. The ability to reconstruct this structure depends on the choice of the calorimeter signal definition used in jet finding, as is qualitatively indicated in the simulated high  $p_T$  QCD event in Fig. 5. A given calorimeter signal definition like clusters may reproduce the jet shape at particle level better in certain regions of the calorimeters than in others. For example, from the depicted event in this figure the cluster signals represent the transverse energy flow of particles inside a jet better than the tower jets in the central and endcap regions, while in the forward region the clusters cannot resolve individual

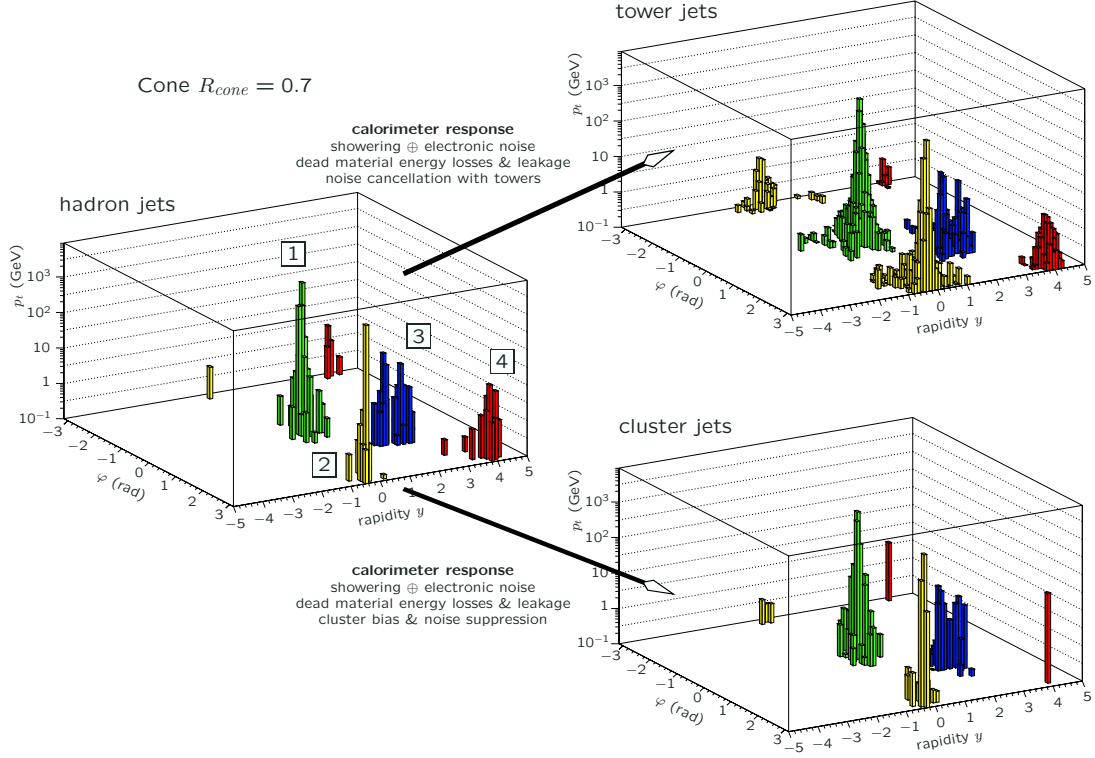

Figure 5: A simulated QCD dijet event with four jets in the final state, as seen at particle level and in the ATLAS calorimeters when using towers or clusters (extracted from Ref. [16]).

showers anymore and thus cannot reproduce the jet shape very well. Here the towers still reflect some spatial structure of the incoming particles.

Another important difference between tower and cluster jets is the number of calorimeter cells used in the jet. While towers include all cells of the ATLAS calorimeters, topological clustering actually applies noise suppression due to the cell signal significance cuts used. This means that many fewer cells contribute to jets in case of clusters, and that the noise contribution per jet is also smaller for cluster jets than for tower jets, see Section 3.3.1 for further discussion.

Jet finding needs physical four-momenta on input. Thus, both towers and clusters are defined as massless pseudo-particles with a four-momentum  $(E, \vec{p})$ , reconstructed from the reconstructed energy  $E$  (either electromagnetic or hadronic scale, see above), and the directions  $\eta$  and  $\phi$ :

$$\begin{aligned}
 E &= |\vec{p}| = \sqrt{p_x^2 + p_y^2 + p_z^2} \\
 p_x &= p \cdot \frac{\cos \phi}{\cosh \eta} \\
 p_y &= p \cdot \frac{\sin \phi}{\cosh \eta} \\
 p_z &= p \cdot \tanh \eta.
 \end{aligned}$$

The directions are fixed to the bin center in the  $(\eta, \phi)$  grid for each tower, while they are reconstructed from the energy-weighted barycenter for topological clusters.

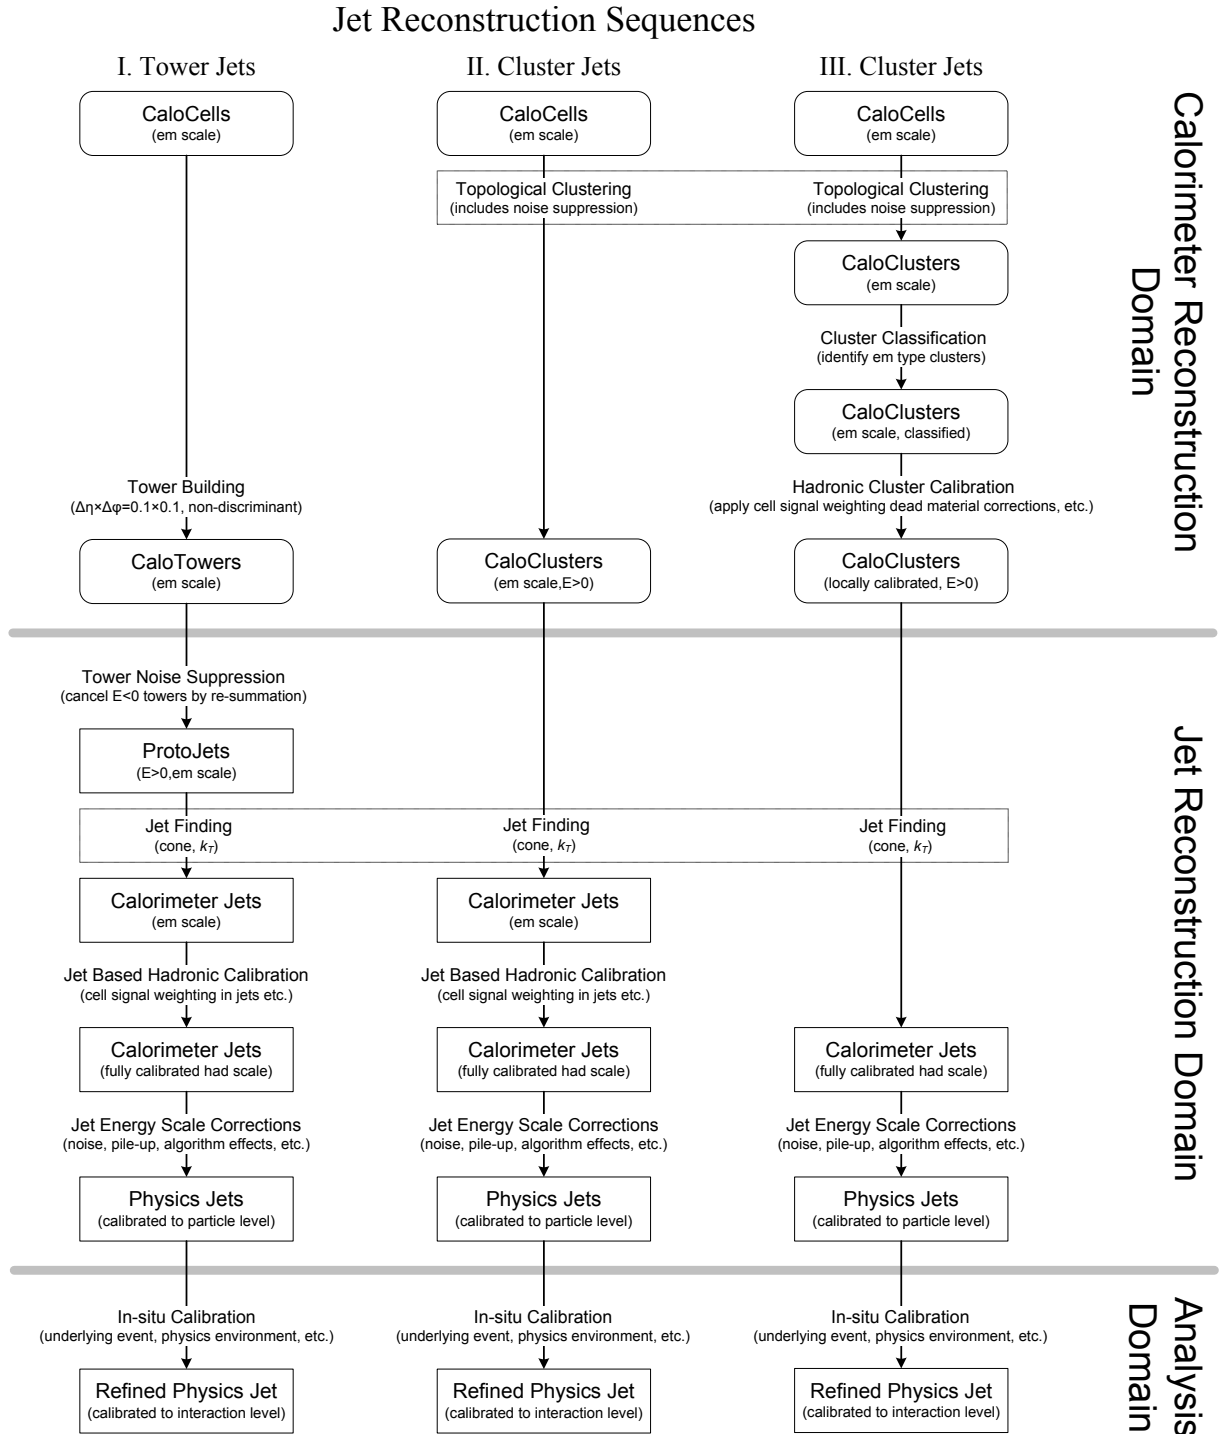

Figure 6: Schematic view on the reconstruction sequences for jets from calorimeter towers (left), uncalibrated (center) and calibrated (right) topological calorimeter cell clusters in ATLAS. The reconstruction (software) domains are also indicated.

#### 2.5.4 Reconstruction flow for calorimeter jets

The general reconstruction algorithm flows for calorimeter jets are summarized in Fig. 6. They reflect the differences between tower and cluster signals. As already discussed, tower signals are on the electromagnetic energy scale while topological clusters are either on this scale or are calibrated on a local hadronic energy scale. Also, tower signals do not include noise suppression, while topological clustering has noise suppression built in.

**Reconstruction sequence I: tower jets** Jet reconstruction from calorimeter towers (left diagram in Fig. 6) starts with a re-summation step, which addresses a possible unphysical four-momentum due to a negative (net) tower signal  $E_{\text{tower}} < 0$ . This can be generated by signal fluctuations from noise (electronics and physics from pile-up) in the cells entering into the corresponding towers. Simply ignoring the negative signal towers enhances the contribution of positive noise fluctuations, but combining negative signal towers with nearby positive signals such that the combined four-momentum is physical with  $E_{\text{tower}} > 0$ , leads to cancellations of some of the noise fluctuations and avoids signal biases. Only negative signal towers without nearby positive signals are completely dropped.

The resulting “protojets” represent either one or a few towers, and have all physically valid four-momenta. They are the input to the actual jet finding algorithm like seeded fixed cone or  $k_T$ . The outputs of the jet finder are then jets with energies on the electromagnetic energy scale. Their constituents are the original calorimeter towers. They are subjected to a cell signal based calibration discussed below in Section 2.5.5. After calibration, jets with  $p_T < 7$  GeV are discarded.

More refined corrections are needed to calibrate the tower jets to the particle level. Those include corrections for residual non-linearities in the jet response due to algorithm effects, like missing energy from the jet, or adding energy not belonging to the jet, in the jet clustering procedure. Other corrections include suppression of signal contributions from the underlying event and/or pile-up. Most of these can only be addressed in the context of a specific physics analysis.

**Reconstruction sequence II: cluster jets** When topological clusters on electromagnetic energy scale are used for jet reconstruction, the reconstruction flow is rather similar to the tower jet reconstruction, see center diagram in Fig. 6. The main difference is the treatment of negative signals. Due to the symmetric noise cut applied in the cell selection in the clustering step, some clusters may have net negative signal as well. These can be ignored for jet reconstruction without significantly biasing the jet signal by positive noise contributions, because the noise suppression applied by the cell clustering already severely reduces any noise contribution. Some additional average cancellation is achieved by the symmetric noise cut, which allows inclusion of some negative cell signals even into positive (physical) clusters.

The cluster jets are initially on the electromagnetic energy scale as well. The same cell signal weighting functions used for tower jets are applied to initially calibrate these jets, with some additional corrections for the fact that these calibration functions have not been optimized for the cluster signals, see Section 2.5.5 for more details. Like in reconstruction sequence I, all jets with  $p_T < 7$  GeV after calibration are discarded.

**Reconstruction sequence III: locally calibrated cluster jets** In this sequence the input objects to jet finding are already calibrated to the local hadronic energy scale [17]. This means that after the jets are formed, they are also calibrated on this scale. Additional corrections needed are related to the fact that all calibrations and corrections for this particular scale have been derived from single pion response only. Additional jet energy losses due to loss of particles in the magnetic field in ATLAS, or in inactive material without leaving any signal above clustering threshold in the calorimeters, have to be corrected in the jet context itself, in addition to the corrections for the physics environment contributions already

discussed for the tower jets. See the right hand side diagram in Fig. 6 for a schematic overview. Fully calibrated jets from this sequence with  $p_T < 7$  GeV are again discarded.

### 2.5.5 Calorimeter jet calibration

The long standing calibration scheme for calorimeter jets in ATLAS is based on cell signal weighting. It can be applied to both tower and cluster jets from the reconstruction sequences I and II, respectively. The basic idea behind this approach, which was originally developed for the CDHS experiment [18] and further refined for the H1 experiment Ref. [19], is that low signal densities in calorimeter cells indicate a hadronic signal in a non-compensating calorimeter and thus need a signal weight for compensation of the order of the electron/pion signal ratio  $e/\pi$ , while high signal densities are more likely generated by electromagnetic showers and therefore do not need additional signal weighting.

To apply the cell signal weighting, first all calorimeter cell signals contributing to a jet are retrieved. This is possible even if the jets have not directly been reconstructed from these cells. The signal in each cell  $i$  in the jet is weighted by a function depending on the cell location  $\vec{X}_i$  and the cell signal density  $\rho_i = E_i/V_i$ , with  $E_i$  being the electromagnetic energy signal of the cell, and  $V_i$  being its volume. The weighting factor is  $\approx 1$  for high density signals and rising up to 1.5, the typical  $e/\pi$  for the ATLAS calorimeters, with decreasing cell signal densities. The weighting functions are universal in that they do not depend on any jet feature or variable. The calibrated jet four-momentum  $(E_{\text{jet, calo}}, \vec{p}_{\text{reco}})$  is then recalculated from the weighted cell signals, which are treated as massless four-momenta  $(E_i, \vec{p}_i)$  with fixed directions:

$$(E_{\text{jet, calo}}, \vec{p}_{\text{calo}}) = \left( \sum_i^{N_{\text{cells}}} w(\rho_i, \vec{X}_i) E_i, \sum_i^{N_{\text{cells}}} w(\rho_i, \vec{X}_i) \vec{p}_i \right). \quad (1)$$

The signal weighting functions have been determined using seeded fixed size cone jets ( $R_{\text{cone}} = 0.7$ ) in fully simulated QCD dijet events by fits of reconstructed calorimeter tower jet energies to matching Monte Carlo truth particle jet energies. Residual non-linearities (as function of  $p_T$ ) and non-uniformities (as function of  $\eta$ ) are corrected by an additional calibration function parametrized in both variables. These corrections have also been calculated for other standard jet finding configurations and calorimeter signals. The calibration has been determined using the ideal, non-distorted detector geometries. See Ref. [17] for more details.

## 2.6 Track jets

Finding jets in reconstructed inner detector tracks is useful to recover possible inefficiencies of the calorimeter signals, especially for jets pointing to transition or crack regions. Even though the scheme of seeding calorimeter jets with track jets in these regions has not been completely evaluated, some recovery may be possible. At least tagging of suspicious event topologies using track jets without matching calorimeter jet, or matching a poorly reconstructed calorimeter jet, allows a suppression of events with significant fake missing transverse momentum in the hadronic final state reconstruction, thus improving the quality of any given sample for physics analysis.

Matching the track jets with calorimeter jets is another promising approach to refine the jet energy measurement jet by jet, and the hadronic final state reconstruction in general. First, the  $p_T$  fraction carried by tracks, defined as

$$f_{\text{trk}} = \frac{p_{T, \text{track}}}{p_{T, \text{calo}}}, \quad (2)$$

with  $p_{T, \text{track}}$  being the transverse momentum from tracks and  $p_{T, \text{calo}}$  being the one reconstructed by the calorimeter, can be measured for each jet within the inner detector acceptance  $|\eta| < 2.5$ . It can then be used to (relatively) improve the jet energy measurement, as indicated in Fig. 7. The figure shows results

obtained from simulations of QCD dijet processes of jets within  $|\eta| < 0.7$  and  $40 < p_T < 60$  GeV. Even though the calorimeter jet calibration performs well on average, there are residual dependencies of the individual jet signal reconstruction quality on the jet fragmentation, i.e. the particle composition of the jet, for which  $f_{\text{trk}}$  provides a handle for a relative correction which can be applied jet by jet. This fragmentation dependency can be understood in that jets with large  $f_{\text{trk}}$  have a larger amount of their energy carried by charged hadrons, which tend to generate a smaller signal in the non-compensating ATLAS calorimeters. The standard jet calibration based on the calorimeter cell signals alone cannot completely recover the corresponding signal loss. This is certainly one of the promising techniques for a relative jet energy scale correction in the context of a refined jet calibration, with the immediate goal of improving the relative jet energy resolution.

Jet finders usually cluster four-momentum in two dimensions, like azimuth  $\phi$  and pseudorapidity  $\eta$ . Inner detector tracks in ATLAS have a reconstructed vertex associated, thus the  $z_{\text{vtx}}$  coordinate can be added as a third dimension to jet finding from these tracks, see Fig. 8. Jet clustering in  $\phi$ ,  $\eta$ , and  $z_{\text{vtx}}$  then allows the assignment of a vertex to a matching calorimeter jet, which is especially of interest in events with multiple interactions from pile-up. In this case jets not associated with the primary vertex can be tagged as such, and removed from the final state in jet counting experiments, e.g. a  $W + n$  jets analysis.

## 2.7 Energy flow jets

In Section 2.6 some aspects of the use of jets from charged tracks reconstructed with the inner detector are discussed. Another approach to improve the jet energy measurement is to match the calorimeter response in towers or clusters with a charged track pointing to it, and use the track kinematics if the track momentum resolution is better than the calorimeter energy resolution for the matched cluster, which for hadrons in ATLAS is the case up to  $p_T \approx 140$  GeV at  $\eta = 0$ . The principal method is referred to as *energy flow* reconstruction, and was pioneered at LEP [20] and is in use in hadron colliders; for example, the CDF application is described in Ref. [21].

The most important feature of energy flow reconstruction is the removal of the calorimeter signal generated by an accepted track. In ATLAS this has been studied using a track-cluster match approach. Figure 9 shows the relative variation of the  $p_T$  resolution for cone jets from energy flow objects and topological clusters in QCD dijet production, both without final energy scale corrections. From this there

Figure 7: The difference between jet  $p_T$  reconstructed from the calorimeter and the matching truth particle jet  $p_T$ , for all jets with  $|\eta| < 0.7$  and  $40 < p_T < 60$  GeV, and jets from this sample in two regions of the track  $p_T$  fraction  $f_{\text{trk}}$  defined in Eq.(2) (left). The plot in the center shows the relative difference  $\Delta p_T/p_{T,\text{truth}}$  for various bins of  $f_{\text{trk}}$  and as function of the calorimeter jet  $p_T$ . The distributions of  $\Delta p_T$  after applying these corrections are shown in the right figure. The lightly shaded area indicates the distribution for all jets, without any selection based on  $f_{\text{trk}}$ .

Figure 8: Track jets in the horizontal  $(x, z)$  plane of a simulated event with multiple vertices. The left figure shows tracks assigned to cone jets with  $p_T > 5$  GeV using the usual two-dimensional clustering algorithm in  $\eta$  and  $\phi$ , with  $R_{\text{cone}} = 0.4$  (same line patterns and shades indicate same jet). Clearly tracks from different vertices can end up in the same jet. The right figure shows cone jets from three-dimensional clustering for the same event, explicitly including the track vertices ( $R_{\text{cone}} = 0.4$ ,  $\Delta z = 10\text{mm}$ ).

Figure 9: The ratio of the relative  $p_T$  resolutions for energy flow and cluster cone jets  $\sigma_{\text{efflow}} / \sigma_{\text{calo}}$ , as determined with fully simulated dijet events, as function of the jet  $p_T$ . Results for both narrow ( $R_{\text{cone}} = 0.4$ ) and wide ( $R_{\text{cone}} = 0.7$ ) jets within  $|\eta| < 1.8$  are shown.

are indications that for jets with  $p_T \lesssim 80$  GeV in this environment, which is characterized by typically low event activity in general, the jet energy resolution can be improved by the energy flow technique. The expected gain is most significant at lower jet  $p_T$ , e.g. about 15% (relative) at  $p_T = 40$  GeV.

## 2.8 Particle jets

Particle jets are only available in simulated events. They are built from stable particles produced by the fragmentation model in the physics generator. Stable particles in ATLAS are those with a laboratory frame lifetime of about 10 picoseconds or more, thus typically including electrons, muons, photons, charged pions, kaons, protons, neutrons, neutrinos, and their corresponding antiparticles. These particles represent the “truth” reference of a hard scattering process for performance studies and simulation based calibration approaches. The particle jets are therefore referred to as *truth particle jets*, or *truth jets*, in the following sections of this note.

Neutrinos and muons generated in the collision are excluded from these truth jets, as they have their own observables, i.e. missing transverse momentum for neutrinos and explicitly reconstructed tracks for muons. Jet finding with generated particles uses the same code as calorimeter reconstruction, obviously excluding the signal preparation for towers in reconstruction sequence I and all calibration steps.

## 3 Jet reconstruction performance in ATLAS

The performance of the ATLAS detector for jet reconstruction has been evaluated within the present day limitations of physics generators, mostly PYTHIA [22], and detector response simulations, all performed with GEANT4 [23, 24]. All results presented here should therefore be considered to be expectations and of preliminary nature.

### 3.1 Preliminaries

The comparisons of calibrated jet features discussed in this section uses calorimeter jets to which the cell signal based calibration has been applied, in addition to the overall scale correction for different jet finder configurations and calorimeter signal choices, i.e. jets from reconstruction sequence I and II introduced in Section 2.5.4, with calibrations applied as described in Section 2.5.5. As already discussed in that section, the parameters of the corresponding calibration functions have been determined using simulations of dijets from QCD processes with the ideal detector geometry, meaning no misalignment between detectors or detector elements, no detector shape distortions, and assuming a perfect knowledge of the material distribution from supports, services, cryostats, etc., in the complex ATLAS geometry.

The simulations performed for the evaluation of the jet reconstruction performance use the same generated physics, meaning the same events at particle level, but include small shifts in relative detector positioning and small changes to the amount (increased) and location (more realistic asymmetric distribution in pseudorapidity and azimuth) of dead material in the detector description. As a consequence, the calorimeters do not respond optimally for this evaluation with respect to jet signals, but the estimated performance is likely closer to the initial one in ATLAS, with some a priori unknown distortions, misalignments, and other imperfections.

Final corrections can be derived once experimental data from the detector become available with sufficient statistics by e.g. following the strategies lined out in Ref. [25]. For the performance expectations presented here these corrections, which could have been derived rather straight forwardly by using the misaligned detector geometry in the simulations for calibration as well, are intentionally not applied to probe some of the initial systematic uncertainties to be expected for the initial running of ATLAS. Note that none of the results presented here include pile-up.

### 3.2 Comparing jet reconstruction algorithm performances

Jet reconstruction performance is typically expressed in terms of expected or measured signal linearity, i.e. flatness of the detector response to particle jets over the whole kinematic range of interest at the LHC (from  $p_T \approx 10$  GeV to a few TeV), signal uniformity in pseudorapidity  $\eta$  and azimuth  $\phi$  over the whole detector system coverage, and the achievable energy resolution. Additional features of jet reconstruction performance are the efficiency to find jets, and the purity of the found jet sample, which is of course related to the number of fake jets reconstructed.

Other jet features studied with the ATLAS detector are the possibility to reconstruct the original source of a given jet. This is particularly interesting for heavily boosted heavy particle decays like for top quarks, where the final state will likely be reconstructed as just one (narrow) jet. The measurement of the jet mass and a substructure analysis are experimental tools which could address this question.

The quality of the reconstructed variables depends on the choice of the calorimeter signal (towers or clusters), the choice of the jet finder and its configuration (wide/narrow jets), and the ability to unfold as much as possible the physics environment, like reflected in underlying event and pile-up contributions. A high precision analysis of a given event topology may require different configurations than offered in default jet reconstruction to optimize the signal. In this section the expected effect of the choices discussed above on the performance variables is shown for selected configurations.

In most cases the performance is evaluated using a truth reference provided in the simulation by jets reconstructed at particle level, see Section 2.8. The detector and truth jets are associated through directional matching. The following list of variables is used:

**Jet directions** are given by pseudorapidity  $\eta$  and azimuth  $\phi$ . As  $\eta$  is directly related to the polar angle  $\theta$ , and thus useful (even for massive jets) to understand the variations of the detector response, the rapidity  $y$  can be used for physics analysis motivated selections. The variables are defined as:

$$\eta = -\frac{1}{2} \ln \left( \frac{p + p_z}{p - p_z} \right) = -\ln \left[ \tan \left( \frac{\theta}{2} \right) \right] \quad (3)$$

$$y = -\frac{1}{2} \ln \left( \frac{E + p_z}{E - p_z} \right) \quad (4)$$

$$\phi = \arctan \left( \frac{p_y}{p_x} \right). \quad (5)$$

**Matching radius**  $R_m$  is defined by the directional distance between truth and detector jets, i.e.

$$R_m = \sqrt{\Delta\eta^2 + \Delta\phi^2}. \quad (6)$$

Two jets are matched if the radial distance between them is  $R_m \leq 0.2$ , if not stated otherwise. Only one match is allowed for each reference (truth) jet. In case of two or more nearby jets, the one closest to the reference is taken for efficiency and purity studies. For signal linearity and uniformity studies the reference and the calorimeter jets are omitted in this case.

**Signal linearity** can be determined by the ratio  $\lambda$  of the energy reconstructed for the calorimeter jet  $E_{\text{jet, calo}}$  and the matched truth jet energy  $E_{\text{jet, truth}}$ ,

$$\lambda = \frac{E_{\text{jet, calo}}}{E_{\text{jet, truth}}}, \quad (7)$$

when  $\lambda$  can be calculated as function of  $E_{\text{jet, truth}}$  or  $E_{\text{jet, calo}}$ .

**Signal uniformity** is measured by the variation of the signal as function of the jet direction in the detector frame, as given by  $\eta$  in Eq.(3). The variable  $\lambda$  defined in Eq.(7) can be used to estimate the uniformity from simulations, if calculated as function of  $\eta$ .

**Relative energy resolution** is given by the width of the distribution of the relative difference between  $E_{\text{jet, calo}}$  and  $E_{\text{jet, truth}}$ :

$$\frac{\sigma}{E} = \sqrt{\left\langle \left( \frac{E_{\text{jet, calo}} - E_{\text{jet, truth}}}{E_{\text{jet, truth}}} \right)^2 \right\rangle - \left\langle \frac{E_{\text{jet, calo}} - E_{\text{jet, truth}}}{E_{\text{jet, truth}}} \right\rangle^2}. \quad (8)$$

**Jet reconstruction efficiency**  $\varepsilon$  is defined by the following ratio:

$$\varepsilon(R_m) = \frac{\# \text{ matches of truth particle jets with reconstructed jets}}{\# \text{ truth particle jets}} = \frac{N_m^{\text{jets}}(R_m)}{N_{\text{truth}}^{\text{jets}}}. \quad (9)$$

It depends on the matching radius  $R_m$  and is determined as function of the true jet energy,  $p_T$ , or  $\eta$ .

**Jet reconstruction purity**  $\pi$  is given by

$$\pi(R_m) = \frac{\# \text{ matches of truth particle jets with reconstructed jets}}{\# \text{ reconstructed jets}} = \frac{N_m^{\text{jets}}(R_m)}{N_{\text{reco}}^{\text{jets}}} \quad (10)$$

and also depends on the choice for  $R_m$ . The fake rate  $f(R_m)$  is then given by  $f(R_m) = 1 - \pi(R_m)$ . Purity is calculated as function of the reconstructed jet energy,  $p_T$ , and/or direction.

Additional variables reconstructed from jets, like substructure and shape measures, are discussed in Section 3.6.

### 3.3 Comparisons of basic jet signal features

The main data source for the evaluation of the performance of the ATLAS calorimeters for jet reconstruction are fully simulated QCD dijet events with at least one of the hard scattered partons having a  $p_T$  within a certain bin. Eight bins are defined, with incrementing delimiters approximately following a  $2^n$  power law:  $17 \rightarrow 35$  GeV,  $35 \rightarrow 70$  GeV, etc., up to the final bin  $p_T > 2240$  GeV with the upper limit set by the kinematic limit introduced by the parton direction and the 14 TeV center-of-mass energy in the  $pp$  collisions at LHC.

#### 3.3.1 Signal linearity and resolution

Signal linearity has been studied in detail for the evaluation of the various calorimeter jet calibration schemes under discussion in ATLAS [17]. The general expectation from these studies with the distorted detector is a response flat within  $\pm 1\%$  for jets with  $p_T \gtrsim 50$  GeV, and a slightly larger deviation from linearity for jets with lower transverse momentum down to  $\sim 10$  GeV [17]. As the calibration functions are determined using one jet finder configuration and one simulated calibration sample in a perfect detector model (see discussion in Section 2.5.5), one can estimate the shift from a response flat within the margins introduced by the distorted detector when other configurations and/or a different calorimeter signal basis are considered. This shift can be expressed as the ratio of  $\lambda_{\text{alt}}$ , as given in Eq.(7), from a given alternative jet reconstruction to  $\lambda_{\text{ref}}$ , the reference from the same jet reconstruction configuration used to derive calibration functions in the ideal detector:

$$\xi = \frac{\lambda_{\text{alt}}}{\lambda_{\text{ref}}} = \frac{E_{\text{jet, calo}}^{\text{alt}} / E_{\text{jet, truth}}^{\text{alt}}}{E_{\text{jet, calo}}^{\text{ref}} / E_{\text{jet, truth}}^{\text{ref}}}. \quad (11)$$

Figure 10: Residual calibration uncertainties for reconstructed jets from various jet finder configurations and the two calorimeter signals, as function of the truth jet  $p_T$  and in two bins of jet rapidity  $y$ . The reference configuration is seeded fixed cone tower jets with  $R_{cone} = 0.7$ . The residual calibration uncertainty is given by  $\xi$ , as defined in Eq.(11).

Figure 11: Residual calibration uncertainty  $\xi$ , calculated relative to the fixed seeded cone ( $R_{cone} = 0.7$ ) tower jet calibration as described by Eq.(11), as function of the truth jet  $p_T$  in the forward direction of ATLAS.

The quantity  $\xi$  can be viewed as a measure of the residual calibration uncertainty with respect to the best calibrated jet reconstruction configuration, and is thus an estimate of one of the systematic uncertainty contributions in the general jet reconstruction. Note that

$$\xi \approx \frac{E_{\text{jet, calo}}^{\text{alt}}}{E_{\text{jet, calo}}^{\text{ref}}}$$

when the alternative reconstruction uses the same jet finder with the same parameters as the reference, because  $E_{\text{jet, truth}}^{\text{alt}} \approx E_{\text{jet, truth}}^{\text{ref}}$  in this case. The prime example here is the comparison of seeded fixed cone tower jets with  $R_{\text{cone}} = 0.7$  (the reference) with cluster jets found with the same configuration.

Figure 10 shows expectations for  $\xi$  as function of the jet  $p_T$  in two different regions of jet rapidity. From this simulation based study it can be concluded that the cell signal based jet calibration, with the additional overall scale corrections discussed in Section 2.5.5 applied, is universal for the distorted detector at a level of about 2% for the studied QCD jets with  $p_T > 20$  GeV and the particular choice of distortions implemented in the detector description of the simulation program. As these distortions include additional inactive material between the electromagnetic liquid argon and the hadronic tile calorimeter (about 10% increase in nuclear absorption length), the effect is in particular emphasized for low  $p_T$  jets in the central region, which mostly occupy the  $0.4 < |y| < 0.4$  bin<sup>2</sup>. Here the sensitivity to the jet algorithm (seeded cone or  $k_T$ ), its configuration (narrow or wide jets), and the choice of calorimeter signals (clusters or tower) is also largest, see Fig. 10.

Sensitivities to signal and jet finder choices are stronger for jets within  $3.7 < |y| < 3.9$ . The calorimeter jet shape in the corresponding forward region is dominated by (lateral) hadronic shower extension rather than the particle flow in a cone in  $(\eta, \phi)$ , meaning that a considerable part of the calorimeter signal can be outside of a chosen jet cone and therefore be lost for the total jet signal. Jets from each of the jet finder configurations and calorimeter signal choices have been individually corrected for these signal losses using simulations with the ideal detector geometry. The effect of the distorted detector, which includes a change of the relative  $z$  position of the endcap and forward calorimeters in ATLAS and thus a change of the aspect ratio of the particle level jet shape to the calorimeter jet shape and consequently different energy losses, can be significant especially for the  $k_T$  jets, as indicated in Fig. 11. Again using the seeded fixed-size cone tower jets with  $R_{\text{cone}} = 0.7$  as a reference, the cluster jets reconstructed with the same algorithm show a similar response, indicated by  $|\xi - 1| < 2\%$  in the whole kinematic range studied here. The narrow cone cluster jets lose about 1% of their energy, rather independent of their  $p_T$ , which can be expected due to the lateral hadronic shower size varying only slightly with energy. The larger effects of the distorted detector on the  $k_T$  jets, like the prediction of a nearly linear rise of  $\xi$  with  $\log p_T$  for  $p_T \lesssim 100$  GeV for all considered  $k_T$  jets, but most pronounced for wide  $k_T$  tower jets, require more investigation of the distortion effects and their reflection in towers and clusters on the more complex dynamics driving the  $k_T$  algorithm.

The jet energy resolution is the other important contribution to precision jet reconstruction. It has been evaluated in the distorted detector geometry with the same QCD sample. The results are again discussed in more detail in Ref. [17]. A typical relative energy resolution, calculated as described by Eq.(8), and achieved without particular corrections for the distorted detector, has a stochastic term of about  $60\%/\sqrt{E(\text{GeV})}$  and a high energy limit of about 3% in the central region of ATLAS, all determined with these simulated events.

It is expected that the relative energy resolution depends on the calorimeter signal choice, the jet algorithm, the underlying event and pile-up activity, and the general particle density and flow of the physics environment. Using QCD dijet simulations, with electronics noise included in the detector simulation but without any pile-up activity, the difference in resolution between tower and cluster jets can be estimated

<sup>2</sup>Note that for the QCD jets under consideration here the jet mass  $m$  is generally small, in particular  $m \ll p$ , i.e.  $y \approx \eta$ .

Figure 12: The difference in relative energy resolution  $\psi_\sigma$  (see Eq.(12)) between seeded cone cluster and tower jets, and  $k_T$  cluster and tower jets, respectively, as function of the matching particle jet energy, and in two different regions of jet rapidity  $y$ . A negative value for  $\psi_\sigma$  indicates a better resolution for cluster jets.

with the test variable  $\psi_\sigma$ , which uses the fractional difference  $\Delta_\sigma$  in the energy resolution

$$\Delta_\sigma = \left(\frac{\sigma}{E}\right)_{\text{cluster}}^2 - \left(\frac{\sigma}{E}\right)_{\text{tower}}^2,$$

with the relative resolutions  $\sigma/E$  as given in Eq.(8).  $\psi_\sigma$  can then be defined as

$$\psi_\sigma = \begin{cases} \sqrt{\Delta_\sigma} & \text{for } \Delta_\sigma > 0 \\ -\sqrt{-\Delta_\sigma} & \text{for } \Delta_\sigma < 0 \end{cases}. \quad (12)$$

Figure 12 shows the prediction for  $\psi_\sigma$  for various jet configurations in two different kinematic regimes defined by the jet rapidity. As this variable mainly folds differences in the stochastic and noise contribution to the jet energy resolution, the effect of noise suppression implicit for cluster jets is particularly visible at low energies and for wider jets, where more calorimeter cells with noise contribute to the tower jets than in narrow jets. At higher jet energies, the energy resolution contribution introduced by signal fluctuations from electronics noise is significantly reduced and  $\psi_\sigma$  is comparable with zero in both kinematic regimes.

The relative difference  $\psi_\sigma$  can be transformed into an energy-equivalent difference in a straight forward manner:

$$\Delta\sigma_{\text{abs}}(E) = \psi_\sigma(E) \cdot E. \quad (13)$$

Figure 13 shows predictions for this difference for the QCD jets discussed here. The general flat (energy independent) behaviour indicates that the differences between cluster and tower jets indeed are mostly

Figure 13: Estimates for the absolute difference in resolution, as defined in Eq.(13) between seeded cone cluster and tower jets ( $R_{\text{cone}} = 0.7$ , open circles  $\circ$ ). The filled circles ( $\bullet$ ) show the same difference for  $k_T$  cluster and tower jets, with  $R = 0.6$ . The solid and dashed lines show results and the range of fits to the data points. Note the linear energy scale and the limited energy range, compared to Fig. 12.

related to electronics noise. The average noise contribution  $\langle \Delta\sigma_{\text{abs}} \rangle$  has been determined by straight line fits to the flat regions. Seeded cone tower jets with  $R_{\text{cone}} = 0.7$  in the lower rapidity regime  $0.2 < |y| < 0.4$  yield  $|\langle \Delta\sigma_{\text{abs}} \rangle| \approx 2.5$  GeV more noise than the corresponding cluster jets. This contribution is estimated to be higher for  $k_T$  jets with  $R = 0.6$ , at approximately 4 GeV.  $|\langle \Delta\sigma_{\text{abs}} \rangle|$  increases in the higher rapidity region  $2.0 < |y| < 2.2$  to about 6 GeV for cone and 8 GeV for  $k_T$  jets, respectively. This observation already reflects the larger electronics noise in the endcap calorimeters, where most of the jets in this rapidity range go. The evaluation of  $\psi_\sigma$  as function of the jet direction, as shown in Fig. 15 in Section 3.4, explores this observation further.

Figure 13 also suggests that for  $E < 50$  GeV,  $k_T$  jets made from clusters in the lower rapidity regime are subjected to fluctuations from other sources than electronics noise, which partly cancel the noise reduction as  $|\Delta\sigma_{\text{abs}}|$  gets smaller with decreasing energy. These fluctuations are not present in  $k_T$  jets made from towers and in seeded cone jets reconstructed from towers or clusters in the same kinematic region, and need further exploration.

### 3.4 Jet signal uniformity

The variation of the jet response as function of the jet direction is a measure of the uniformity of the jet signals and more powerful to diagnose possible detector inefficiencies than the linearity studies discussed in the previous section. Figure 14 shows the variation of the response to wide and narrow seeded cone and  $k_T$  tower jets as function of the jet pseudorapidity<sup>3</sup> for simulated QCD dijet events. The additional inactive material introduced between the electromagnetic and hadronic calorimeters in the central region, which is part of the distorted detector geometry model, especially affects the response to the lower energy jets. The drop in the jet response is also more enhanced for lower energetic jets in the crack region around  $|\eta| \approx 1.5$ , with up to 10% of signal loss, again due to more inactive material in this region. The response to the higher energetic jets is more uniform, as expected, with a signal drop in the cracks around 4%, which is also observed for the crack at  $|\eta| \approx 3.2$ .

<sup>3</sup>Contrary to the preceding discussion of the signal linearity and energy resolution, where the rapidity  $y$  is used to categorize different kinematic regimes for jets, in the discussion of the signal uniformity the pseudorapidity  $\eta$  is preferred, as it directly reflects a direction in ATLAS (see Eq.(3) in Section 3.2) and thus is more appropriate to characterize the response in a certain calorimeter region.

Figure 14: The uniformity of the ATLAS calorimeter response for wide ( $R_{\text{cone}} = 0.7$ ) and narrow ( $R_{\text{cone}} = 0.4$ ) seeded fixed sized cone jets, and for wide ( $R = 0.6$ ) and narrow ( $R = 0.4$ )  $k_T$  jets. The upper two plots show the response variation as function of the jet pseudorapidity  $\eta$  for tower jets in two different jet energy ranges, while the lower plots show the signal difference between cluster and tower jets  $\Delta E_{\text{jet,calo}} = E_{\text{jet,cluster}} - E_{\text{jet,tower}}$  as function of  $\eta$ , again in two jet energy bins. The  $p_T$  variation for the two energy bins is shown in the middle section, for comparisons.

There are only relatively small difference between the seeded cone and  $k_T$  jet signal uniformity, which are more pronounced at lower jet energies. Using clusters instead of towers as the calorimeter signal basis does not affect the signal uniformity for the higher energetic jets, but is expected to recover some signal losses, of the order of 1%, for the lower energetic jets.

Predictions for the dependency of the relative energy resolution on the jet direction is shown in Fig. 15, for the same QCD jet sample. From this study there are significant differences expected between the seeded cone and the  $k_T$  algorithm for lower jet energies. Both for wide and narrow jets the cone algorithm seems to perform better, especially in the endcap calorimeter region. For higher energetic jets these differences become insignificant.

Testing the difference between cluster and tower jet energy resolution has been done using the relative resolution difference  $\psi_\sigma$ , as defined in Eq.(12). For the lower energetic jet sample the noise-like contribution to  $\psi_\sigma$  already observed in Fig. 12 is confirmed, with the additional observation that in the endcap calorimeters clusters seem to reduce these fluctuations even more than in the central region. High energetic cluster and tower jets perform very similarly. From the absolute differences between the resolutions shown in Fig. 13, which is about 2.5 – 8 GeV depending on the kinematic regime and the chosen jet finder and its configuration, the expected value for  $\psi_\sigma$  for higher jet energies is about 0.2 – 0.7%, which is in agreement with the predictions for the high energy jet sample shown in Fig. 15. The larger and positive  $\psi_\sigma$  at higher pseudorapidities observed especially for narrow  $k_T$  jets indicates signal fluctu-

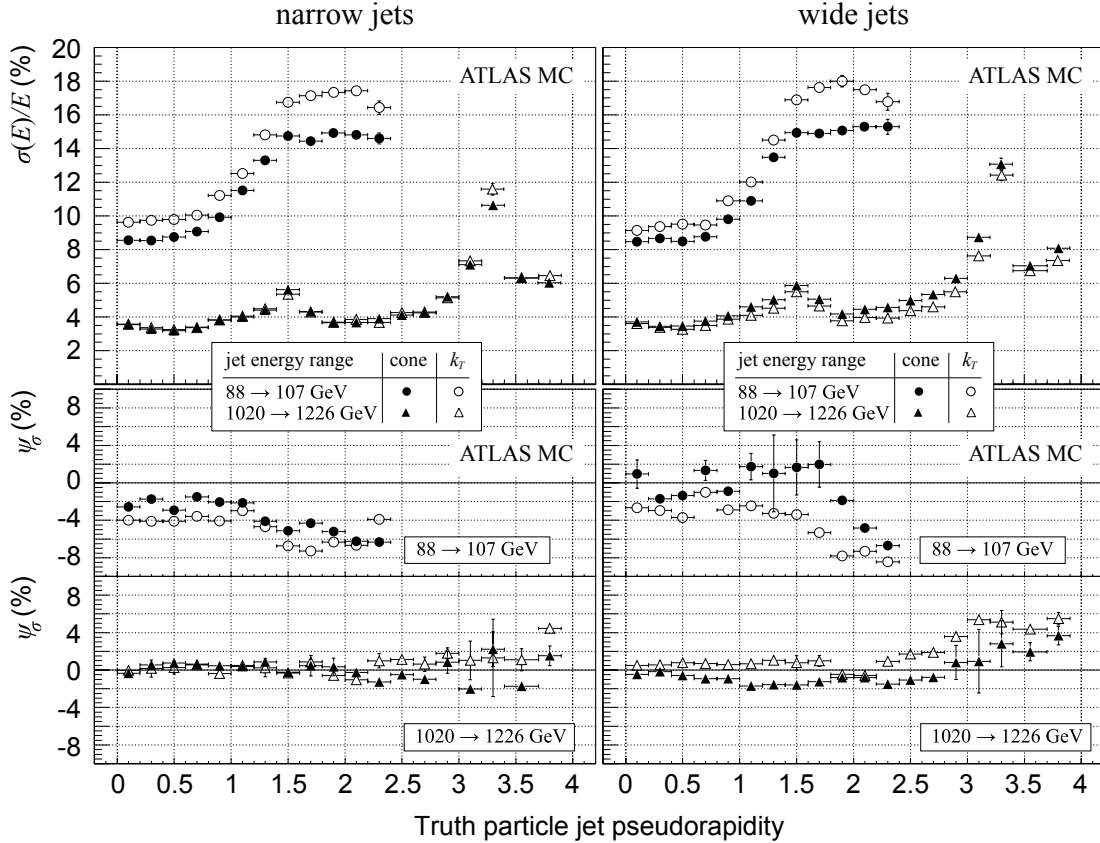

Figure 15: Predictions for the direction dependence of the relative jet energy resolution for seeded cone (wide,  $R_{\text{cone}} = 0.7$ , left, and narrow,  $R_{\text{cone}} = 0.4$ , right) and wide ( $R = 0.6$ ) and narrow ( $R = 0.4$ )  $k_T$  tower jets in two different jet energy bins (upper plots). The relative resolution difference to cluster jets  $\psi_\sigma$ , as defined in Eq.(12), is shown for the same jet samples in the bottom plots.

ations introduced by clustering in the forward region. A more detailed investigation of the  $k_T$  algorithm performance when configured for narrow jets in this region is under way.

### 3.5 Efficiency and purity

The efficiency of the jet reconstruction in ATLAS depends not only on the jet  $p_T$  but also on the jet direction and the physics environment. For basic performance evaluation it has been studied using QCD dijet production. Figures 16, 17, and 18 show the expectations for seeded cone jets with  $R_{\text{cone}} = 0.7$  and 0.4, and  $k_T$  jets with  $R = 0.4$  and 0.6, respectively, in various kinematic regimes defined by the jet rapidity  $y$ . It is noticeable that the efficiency at lower  $p_T$  is rather low, with the wide  $k_T$  jets performing better than the corresponding wide cone jets. Both jet algorithms have similar efficiencies for narrow jets for  $0.2 < |y| < 0.4$ , with increasingly better efficiencies predicted for  $k_T$  jets at higher rapidities.

Figures 16 through 18 also show the estimated differences in the jet reconstruction efficiency between tower and cluster jets, defined as  $\Delta\epsilon = \epsilon_{\text{cluster}} - \epsilon_{\text{tower}}$ , with  $\epsilon_{\text{cluster}}$  and  $\epsilon_{\text{tower}}$  defined in Eq.(9). In general cluster jets are expected to be reconstructed with higher efficiency in the low  $p_T$  regime, especially in case of wide jets and in the forward direction. Narrow seeded cone jets are reconstructed with basically the same efficiency for both calorimeter signal choices, except at  $p_T \lesssim 50$  GeV in the forward region, where cluster jets are again more efficient.

The predictions for  $\Delta\epsilon$  for wide  $k_T$  indicate similar behaviour as the seeded cone jets in the central calorimeter region, but a much less pronounced difference between the tower and cluster jets in the forward region. There are also indications the narrow  $k_T$  jet reconstruction efficiency is slightly improved when using clusters, see again Fig. 16 through Fig. 18. No significant variation of the jet reconstruction efficiency as function of the jet direction is expected, especially not for higher  $p_T$  jets.

The fake rate  $f = 1 - \pi$  (see also Eq.(10)) for jet reconstruction in QCD dijet events has also been studied. The rate drops quickly from more than 50% at jet  $p_T$  of 10 GeV to around 1% for jets with  $p_T > 50$  GeV. There are indications that wide jets reconstructed from topological clusters have a lower number of fakes at low  $p_T$ , especially in the central region. Also, the  $k_T$  algorithm seems to generate fewer wide jets than the cone algorithm in this region, independent of the calorimeter signal choice. These differences are expected to be much smaller for narrow jets.

### 3.6 Jet composition and mass

The reconstruction of jet masses and substructure has gained interest at LHC, especially because of the expected production of heavy particles with masses of  $\mathcal{O}(100)$  GeV and transverse momenta of several hundred GeV. These may decay hadronically into very collimated final states. An important standard model example is the  $W$  boson [26]. Other examples include SUSY [27], excited heavy quarks [28], and in exotic final states involving extra dimensions [29].

In any case, the complete final state of a heavy and boosted particle may be reconstructed into one jet, which in the example of a fully hadronically decaying top quark actually contains three highly collimated jets. The mass of the reconstructed jet is then one of the indicators of its origin, in addition to a possible substructure reconstruction reflecting the three “internal” jets.

The reconstruction of the jet mass is inherently difficult from calorimeter signals, as the shower development washes out the directions and energies of individual particles in the jet. In addition, the true jet mass is of course best reconstructed if all of its original particles can be measured at high precision. The mass reconstruction is thus disturbed by undetected particles, like the ones curling in the solenoidal magnetic field in the inner detector cavity of ATLAS, and the ones losing too much energy in upstream inactive material to generate a signal above threshold in the calorimeters.

Figure 19 shows the expected composition of  $k_T$  jets with  $R = 0.6$  built from particles, towers, and clusters in three different rapidity regions. The number of constituents shown in this figure is of course

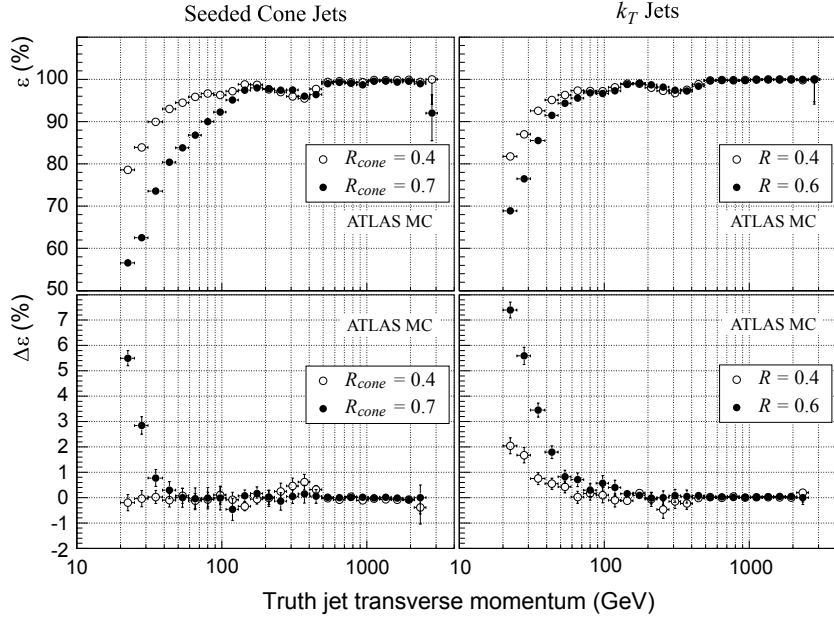

Figure 16: The calorimeter jet reconstruction efficiency  $\varepsilon$  in ATLAS, calculated from simulations using Eq.(9), for seeded cone tower jets with  $R_{\text{cone}} = 0.7$  and  $R_{\text{cone}} = 0.4$ , as function of the truth particle jet  $p_T$ , in  $0.2 < |y| < 0.4$  (top left). The plot on the top right shows predictions for wide ( $R = 0.6$ ) and narrow ( $R = 0.4$ )  $k_T$  tower jet reconstruction efficiencies in the same kinematic regime. The difference in efficiency between cluster and tower jets, defined as  $\Delta\varepsilon = \varepsilon_{\text{cluster}} - \varepsilon_{\text{tower}}$ , is shown in the lower left plot for cone and in the lower right plot for  $k_T$  jets.

Figure 17: Predictions for the calorimeter jet reconstruction efficiency in ATLAS for wide and narrow seeded cone (top left) and  $k_T$  (top right) tower jets with  $2.0 < |y| < 2.2$ , shown together with corresponding differences in efficiency between cluster and tower jets (bottom plots), again as function of the truth particle jet  $p_T$  (see caption of Fig. 16 for more details).

Figure 18: Jet reconstruction efficiencies  $\varepsilon$  as function of the truth particle jet  $p_T$ , for wide and narrow seeded cone and  $k_T$  tower jets in ATLAS (top), estimated with simulations of QCD dijet processes, in the jet rapidity range  $3.7 < |y| < 3.9$ . The corresponding difference in efficiency between cluster and tower jets is shown in the bottom plots. See caption of Fig. 16 for more details.

depending on the calorimeter signal choice, i.e. towers or clusters. The variation in the number of clusters between the rapidity regions reflects the changing spatial resolution power of the calorimeter with respect to resolving individual showers inside a jet. The observation that the number of particles inside jets seems to drop at highest  $p_T$  indicates a change in the origin of the jets. Most jets at lower  $p_T$  in the studied QCD sample are gluon jets, while for higher  $p_T$  a significant fraction of jets is produced by quarks. As gluons have a larger probability to radiate off other gluons than quarks have, one can expect more particles inside gluon jets, and even more jets in the final state in case of gluons.

The relative sensitivity of the jet mass reconstruction to low signal contributions has been studied for cluster, tower and particle jets with QCD dijet simulations. The relative change in the jet mass if  $p_T$  thresholds are applied to the constituents, is defined as

$$\Delta m_{\text{rel}}(p_T^{\text{min}}) = \frac{m(p_T > p_T^{\text{min}})}{m(p_T > 0)}. \quad (14)$$

Here  $m(p_T > p_T^{\text{min}})$  means the jet mass recalculated using only jet constituents with a transverse momentum above  $p_T^{\text{min}}$ , while  $m(p_T > 0)$  is the jet mass using all constituents. Figure 20 shows the expectations for the variation of  $\Delta m_{\text{rel}}$  as a function of the reconstructed  $m(p_T > 0)$ , for different  $p_T^{\text{min}}$ . Especially for high mass jets the cluster jets show a similar behaviour as the particle jets, indicating that clusters are probably better reflecting the particle composition in these jets than the tower jets. Note that  $p_T > 400$  MeV is around the threshold for charged particles to reach the calorimeter in the magnetic field of the inner detector, and is also close to the general signal threshold for the calorimeters in the central region of ATLAS.

Figure 19: The average number of constituents of  $k_T$  jets with  $R = 0.6$  as function of the jet  $p_T$ , in three different regions of ATLAS, as predicted by simulations of QCD dijet events (figure adapted from Ref. [16]).

Figure 20: The variation of the jet mass re-reconstructed from its constituents with different levels of biases in  $p_T$ , as function of the least-biased mass using all constituents, for simulated tower, cluster, and particle level jets in QCD dijet events in ATLAS (figure adapted from Ref. [16]).

### 3.7 Jet substructure

The sensitivity in the mass reconstruction observed in Fig. 20 suggests the need for jet variables less sensitive to the soft particle contribution and response, yet providing sensitivity to the possible origin of the jet. One of the interesting variables is the characteristic scale  $y_{\text{scale}}$  for sub-jet splitting in  $k_T$  jets, i.e. the  $p_T$  scale at which the  $n$  last recombinations of the  $k_T$  algorithm are undone. It can be defined using  $y_n$  such that

$$y_{\text{scale}}^2 = p_T^2 \times y_n.$$

For example,  $n = 2$  means splitting into two sub-jets, identical to undoing the last recombination in the  $k_T$  algorithm.  $y_{\text{scale}}$  is logarithmically below the jet  $p_T$  in gluon and quark jets, due to the strongly ordered (in  $k_T$ ) QCD evolution, see e.g. Ref. [30]. In case of a strongly boosted  $W$  boson decaying into quark and anti-quark, on the other hand,  $y_{\text{scale}}$  is closer to the  $W$  mass  $m_W$ . The left plot in Fig. 21 shows a qualitative comparison of the  $y_{\text{scale}}$  spectrum for jets with masses  $m_{\text{jet}} > 40$  GeV in simulated QCD dijet processes with the one for jets from simulated boosted  $W$  boson decays with the same mass cut applied.

Figure 21: Distributions of the scale variable  $y_{\text{scale}}$  indicating the threshold for splitting a given jet with mass  $m_{\text{jet}} > 40$  GeV into two sub-jets, for simulated QCD dijet processes and boosted  $W$  bosons decaying hadronically (left figure). The right figure shows predictions of the resolution power for  $y_{\text{scale}}$  for the boosted  $W$  bosons. The filled area distribution shows the spectrum for  $\Delta y_{\text{scale}} = y_{\text{scale, reco}} - y_{\text{scale, truth}}$  obtained with fully detailed simulations, while the solid distribution shows the optimistic estimate from a smeared particle-level calculation. Both distributions are normalized to unity.

The resolution power of ATLAS for a measurement of  $y_{\text{scale}}$  has been studied for splitting into two jets, i.e.:

$$y_{\text{scale}} = \sqrt{y_2} \times p_T,$$

with a sample of simulated highly boosted  $W$  decaying hadronically. For these the corresponding  $y_{\text{scale}}$  distribution approximately peaks at  $m_W/2$ , as expected, see Fig. 21. The resolution power for  $y_{\text{scale}}$  can be evaluated by comparing this variable reconstructed from the calorimeter jet with the one from the matching particle level jet. The right plot in Fig. 21 shows the resolution for full simulation and for a smeared particle-level fast simulation. Pending a full scale evaluation in the context of a physics analysis, the present observation based on the the similarity of both distributions is that the reconstruction of  $y_{\text{scale}}$  does not seem to be too sensitive to details affecting the calorimeter signal, like showering, limited acceptance for low energetic particles, and similar. The prediction for the experimental  $y_{\text{scale}}$  resolution from this figure is about 12%, while the optimistic simulation based on four-momentum smearing predicts about 9%.

## 4 Forward jet reconstruction and jets in minimum bias events

The ATLAS detector provides near hermetic coverage within pseudorapidities of approximately  $-4.9 < \eta < 4.9$ . The forward region is particularly challenging for jet reconstruction, as the jets of interest often have rather low transverse momentum (at high energy) and are thus closer to the fluctuations introduced by pile-up at design luminosity at LHC. For example, in a jet cone with  $R_{\text{cone}} = 0.7$  one expects fluctuations in transverse momentum of the order of 12 GeV [31], meaning that the minimum  $p_T$  which can safely be reconstructed is around 40 GeV. The estimates for jet performance in the forward region presented here have been calculated without pile-up, i.e. only electronics noise is folded into the reconstructed signals.

Events with depleted hadronic activity in the central region of the  $pp$  collisions are important signatures for discoveries, including but not limited to leptonically decaying Higgs bosons produced in vector boson fusion (VBF) events, like  $WW$  scattering. To reconstruct this signal with significant efficiency a central jet veto can be applied. The effectiveness of this veto can be understood from the efficiency to reconstruct jets in minimum bias events without hard scattering, and the rate for fake jet reconstruction. This has been studied with simulations for ATLAS and the results are presented in Section 4.2.

### 4.1 Forward jets

Recent studies indicate that the detection of forward going (light quark) jets with pseudorapidities  $2.7 \leq |\eta| \leq 4.9$  helps to significantly increase the discovery potential not only for heavy Higgs bosons [13], but also for intermediate mass Higgs bosons produced in VBF [32]. This region in the ATLAS detector features a complex calorimeter geometry in the transition region from the end-cap to the forward calorimeters. This leads to a loss of precision from the changing readout geometries. Some aspects of the performance of the ATLAS detector for these forward jets are discussed in this section.

The VBF events have a specific topology in that on average two hard *tag jets* are produced by the two quarks radiated off the vector boson. Figure 22 shows predictions for the jet multiplicity distributions in these events, both over the whole detector acceptance ( $|\eta| < 4.9$ ), where most often the two tag jets are found, and in the forward direction ( $2.7 < |\eta| < 4.9$ ) only. From this the expectation is in most events only one of the jets is going into the forward direction, at least for the particular Higgs boson mass considered here ( $m_H = 120$  GeV). This observation is independent of the jet size for seeded cone and  $k_T$  jets.

The relative transverse momentum resolution for both forward seeded fixed cone and  $k_T$  jets in VBF produced  $H \rightarrow \tau\tau \rightarrow \mu\mu$  events is estimated at about 9% for  $20 < p_T < 120$  GeV. Signal linearity is expected to be within  $\pm 2\%$  for these jets, at least for  $p_T \gtrsim 30 - 40$  GeV, see Fig. 23. The precision achieved in the reconstruction of the jet kinematics for even lower  $p_T$ , an attempt only realistic in low luminosity running at LHC, seems to be limited from this study to  $\approx 5\%$ .

Predictions for the efficiency and purity of forward jets reconstructed with the seeded cone ( $R_{\text{cone}} = 0.4$ ) finder are shown in Fig. 24. Here the indication is that using topological cell clusters as calorimeter signals for jet reconstruction makes jet reconstruction more efficient at the likely less relevant lower end of the jet  $p_T$  spectrum ( $p_T \lesssim 30 - 40$  GeV), but generates more fake jets in the same  $p_T$  range, i.e. has a lower purity in this region for this event sample. As both calorimeter signals reconstruct  $k_T$  jets with basically the same efficiency and purity in the whole kinematic range of interest for these VBF events, there is an indication that the splitting of cell signals to fill towers, which is predominant in the forward region, generates less seeds than the more integrating cell clustering, where cell signals are summed up rather than split and thus create more likely signal objects above the seed threshold. See also text and Fig. 3 in Section 2.5.1 for tower formation, and Section 2.5.2 for clustering.

Figure 22: Simulated jet multiplicities for seeded cone jets ( $R_{\text{cone}} = 0.4$ ) with  $p_T > 20$  GeV, built from topological cell clusters and generated particles, respectively, in VBF produced Higgs boson events (left). The Higgs boson decays as  $H \rightarrow \tau\tau \rightarrow \mu\mu$ . The right plot shows the multiplicities of forward going jets with rapidities  $2.7 \leq |y| < 4.9$ .

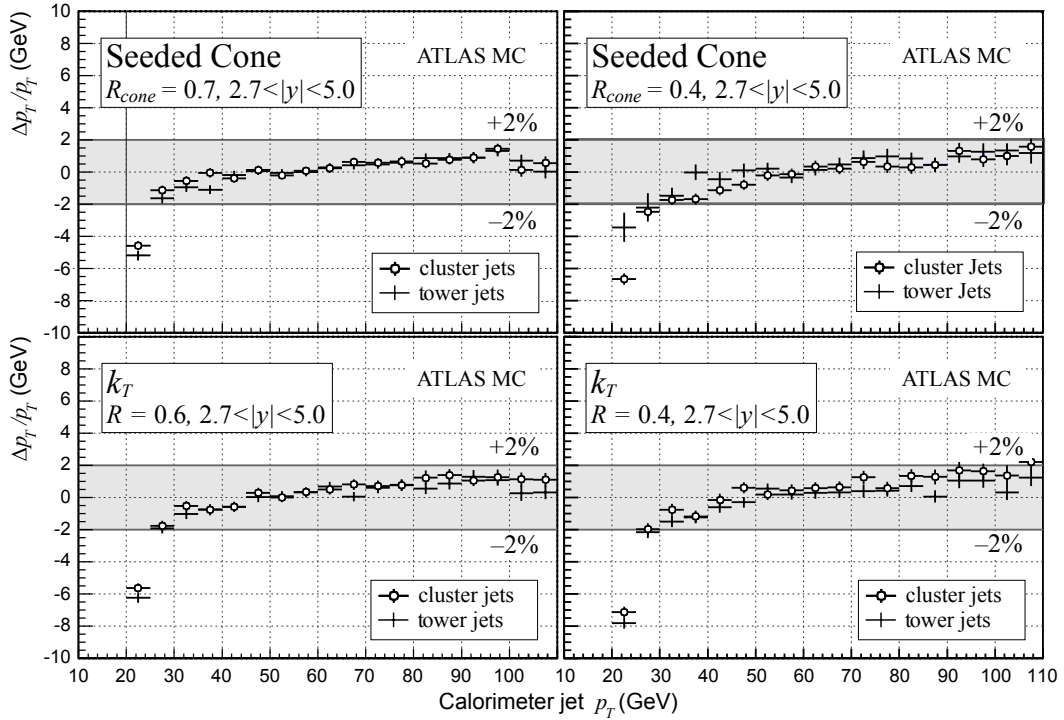

Figure 23: Relative deviation of reconstructed transverse momentum  $p_T$  from calorimeter jets and the  $p_T$  from the matched particle jet in VBF Higgs boson production, for various jet finder configurations and the two calorimeter signal definitions (towers and clusters).

Figure 24: Estimated efficiency to reconstruct narrow seeded cone tower and cluster jets ( $R_{\text{cone}} = 0.4$ ) generated in VBF Higgs boson production in the forward direction ( $2.7 < |\eta| < 4.9$ ), as function of the truth jet transverse momentum (left). The plot on the right shows the corresponding fake reconstruction rate as function of the transverse momentum of the calorimeter jet.

## 4.2 Jets in minimum bias events

Soft underlying physics, as generated by the underlying event in hadron colliders and the multiple soft interactions at high luminosity is an important source of jet production not directly related to the triggered hard scattering process of interest. For efficient application of a central jet veto, which is an important tool in background suppression in VBF produced Higgs boson events, it is crucial to understand the jet rate from soft interactions in this region, and the particular characteristics of these jets. The latter point is subject to ongoing studies, but first estimates on the jet multiplicity and rate from simulated single minimum bias events are available.

Figure 25 shows the expected average number of jets in these events as function of the  $p_T$  threshold applied in the final jet selection, for various calorimeter signal definitions and the most commonly used jet finder configurations. The  $k_T$  jet multiplicity for narrow ( $R = 0.4$ ) jets is rather independent of the calorimeter signal choice, while for wider jets ( $R = 0.6$ ) the cluster jets have a lower average multiplicity, i.e. are less problematic for a central jet veto. For seeded cone jets, the wider ( $R_{\text{cone}} = 0.7$ ) tower and cluster jets have very similar multiplicities, while here the narrow tower jets ( $R_{\text{cone}} = 0.4$ ) have a lower multiplicity than the cluster jets.

Predictions for the probability  $P(N_{\text{jet}} \geq 1, p_T > 20 \text{ GeV}, \eta_{\text{range}})$  of reconstructing at least one jet per single minimum bias event with  $p_T > 20 \text{ GeV}$  within a pseudorapidity range of  $|\eta| < \eta_{\text{range}}$  is shown in Fig. 26. Narrow jets from towers and clusters behave rather similarly for both the seeded cone and the  $k_T$  algorithm. Wider jets are more often found in calorimeter tower jets than in topological cluster jets. In general the  $k_T$  algorithm is less likely to reconstruct wider jets with  $R = 0.6$  than the seeded cone is with  $R_{\text{cone}} = 0.7$ . Here  $P(N_{\text{jet}} \geq 1, p_T > 20 \text{ GeV}, \eta_{\text{range}})$  has been calculated including the occasional jet from the minimum bias (soft or semi-hard) interaction as well as “true” fake jets from calorimeter signal fluctuations due to noise. Both lead to efficiency losses in an analysis selecting final states with no hadronic

Figure 25: Estimates for the average number of jets per minimum bias event, as function of the  $p_T$  threshold applied to the final jet. Shown are results for wide and narrow cluster and tower jets in minimum bias simulations.

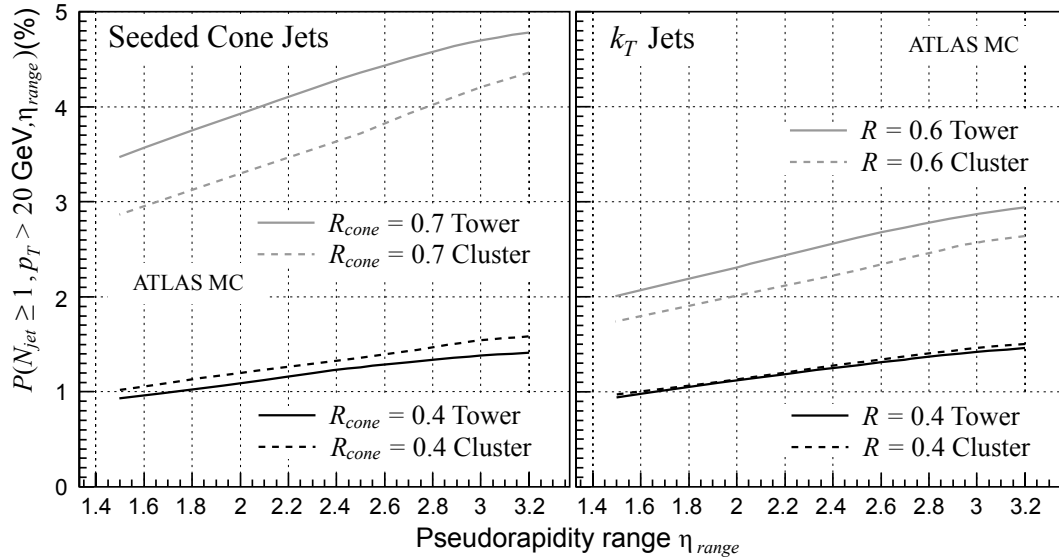

Figure 26: Prediction from full simulations for the probability  $P(N_{\text{jet}} \geq 1, p_T > 20 \text{ GeV}, \eta_{\text{range}})$  to reconstruct at least one jet with  $p_T > 20 \text{ GeV}$  within a pseudorapidity range  $|\eta| < \eta_{\text{range}}$  considered for jet reconstruction in single minimum bias events, as function of  $\eta_{\text{range}}$ . The jet veto efficiency in the region  $|\eta| < \eta_{\text{range}}$  can be estimated from these curves as  $1 - P(N_{\text{jet}} \geq 1, p_T > 20 \text{ GeV}, \eta_{\text{range}})$ .

activity in a given region  $|\eta| < \eta_{\text{range}}$ . Note that the expectations for the jet veto efficiency discussed here are estimated by  $1 - P(N_{\text{jet}} \geq 1, p_T > 20 \text{ GeV}, \eta_{\text{range}})$  under the assumption that the minimum bias events generate a similar underlying activity as can be expected in signal events. An additional loss of signal events is associated with the multiple soft interactions from pile-up. One expects  $\sim 25$  minimum bias interactions per bunch crossing at the design luminosity of  $\mathcal{L} = 10^{34} \text{ cm}^{-2} \text{ s}^{-1}$ . Experimental effects introduced by the calorimeter readout can increase this number by another factor of 2, giving jet veto efficiencies in the order of 95(50)% for narrow jets with  $p_T > 20 \text{ GeV}$  at  $\mathcal{L} = 10^{33} \text{ cm}^{-2} \text{ s}^{-1}$  ( $10^{34} \text{ cm}^{-2} \text{ s}^{-1}$ ).

Reconstructing jets in minimum bias events can provide important information for the modeling of soft physics and on the underlying event for hard scattering processes if correlation effects are neglected. For example, the pseudorapidity distributions of  $k_T$  jets with  $p_T > 10 \text{ GeV}$  are shown in Fig. 27. Most jets above threshold are centrally produced with  $|\eta| < 1$  and reconstructed with some limited efficiency, both for towers and clusters. The fake rate for jet reconstruction at this  $p_T$  threshold can be considerable ( $\mathcal{O}(30\%)$  in the same central region), but decreases quickly with increasing jet  $p_T$ , thus likely restricting the accessible experimental phase space to test jet production in soft or semi-hard proton collisions with precision on production rates or cross section.

Figure 27: The pseudorapidity distribution of jets with  $p_T > 10 \text{ GeV}$  in single minimum bias events in ATLAS (top plots for  $k_T$  with  $R = 0.6$  and  $R = 0.4$ , respectively). The distributions for the calorimeter jets exclude fake jets, i.e. each reconstructed calorimeter jet is matched with a truth particle jet. The efficiency for jet reconstruction in these events is shown in the bottom plots.

## 5 Conclusions and outlook

ATLAS supports a highly configurable and flexible jet reconstruction framework, which can easily be adapted to accommodate new jet algorithms or signal definitions from the detectors. At the same time, a default set of configurations for jet finding strategies is provided: a seeded fixed cone algorithm with split and merge, and the  $k_T$  algorithm, both with two different parameters controlling the size of the

reconstructed jet. For the seeded cone, cone radii of  $R_{\text{cone}} = 0.7$  and  $R_{\text{cone}} = 0.4$  are available. Similarly, the default choices for narrow and wide  $k_T$  jets are distance parameters  $R = 0.4$  and  $R = 0.6$ , respectively. For the detector jets, which are reconstructed from projective calorimeter towers or topological cell clusters, a calorimeter cell signal weighting based calibration is applied, with calibration weights derived from simulations with an ideal ATLAS detector geometry model, together with an additional jet energy scale correction parametrized in pseudorapidity and transverse momentum.

Performance predictions for a slightly misaligned and distorted ATLAS detector system have been extracted mostly from PYTHIA generated QCD dijet processes simulated through the detector with GEANT4. The emphasis in these studies was to estimate possible deviations from signal linearity and uniformity, the deterioration of the relative jet energy resolution, the effect on jet reconstruction efficiencies and the fake jet reconstruction rate for the first collisions, when the inactive material distributions and the alignment of detector components may not be well known. The corresponding pre-collision physics data estimates have been derived from Monte Carlo for the default jet configurations for the two considered calorimeter signal definitions (tower and cluster). A preliminary conclusion from these studies is that the signal linearity can likely be controlled at the level of 2 – 3%, depending on the detector region. The effect of the combination of a particular calorimeter signal choice with a given jet reconstruction configuration has been found to be consistent with expectations, i.e. the noise suppression intrinsic to clusters can be observed. In general there are strong indications that the effect of uncertainties in the knowledge of the detector geometry only leads to a modest degradation of the jet reconstruction performance.

Special challenges to jet reconstruction in the forward direction or jet vetoes in the central region, have been evaluated and found to be of acceptable performance for physics analyses like vector-boson fusion produced Higgs boson events. Pile-up at high LHC luminosities leads to considerable degradation especially of the jet veto efficiency. Due the large uncertainties in the modeling of soft physics underlying and overlapping the  $pp$  collisions, a precise quantitative evaluation of this degradation needs to be postponed until experimental minimum bias data and other event topologies become available with sufficient data quality and statistics.

In preparation for the experimental data ATLAS is now focusing on “data only” calibration approaches using tools like  $p_T$  balance in prompt photon production and in QCD dijets. Additional efforts are concentrating on the subtraction of the pile-up contribution to jets, which can be estimated measuring the (transverse) energy scattered into a given area in pseudorapidity and azimuth in minimum bias events.

# Detector Level Jet Corrections

## Abstract

The jet energy scale is proven to be an important issue for many different physics analyses. It is the largest systematic uncertainty for the top mass measurement at Tevatron, it is one of the largest uncertainties in the inclusive jet cross section measurement, whose understanding is the first step towards new physics searches. Finally, it is an important ingredient of many standard model analyses. This note discusses different strategies to correct the jet energy for detector level effects.

## 1 Introduction

The jet calibration process can be seen as a two-step procedure. In the first step, the jet reconstructed from the calorimeters is corrected to remove all the effects due to the detector itself (nonlinearities due to the non-compensating ATLAS calorimeters, the presence of dead material, cracks in the calorimeters and tracks bending in/out the jet cone due to the solenoidal magnetic field). This calibrates the jet to the particle level, i.e. to the corresponding jet obtained running the same reconstruction algorithm directly on the final state Monte Carlo particles. The second step, is the correction of the jet energy back to the parton level, which will not be discussed in this section.

There are currently several calibration approaches studied in the ATLAS collaboration based on the calorimeter response on the cell level or layer level and either in the context of jets or of clusters.

The first part of the section describes a possible approach for the calibration to the particle jet. The energy of the jet is corrected using cell weights. The weights are computed by minimizing the resolution of the energy measurement with respect to the particle jet. The performance of the calibration in terms of jet linearity and resolution is assessed in a variety of events (QCD dijets, top-pairs and SUSY events). The different structure of these events (different color structure, different underlying event) will manifest itself as a variation in the quality of the calibration. This method has been the most widely used so far in the ATLAS collaboration.

Other methods have also been studied. Here we discuss one alternative global calibration approach, which makes use of the longitudinal development of the shower to correct for calorimeter non-compensation. The jet energy is corrected weighting its energy deposits in the longitudinal calorimeter samples. Although the resolution improvement is smaller with respect to other methods, this method is simple and less demanding in terms of agreement between the detector simulation predictions and real data.

The second part of this section describes the concept of local hadronic calibration. First clusters are reconstructed in the calorimeters with an algorithm to optimize noise suppression and particle separation. Shower shapes and other cluster characteristics are then used to classify the clusters as hadronic or electromagnetic in nature. The hadronic clusters are subject to a cell weighting procedure to compensate for the different response to hadrons compared to electrons and for energy deposits outside the calorimeter. In contrast to the cell weights mentioned above no minimization is performed and the actual visible and invisible energy deposits in active and inactive calorimeter material as predicted by Monte Carlo simulations are used to derive the weights. One of the advantages of this method is that the jet reconstruction runs over objects which have the proper scale (in contrast to the global approach, where the scale corrections are applied after the jet is reconstructed from uncorrected objects).

The third part of the note describes refinements of the jet calibration that can be done using the tracker information: the residual dependence of the jet scale on the jet charged fraction can be accounted for improving the jet resolution. An algorithm to correct the  $b$ -jet scale in case of semileptonic decays will also be discussed.

## 2 The calibration to the truth jet

According to the perturbative QCD, jets are the manifestations of scattered partons (quarks and gluons). After undergoing fragmentation, a collimated collection of hadrons emerges and its energy is measured in the calorimeter system. In addition to this hard scattering, the final state also contains energy coming from multiple proton–proton (pile–up) interactions and the underlying event.

The typical output of an event generator will provide theoretical predictions about the particle content and spectra at this stage, the so called particle level. Jets resulting from the application of a jet reconstruction algorithm at the particle level are thus relevant as “truth”, since they represent the final state jets that ideally must be reconstructed starting from the detector level. In the following we refer to them using the expression “truth jets”.

Since jet fragmentation functions are independent of jet energy, the fraction of the total jet energy carried by the different particle types in a jet is basically independent of energy. Figure 1 shows the relative contribution of the different particle types to the jet energy as a function of the jet  $E_T$ . About

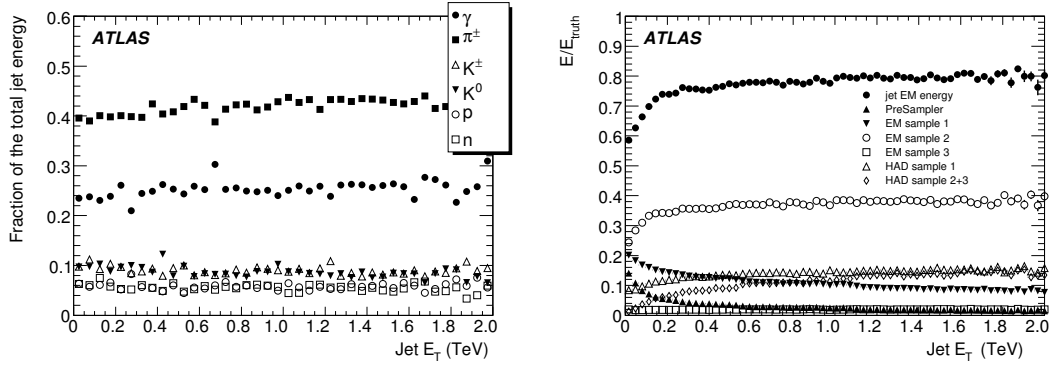

Figure 1: Left: fractional energy carried by different particle types as a function of the jet energy. Right: fraction of true energy deposited in the different calorimeter samplings for a jet in the central ( $|\eta| < 0.7$ ) calorimeter region as a function of its true energy.

40% of the total energy is carried by charged pions, 25% is carried by photons (mainly coming from the  $\pi^0$  decay), another 20% is accounted for by kaons, nearly 10% by protons and neutrons. Therefore, 25% of the energy deposits in the calorimeters come directly from pure electromagnetic showers. The right plot of Fig. 1 shows the average fractional energy deposit in the different calorimeter samplings with respect to the true jet energy in the central calorimeter regions ( $|\eta| < 0.7$ ). Most of the energy (about 2/3 of the reconstructed energy) is measured by the electromagnetic calorimeter. The total reconstructed energy differs significantly from the true jet energy. This is because of a number of detector effects:

- if the calorimeters are non-compensating (as in ATLAS), their response to hadrons is lower than that to electrons and photons, and is non-linear with the hadron energy.
- part of the energy is lost because of dead material, cracks and gaps in the calorimeters, and is also non-linear with hadron energy.
- The solenoidal magnetic field will bend low energy charged particles outside the jet cone.

The reconstructed jet energy must be corrected for these effects to obtain the best estimator for true jet energy.

In the following we will discuss two possible strategies. The first one (referred to as global calibration) aims to provide calibration coefficients at jet level; the second one, the local calibration, provides

calibration constants at the jet constituent level. The performance of both the approaches will be discussed in detail. Both methods use simulated events to obtain the calibration coefficients.

### 3 An energy density based cell calibration

The shower produced by a jet impinging on the calorimeters is composed of an electromagnetic and a hadronic component. The electromagnetic component is characterized by a compact, highly dense, energy deposit, while the hadronic one is broader and less dense. This fact can be used to correct the energy measurement to recover for the non-linear calorimeter response to the hadrons.

After jet reconstruction using calorimeter cells calibrated at the electromagnetic scale, the total energy of a jet is reconstructed by summing the energies of its constituent cells multiplied by a weight which depends on the energy density of the cell itself. We thus define the EM scale jet energy as:

$$E_{\text{em}} = \sum_{i=\text{cells}} E_i \quad (1)$$

where  $E_i$  is the energy in the cell  $i$  for the considered jet. We then define a jet weighted 4-vector

$$E = \sum_{i=\text{cells}} w_i E_i \quad \vec{P} = \sum_{i=\text{cells}} w_i \vec{P}_i \quad (2)$$

where  $E_i$ ,  $\vec{P}_i$  are the  $i$ -th cell energy and momentum (whose direction is defined by the position in the calorimeter and whose magnitude is equal to  $E_i$ ), and  $w_i$  are correction factors that need to be determined. They depend on the cell energy density  $E_i/V_i$ , where  $V_i$  is the volume of the  $i$ -th cell.

In order to reduce the number of weights to be computed, the following steps are done:

- The energy density distributions of the cells are divided into different bins with width increasing logarithmically with the cell energy density.
- The calorimeters are subdivided into several regions  $k$ . The longitudinal segmentation is partially exploited. Broad pseudorapidity bins are also defined. Table 1 shows the defined regions.
- The weight in the  $k$ -th calorimeter region, in the  $j$ -th energy density bin is defined to be:

$$w_i^{(k,j)} = \sum_{m=0}^{N_p-1} a_m^{(k)} \log^m(E/V)_j \quad (3)$$

where  $N_p$  (the number of parameters used in the fit) is a number which depends on the region  $k$  considered. The value of  $\log(E/V)_j$  is defined at the lower edge of the  $j$ -th bin.

With this procedure, the number of independent parameters to be determined is significantly reduced (see Table 1). The pre-sampler and the strip-layer of the EM calorimeter have a single weight, constant with respect to the density of the energy deposits. The last three rows of the table refer to three energy terms which are also corrected with a single multiplicative factor: they are the cryostat term, the scintillator term and the gap term. The cryostat term is computed as the geometrical average of the energy deposited in the back of the electromagnetic barrel and the first layer of the TileCal barrel. It was in fact found in the past [1] that this gives a good estimate of the energy loss in the cryostat. The scintillator and gap terms correspond to the energy deposited in the scintillation counters in the region between the Tile barrel and extended barrel [2]. The weights applied to these terms are meant to recover for the presence of a large amount of dead material.

The parameters have been determined considering QCD dijet events, simulated with PHYTHIA6.4 [3] with the ATLAS settings [4], and the detector simulated using GEANT4. The events have been generated

Table 1: Definition of regions defined for the minimization that determines the cell weights. The third column shows the number of parameters used in the minimization.

Region name	Longitudinal Sample	Number of parameters $N_p$

J1	$17 \text{ GeV} < p_T < 35 \text{ GeV}$
J2	$35 \text{ GeV} < p_T < 70 \text{ GeV}$
J3	$70 \text{ GeV} < p_T < 140 \text{ GeV}$
J4	$140 \text{ GeV} < p_T < 280 \text{ GeV}$
J5	$280 \text{ GeV} < p_T < 560 \text{ GeV}$
J6	$560 \text{ GeV} < p_T < 1120 \text{ GeV}$
J7	$1120 \text{ GeV} < p_T < 2240 \text{ GeV}$
J8	$p_T > 2240 \text{ GeV}$

in bins of the partonic  $p_T$ , as illustrated in Table 2. Approximately 10k events have been used for each bin. The jets have been reconstructed using calorimeter towers as input. The jet reconstruction algorithm used is a seeded cone algorithm with a seed threshold of  $E_T = 1 \text{ GeV}$ , and a cone size  $R_{\text{cone}} = 0.7$ . Jets with a reconstructed axis lying close to the gap region ( $1.3 < |\eta| < 1.5$ ), or to the crack region ( $3.0 < |\eta| < 3.5$ ), or in the very forward region ( $|\eta| > 4.4$ ), are excluded from the minimization.

Reconstructed jets are associated to the nearest truth jet (in  $\phi - \eta$  space), obtained, as discussed in Section 2, running the same reconstruction algorithm on the final state particles from the event generator.

The following quantity is minimized using MINUIT:

$$\chi^2 = \sum_e \left( \frac{E^{(e)} - E_{\text{truth}}^{(e)}}{E_{\text{truth}}^{(e)}} \right)^2, \quad (4)$$

where the sum runs over the considered events  $e$ ,  $E^{(e)}$  is defined in equation (2) and  $E_{\text{truth}}^{(e)}$  is the energy of the matched truth jet.

It should be noted that this approach partially absorbs effects that are not purely calorimetric into the weights. In particular, the energy smearing introduced by the central solenoidal magnetic field, which bends low  $p_T$  particles in and out of the jet cone, is not treated separately, but the effect is proven to be small for the cone  $R_{\text{cone}} = 0.7$  jets used for the minimization.

In order to correct for residual non-linearities in the jet response, a further, reconstruction algorithm dependent, correction function is introduced. The final 4-vector of a jet is thus defined as

$$E_\delta = \rho_\delta(E_T, \eta)E \quad \vec{p}_\delta = \rho_\delta(E_T, \eta)\vec{P} \quad (5)$$

where  $\delta$  indicates the dependence on the jet reconstruction algorithm and  $E_T$  and  $\eta$  are the transverse energy and the pseudorapidity of the 4-vector  $p^\mu$ . The *scale factor*  $\rho_\delta(E_T, \eta)$  is obtained fitting the ratio  $E_T/E_{T, \text{truth}}$  in 44 bins of  $\eta$  as a function of  $E_T$  with the following function:

$$f(E_T) = \sum_{i=0}^3 c_i \log^i E_T \quad (6)$$

and, for a given  $\delta$  and  $\eta$  bin,

$$\rho = 1/f. \quad (7)$$

The scale factor corrects for the residual non-linearity introduced by the cracks and gaps in the calorimeter and for differences introduced by the use of different reconstruction algorithms, finally recovering the truth jet scale. The size of this final correction is at the level of few percent (up to 5%) in the crack and gap calorimeter region, while it is of the order of 1-2% (depending on the jet algorithm) in the rest of the  $p_T$ - $\eta$  phase space.

Therefore, the complete set of calibration parameters for a given reconstruction algorithm includes the cell energy density dependent weights obtained with cone  $R_{\text{cone}} = 0.7$  jets, plus specific scale factors.

### 3.1 Results on dijet events

All the jet corrections computed as described in the previous section (scale factor included) have been applied to dijet events. The parameters that are considered in order to assess the quality of the calibration are the jet linearity, defined as the ratio between the reconstructed jet energy and the corresponding truth jet energy (as defined in Section 2) and the energy resolution.

The matching between the reconstructed jets and the truth jets is done considering their separation in a  $\eta - \phi$  plane, defined as

$$R_{\text{cone}} = \sqrt{\Delta\phi^2 + \Delta\eta^2} \quad (8)$$

A truth jet is matched with a reconstructed jet if  $R_{\text{cone}} < 0.2$ .

Once the matching is done, the  $E - \eta$  phase space of the truth jets is subdivided into bins. For each bin in energy and pseudorapidity, a histogram is filled with the ratio between the reconstructed energy and the truth energy  $E_{\text{rec}}/E_{\text{truth}}$ . The resulting histogram is first fitted with a gaussian in the whole histogram range. This provides two estimates ( $\mu_{\text{raw}}$ ,  $\sigma_{\text{raw}}$ ) for the mean value and the width of the distribution. The fit is then repeated in the range  $\mu_{\text{raw}} \pm 2\sigma_{\text{raw}}$ . This provides the final values ( $\mu$ ,  $\sigma$ ) that are used in the summary plots. Two examples of such histograms are shown in Fig. 2 for two different pseudorapidity and energy bins.

Figure 3 shows the dependence of  $\langle E_{\text{rec}}/E_{\text{truth}} \rangle$  (linearity, in the following) on the truth jet energy  $E_{\text{truth}}$  for jets reconstructed from calorimeter towers. The plot on the left refers to jets reconstructed with a cone algorithm with radius of 0.7 while the one on the right is for  $k_T$  algorithm with  $R = 0.6$  [5].

Figure 2: Two example histograms of  $E_{\text{rec}}/E_{\text{truth}}$ . On the left, the histogram is done for  $88 \text{ GeV} < E_{\text{truth}} < 107 \text{ GeV}$  and  $|\eta| < 0.5$ , on the right for  $158 \text{ GeV} < E_{\text{truth}} < 191 \text{ GeV}$  and  $1.0 < |\eta| < 1.5$ .

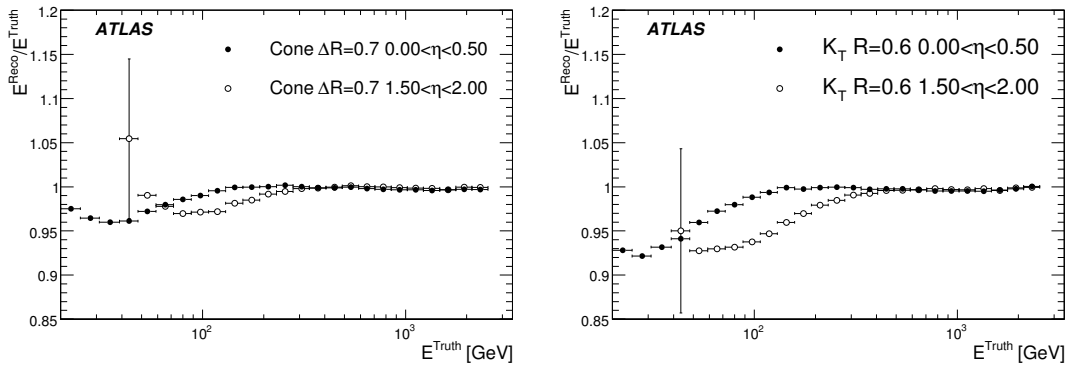

Figure 3: Dependence of the ratio  $E_{\text{rec}}/E_{\text{truth}}$  on  $E_{\text{truth}}$  for jets reconstructed with a cone algorithm with  $R_{\text{cone}} = 0.7$  and with a  $k_T$  algorithm with  $R = 0.6$ . The black (white) dots refer to jet with  $|\eta| < 0.5$  ( $1.5 < |\eta| < 2$ ). An ideal detector geometry has been used to simulate the events.

The results show that the linearity is recovered over a wide energy range, both in the central ( $|\eta| < 0.5$ ) and in the intermediate ( $1.5 < |\eta| < 2$ ) regions. For the cone algorithm, at low energy ( $E = 20 - 30$  GeV), the linearity differs by up to 5% from 1 in the central region. At low energy, there is a 5% residual non linearity, not fully recovered by the parametrization chosen for the scale factor.

Concerning the intermediate pseudorapidity region, we can see a similar behavior around 100 GeV (note that in this region  $E \sim 100$  GeV corresponds to  $E_T = E/\cosh \eta \sim 35$  GeV).

The linearity plot for the  $k_T$  algorithm shows a more pronounced deviation from 1 at low energy ( $\langle E_{\text{rec}}/E_{\text{truth}} \rangle = 5\%$  at 50 GeV, 8% at 30 GeV). The linearity is fully recovered above  $\sim 100$  GeV in the central region,  $\sim 300$  GeV in the intermediate region.

The uniformity of the response over pseudorapidity is also satisfactory. Figure 4 shows the dependence of the ratio  $E_T^{\text{rec}}/E_T^{\text{truth}}$  on the pseudorapidity of the matched truth jet for three different transverse energy bins. Again, the left plot refers to cone 0.7 jets, while the right one refers to  $k_T$  jets with  $R = 0.6$ . We can observe that for the lowest considered transverse energy bin, the ratio increases with the pseudorapidity. This is a consequence of the fact that energy increases with  $\eta$  at fixed  $E_T$  and that the linearity improves with increasing energy.

Figure 4: Dependence of the ratio  $E_T^{\text{rec}}/E_T^{\text{truth}}$  on the pseudorapidity for the cone algorithm with  $R_{\text{cone}} = 0.7$  (on the left) and for the  $k_T$  algorithm with  $R = 0.6$  (on the right). An ideal detector geometry has been used to simulate the events.

We can also observe (in particular for the  $k_T$  algorithm) the remnants of the calorimeter structure, which is not completely corrected by the procedure. There is a first, small dip at  $|\eta| \sim 1.5$ , in correspondence with the gap between the TileCal barrel and extended barrel [2]. A second dip is observed in correspondence with the calorimeter crack between the End-Cap and the forward calorimeters.

Even if the effect is smaller when higher  $E_T$  bins are considered, it is still present in the crack region. Jets with  $E_T \sim 400$  GeV still show a slight  $\eta$  dependence in their response. As a last indicator of the quality of the correction factors, we consider the energy resolution  $\sigma(E_{\text{rec}})/E_{\text{rec}}$ . The dependence of the energy resolution on the jet energy is shown in Fig. 5 for the cone (left) and  $k_T$  (right) algorithms in two pseudorapidity bins. The fit to the data is done considering three terms contributing independently to the resolution:

$$\frac{\sigma}{E} = \frac{a}{\sqrt{E} \text{ (GeV)}} \oplus b \oplus \frac{c}{E}. \quad (9)$$

The sampling term ( $a$ ) is due to the statistical, poissonian, fluctuations in the energy deposits in the calorimeters. The constant term ( $b$ ) reflects the effect of the calorimeter non-compensation and all the detector non-uniformities involved in the energy measurement. The noise term ( $c$ ) is introduced to describe the noise contribution to the energy measurement. Although the physics origin of the different

terms is quite clear, it should be kept in mind that many different ways of combining them have been used in literature. In particular, the three parameters are correlated, and their values depend on the particular functional form used to parameterize the resolution.

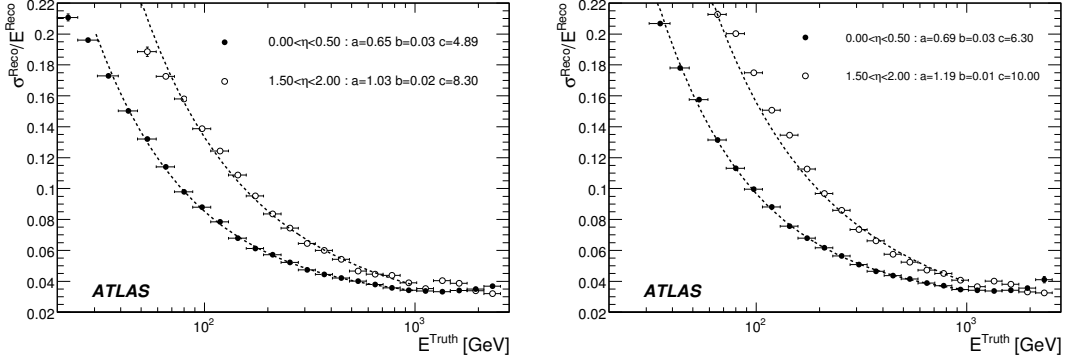

Figure 5: Energy resolution as a function of the jet energy for the cone algorithm with  $R_{\text{cone}} = 0.7$  (on the left) and for the  $k_T$  algorithm with  $R = 0.6$  (on the right). The black (white) dots refer to jets with  $|\eta| < 0.5$  ( $1.5 < |\eta| < 2$ ). The smooth curves correspond to a fit done using the parametrization of Eq. 9. An ideal detector geometry has been used to simulate the events.

The fit is performed between 30 GeV and 1 TeV. In the central region, the resolution of the  $k_T$  algorithm is significantly worse than that of the cone algorithm at low energy, while it is similar in the high energy region. The dependence of the resolution on the pseudorapidity is shown in Fig. 6. Again, the effect of the gap and crack regions are visible in particular for the lowest  $E_T$  bin, where a clear worsening of the resolution is present in particular around  $\eta = 3.2$ .

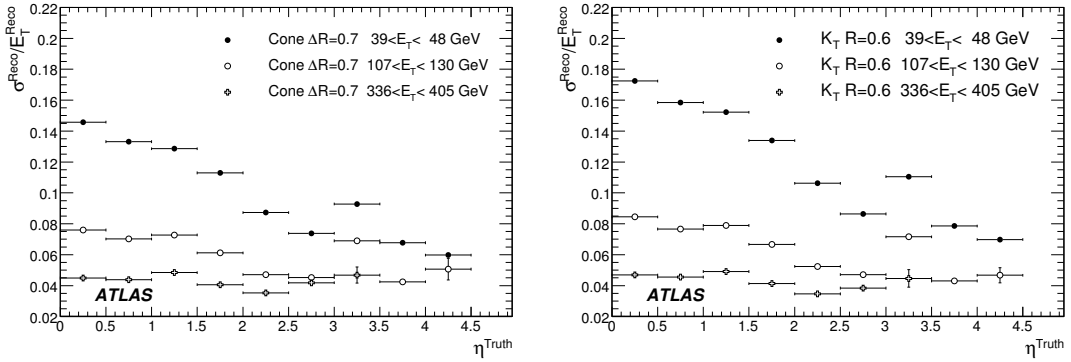

Figure 6: Energy resolution as a function of the pseudorapidity for the cone algorithm with  $R_{\text{cone}} = 0.7$  (on the left) and for the  $k_T$  algorithm with  $R = 0.6$ . An ideal detector geometry has been used to simulate the events.

The analysis has been repeated also for jets obtained using the uncalibrated topological clusters (see Section 5) as input for the jet reconstruction algorithms, obtaining very similar results for the linearity and the uniformity. The values of the parameters obtained with the fit of the function expressed in equation (9) to the simulation results are given in Table 3.

First, at fixed pseudorapidity, the sampling term is almost constant for the different reconstruction algorithms and for the different inputs. The sampling term in the central calorimeter region is about 65%, in rough agreement with what has been found previously with similar calibration approaches [6]. The

constant term is also independent of the reconstruction algorithm and input type. The noise term on the other hand shows a slight variation between jets reconstructed from towers or from topological clusters, and is a significant contribution to the jet energy resolution for energies below 100 GeV. In particular, the noise term is lower if topoclusters are used. A significant difference is also observed between the cone and the  $k_T$  algorithm, the latter showing a larger noise value.

Table 3: Parameters of the resolution parametrization described in the text as obtained with the fit of the resolution curves of Fig.9.

Reconstruction Algorithm	$0 < \eta < 0.5$			$1.5 < \eta < 2.5$		
	a (%)	b (%)	c (GeV)	a (%)	b (%)	c (GeV)
Cone $R_{\text{cone}} = 0.7$ Tower	$64 \pm 4$	$2.6 \pm 0.1$	$4.9 \pm 0.5$	$103 \pm 10$	$2.6 \pm 0.8$	$8 \pm 1$
$k_T R = 0.6$ Tower	$68 \pm 5$	$2.5 \pm 0.2$	$6.3 \pm 0.5$	$110 \pm 1$	$1 \pm 1$	$12.2 \pm 2.5$
Cone $R_{\text{cone}} = 0.7$ Topo	$63 \pm 4$	$2.7 \pm 0.1$	$4.2 \pm 0.5$	$107 \pm 8$	$1 \pm 1$	$6.5 \pm 1.5$
$k_T R = 0.6$ Topo	$64 \pm 5$	$2.7 \pm 0.2$	$5.4 \pm 0.5$	$112 \pm 4$	$1 \pm 1$	$10.0 \pm 1.5$

### 3.2 Results on $t\bar{t}$ and SUSY events

We now verify the quality of the jet calibration on two radically different physics samples. We consider first a  $t\bar{t}$  sample, generated with MC@NLO [7]. The event generator used to produce the final state particles is HERWIG interfaced with JIMMY [8], whose fragmentation model is different from the PHYTHIA one considered so far. Moreover, most of the jets in  $t\bar{t}$  events are produced by the fragmentation of quarks, while the QCD dijet events contain mostly gluon jets for moderate  $E_T$ . The simulation layout used for the  $t\bar{t}$  events is the same distorted layout discussed in [9], i.e. a geometry with increased dead material in particular in the gap region.

We consider a cone algorithm with  $R_{\text{cone}} = 0.4$  since it is the one most widely used for analyses concerning the top quark in ATLAS. The performance on QCD dijet events has been checked and the results are very similar to those discussed in Section 3.1 and in [9] for the cone with  $R_{\text{cone}} = 0.7$

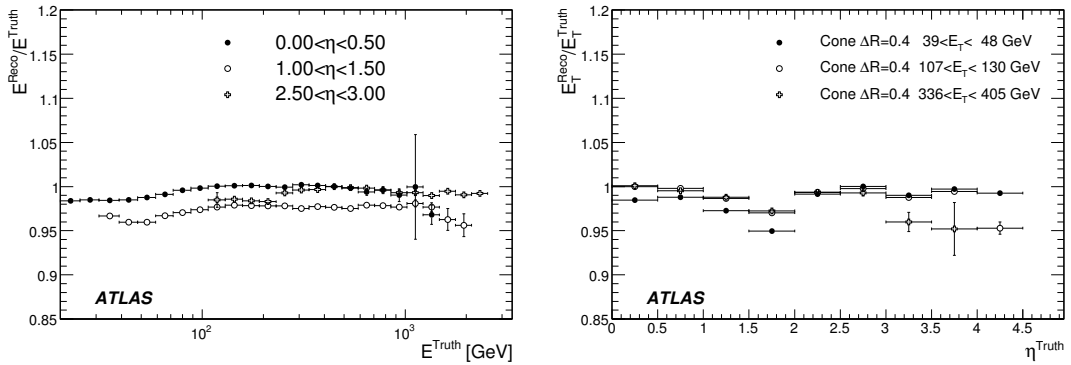

Figure 7: Linearity as a function of energy for three pseudorapidity regions (on the left) and of the pseudorapidity for three transverse energy bins (on the right) for cone 0.4 tower jets in  $t\bar{t}$  events.

The linearity as a function of the energy and the pseudorapidity is shown in Fig. 7. Despite the fundamentally different event structure, an overall acceptable linearity is found also in top events.

We finally consider SUSY events. The sample has been generated with HERWIG/JIMMY and simulated with a distorted geometry. Such events are characterized by a high multiplicity of quark jets

Figure 8: Linearity as a function of energy for three pseudorapidity regions (on the left) and of the pseudorapidity for three transverse energy bins (on the right) for cone 0.4 tower jets in SUSY events.

(the SUSY point chosen is discussed in [10]). They are thus useful to assess the performance of the jet calibration in busy events.

The linearity (Fig. 8) is overall good. In the central region, a deviation from 1 of maximum 4% is observed at low jet energy. Apart from the expected dip at  $\eta = 1.5$ , we observe, also, a good uniformity of the linearity as a function of the pseudorapidity. At large pseudorapidity ( $|\eta| > 3.5$ ), the linearity is off by 5-6%.

### 3.3 A check of the systematics with real data

We applied the method discussed so far to single pions from the ATLAS combined test beam of the year 2004 [11]. The weights have been computed on events fully simulated with GEANT4 using the test beam geometry.

Positively charged beams of different energy impinging with an incident angle of 20 degrees on the calorimeters surface have been considered. The beams are composed of pions, protons, positrons and muons. Signals from scintillators present upstream and downstream of the calorimeters are used as vetoes to reject early showering particles and muons, respectively. To reject the electrons we required an energy deposit in the first two layers of the electromagnetic calorimeter of less than a certain threshold (75% - 90% of the beam energy). A fraction of protons equal to that expected for the chosen beam line has been added to the simulated sample.

The energy distributions obtained for each energy point at the electromagnetic scale and after the calibration are fitted with a Gaussian function. The Gaussian mean values ( $\langle E \rangle$ ) are used to evaluate the calibration procedure.

In Fig. 9 (left) the ratios  $\langle E \rangle / E_{\text{beam}}$  are shown as a function of the beam energy. The black dots refer to the Monte Carlo at the electromagnetic scale. The black squares refer to the Monte Carlo after the weighting. The procedure restores the linearity at the 2% level for the simulation.

In the same figure the results on the real data are also shown (gray markers). In this case the linearity is also restored to within a few percent.

To evaluate these differences, we define the ratio  $R = \langle E_{\text{data}} / E_{\text{MC}} \rangle$ . Fig. 9 (right) shows the double ratio  $R_{\text{HAD}} / R_{\text{EM}}$  of the points of Fig. 9 (left). This plot is showing the effect of the calibration procedure on the agreement between data and simulation. The agreement is worse after the application of the calibration procedure by maximum 4%.

Figure 9: On the left:  $\langle E \rangle / E_{\text{beam}}$  for simulated (black points) and real (gray points) data at the EM (dots) and calibrated (squares) scales. On the right: Double ratio  $R_{\text{HAD}} / R_{\text{EM}}$ .

### 3.4 Summary

The tests discussed in this Section are meant to demonstrate the robustness of the jet corrections computed as discussed at the beginning of the present Section. Summarizing, we can say that the discussed strategy is able to recover the linearity of the jet energy measurement over a wide energy range, invoking a relatively low number of parameters (of the order of 50) constrained by a fit on QCD dijet events. The fact that the jet corrections can be applied with success to events generated with different showering models, with a very different quark-gluon jet ratio and different topologies, gives confidence in the correction strategy as a method to remove the detector effects.

## 4 Alternative global calibration methods

Although the discussed calibration scheme is the most widely used at present in the ATLAS collaboration, it is not the only one that has been investigated.

### 4.1 Longitudinal shower development

On average, the early part of a hadron shower is dominated by electromagnetic energy deposited by neutral pions and the ratio of visible to invisible energy is large. In the deeper part of the shower this ratio becomes smaller and more of the hadron shower goes undetected. This can be seen in the a quantitative study that was carried out by the ATLAS TileCal collaboration in the 1996 test-beam [12]. It shows that in the first interaction length of the calorimeter approximately 70% of the energy of the hadron shower is deposited as visible electromagnetic energy. The fraction falls off with depth in the calorimeter and at  $6\lambda$  only 25% the energy of the hadron shower is deposited as electromagnetic energy. Therefore a longitudinal weighting of energy deposition as a function of depth can provide improved resolution and linearity [13]. Figure 1 (right) shows the fraction of energy deposited by a hadronic jet at different depths in the calorimeter. The layers used in this weighting scheme are defined below based on the properties and geometry of different calorimeters.

The above motivation for longitudinal weighting is based on the average shower behavior. Hadron showers fluctuate event-by-event and in a jet, the incoming particle type and energy also varies depending on how the jet fragmentation proceeds. Figure 1 (left) shows the average energy carried by different particle types in a jet. To better account for these differences in shower fluctuation and electromagnetic content of a hadronic jet, the longitudinal weighting is performed in bins of the fraction of energy deposited in the LAr calorimeter. Furthermore, the Atlas calorimeter has a significant variation in geometry as a function of pseudo-rapidity and we therefore fit the parameters in independent bins of jet  $\eta$ .

As shown below, a longitudinal weighting based on the above properties of hadron shower development and jets shows a significant improvement in jet energy resolution and linearity with respect to uncorrected jet energy.

#### Longitudinal weighting method

In general the choice of energy layers to be weighted are motivated from the following. In the barrel LAr calorimeter, the first three depths (presampler, EMB1, EMB2) provide a total of  $24X_0$ . This gives 99% containment for photons with energies up to 140 GeV [14]. For hadronic jets, the energy in these layers is expected to be predominately from neutral pions. The presampler and EMB1 are defined as a single layer for longitudinal weighting purposes. The weight for this layer is expected to be sensitive to energy losses in the inner detector. EMB2, which has  $18X_0$  is weighted alone. The EMB3 is thin and has small energy deposit. Therefore the energy in this layer is added to the energy in the first layer of the Tile calorimeter. This allows for simulations to provide an average correction for energy loss in the cryostat. Depending on the jet pseudorapidity, a different number of calorimeter layers are used in the fitting. Up to a pseudorapidity of 1.5 the jet energy is fitted in four layers in the calorimeter defined as follows:

$$\begin{aligned} E_0 &= E_{\text{presampler}} + E_{\text{EMB1}} \\ E_1 &= E_{\text{EMB2}} \\ E_2 &= E_{\text{EMB3}} + E_{\text{Tile1}} \\ E_3 &= E_{\text{Tile2}} + E_{\text{Tile3}} + E_{\text{HCAL}}. \end{aligned}$$

For a jet  $\eta$  between 1.5 and 3.2 the jet is fitted for two layers in the calorimeter defined as follows.

$$E_0 = E_{\text{presampler}} + E_{\text{LArEM1}} + E_{\text{LArEM2}}$$

$$E_1 = E_{\text{LArEM3}} + E_{\text{Tile1}} + E_{\text{Tile2}} + E_{\text{Tile3}} + E_{\text{HCAL}} + E_{\text{FCAL}}$$

Beyond  $\eta$  of 3.2 up to 4.4 the jet is not divided into calorimeter layer segments and the full jet energy is fitted.

The general strategy of deriving weights for different layers is to minimize the function:

$$S = \sum_n \left[ (E_n^{\text{Ref}} - E_n^{\text{rec}})^2 + \lambda (E_n^{\text{Ref}} - E_n^{\text{rec}}) \right] \quad (10)$$

with

$$E_n^{\text{rec}} = \sum_i w_i E_i \quad (11)$$

where the  $w_i$  are weights assigned to the elements  $E_i$  of a calorimeter layer in a jet.  $E_n^{\text{Ref}}$ , the true energy to which we want to calibrate, is defined as the energy of all the MC generated particles contained in the cone of the reconstructed jet. The Lagrange multiplier  $\lambda$  constrains the minimization such that  $\langle E^{\text{Ref}} - E^{\text{rec}} \rangle = 0$ . The minimization is performed separately for jets classified in bins of eta (44 eta bins of size 0.1), three fractional energies ( $f_{\text{em}}$ ) deposited in the EM calorimeter and two energy bins. The fractional energy  $f_{\text{em}}$  is defined as

$$f_{\text{em}} = (E_{\text{Presampler}} + E_{\text{LArEM1}} + E_{\text{LArEM2}}) / E^{\text{rec}}. \quad (12)$$

Three bins in  $f_{\text{em}}$  are chosen such that each bin has roughly the same statistics. At high energies the three bins are (small: 0.0-0.65), (mid: 0.65-0.75) and (large: 0.75-1.0). At low energies they are

Figure 10: The longitudinal weights as a function of jet energy for four layers in three  $f_{\text{em}}$  bins and for central jet  $\eta$ .

(0.0-0.75), (0.75-0.85) and (0.85-1.0). The bin size varies with energy since more energetic jets deposit more energy in the deeper part of the calorimeter. Bins in  $f_{\text{em}}$  are used only for jets with  $\eta < 3.2$ .

For each layer, weights are chosen to have the following dependence on the true jet energy:

$$w = a + b \log(E/E_{\text{Cut}}), \quad (13)$$

where  $a$  and  $b$  are the parameters to be determined by minimization. When applying these weights to jets, the uncorrected jet energy is used instead of the true jet energy. The result is iterated until a stable value of the corrected jet energy is obtained.

In the above equation,  $E_{\text{Cut}}$  is an arbitrary energy chosen according to the following criteria. Since the energy range covered is quite large (25 GeV - 2 TeV) the fit is performed in two independent energy bins. For  $|\eta| < 1.2$ ,  $E_{\text{Cut}} = 300$  GeV, for  $1.2 < |\eta| < 3.2$ ,  $E_{\text{Cut}} = 450$  and for  $|\eta| > 3.2$  it is set to  $35 \cdot \cosh(\eta)$  GeV. By choosing  $E_{\text{Cut}}$  to be the bin boundary one forces the weight to be equal to the value of  $a$  at the boundary. The energy range below  $E_{\text{Cut}}$  is fitted with a fixed value of  $a$ . This ensures a smooth behavior of weights across  $E_{\text{Cut}}$  and reduces the lower energy fit from a two parameter to a one parameter fit. The same smoothness in the behavior of weights across  $\eta$  and  $f_{\text{em}}$  is not strictly imposed in the present fit, although the weights do not have strong variation across the bin boundaries.

The fitting procedure was applied to a fully simulated and reconstructed QCD dijet sample. To suppress noise, topological clusters were used. The jet algorithm (cone  $R_{\text{cone}} = 0.7$ ) is run on calorimeter towers which contain only cells which are included in the reconstructed topological clusters. Half of the events in the sample were used to determine the layer weights. These weights were then applied to the other half of the events to determine the effect of the weights on jet energy linearity and resolution.

Figure 10 shows the behavior of the weights in bins of  $f_{\text{em}}$ . A common feature in all the weight distributions is a small variation with respect to the jet energy, especially for high energies. This ensures insensitivity to the use of the true jet energy in equation 13. Layer 2, which measures the bulk of the jet energy has a weight close to 1 when  $f_{\text{em}}$  is large i.e when the jet is predominantly electromagnetic in nature. When  $f_{\text{em}}$  is small i.e when the jet is predominantly hadronic, the layer 2 weights are around 1.4. Layer 1 acquires a generally higher weight due to losses in the inner detector, even though it is within the early part of the jets. Layer 3 and 4 get weights larger than 1 corresponding to jets being predominantly hadronic in these layers. Layer 3 gets larger weights than layer 2 since it also corrects for energy lost in the cryostat.

Figure 11 shows the jet energy scale linearity as a function of jet energy (left). The corrected jet energy scale is linear to about 2% with the largest non-linearity coming from low energies where the uncorrected non-linearity is approximately 30%. Figure 11 (right) shows the corresponding linearity as a function of detector pseudo-rapidity for jets of 1000 GeV in energy. The typical non-uniformity is about 1%, increasing to about 2% in the region of  $\eta \sim 3.0$ . Jet energy resolutions as a function of the jet energy scale is shown in Fig. 12 for two different jet eta regions. At high energy the jet resolution approaches about 4%.

In terms of jet energy linearity, the longitudinal weighting and H1-style weighting scheme (Section 3) have comparable performance, although the H1-style weighting scheme shows a slightly better resolution. This is expected since H1-style weighting uses local cell energy density to discriminate between EM and non-EM like energy deposits. In contrast, longitudinal weighting is less sensitive to local energy fluctuations, which may be an advantage in the early data taking period, when the simulation of energy deposition in the calorimeter may not accurately reproduce the data.

## 5 Local hadron calibration

In contrast to the global calibration method just described, where first jets are made from towers or clusters on the electromagnetic scale and the calibration is applied after jet-making on cell or sampling

Figure 11: Jet energy linearity as a function of jet energy (left), and as a function of jet pseudorapidity (right). The points are for jets reconstructed at the electromagnetic scale (EM), for the global weighting scheme described here (Samp) and for the H1-style calibration described in the previous Section. The jets have a cone radius of  $R_{\text{cone}} = 0.7$ .

Figure 12: Jet energy resolution for jets with a cone radius of 0.7 for two regions in pseudorapidity. The three sets of point show the resolution at the detector (EM) scale, after H1-style and longitudinal weighting.

level, the local hadron calibrated jets are made from clusters which are already calibrated to the hadronic scale.

### 5.1 Topological clusters

The cluster algorithm used is described in detail in Ref. [15]. Clusters grow dynamically around seed cells based on noise thresholds and are re-grouped in a second splitter step around local maxima.

The aim of the clustering step before the actual jet making is two-fold:

1. To suppress noise from electronics and pile-up by reducing the number of cells included in the jets via noise-driven clustering thresholds.
2. To improve the correspondence between clusters and particles. Due to the dynamic nature of the cluster growing, individual clusters correspond better to stable particles than towers or cells and the jet constituents can serve to further study the substructure of jets.

To illustrate the effect of noise reduction by using topological clusters as input to jets the amount of noise at the electromagnetic scale and the number of cells per jet for cone jets with  $R_{\text{cone}} = 0.7$  is compared in Fig. 13 for jets from dijet simulations with towers as input and with topological clusters as input. The noise reduction is a direct consequence of selecting fewer cells with topological clusters. The effect is largest for low energetic jets since the size and number of signal clusters becomes small. The number of cells per jet for tower jets does not depend on the energy since no threshold for the towers is applied. Subsequently the noise changes only if a cell included in a tower jet switches to a lower gain. For the displayed energies this effect is visible in the forward region only. For jets from topological clusters the noise increases with energy and at transverse energies of 150 GeV it is typically a factor of 2 lower than for a corresponding tower jet except for the very forward region where the signals are so dense that the topological clusters again include almost all cells and the noise level reaches that of the tower jets.

Figure 14 shows the correspondence of clusters and stable truth particles in a dijet simulation. The sample shown is a PYTHIA QCD dijet sample with the transverse energy of the leading jet between 140 GeV and 280 GeV. Roughly 1.6 truth particles correspond to each of the  $65 \pm 30$  clusters for a cut at 1 GeV in transverse energy, but the ratio does not depend on the cut. It is close to the expected ratio of  $\sim 4/3$  since about 1/2 of the stable particles in jets are photons from  $\pi^0$ -decays, which usually merge to one cluster.

Figure 13: Noise contents (left) and number of cells per jet (right) of Cone jets with  $R_{\text{cone}} = 0.7$  for different energies for towers as input (open symbols) and topological clusters as input (filled symbols).

Figure 14: Number of topo clusters with  $E_\perp > 1$  GeV vs. number of stable truth particles with  $E_\perp > 1$  GeV from a QCD dijet simulation.

## 5.2 Cluster Calibration

The local hadron calibration of topological clusters is described in detail in Ref. [16]. The calibration starts by classifying clusters as mainly electromagnetic, hadronic, or unknown depending on cluster shape variables, moments derived from the positive cell contents of the cluster and the cluster energy. The classification is based on predictions from GEANT4 [17, 18] simulations for charged and neutral pions. The expected phase space population in logarithmic bins of the cluster energy, cluster depth in the calorimeter, and average cell energy density and linear bins in  $|\eta|$  from neutral and charged pions with a ratio of 1 : 2 is converted to a classification weight, reflecting the a-priori assumption that 2/3 of the pions should be charged.

Roughly 90% of the energy of charged pions is classified as hadronic by this procedure for all energies, while for neutral pions 90% of their energy is classified as electromagnetic on average beyond 100 GeV and the performance drops with the logarithm of the pion energy to about 50% at 10 GeV. The ideal fraction of 100% is not reached for the charged pions as sometimes the shower is split into more than one cluster with one of them being predominantly electromagnetic in nature. At low energies neutral pion clusters occupy the same phase space as charged pion clusters and the a-priori precedence for charged pions makes the classification as electromagnetic less likely. This leads to the high fraction of neutral pion energy classified as hadronic at low energies which is still acceptable, since the weights applied here are close to 1. Clusters classified as hadronic receive cell weights derived from detailed GEANT4 simulations of charged pions with so-called calibration hits in active and inactive calorimeter materials, which contain the energy from ionization losses and also from invisible processes, such as nuclear excitation, and from escaping particles, such as neutrinos. Cells in individual calorimeter samplings are treated in 0.2-wide  $|\eta|$ -bins. The weights are binned logarithmically in cluster energy and cell energy density. A flat distribution in the logarithm of the particle energy was used to generate the single pion events.

Out-of-cluster (OOC) corrections are applied to correct for energy deposits inside the calorimeter but outside calorimeter clusters due to the noise thresholds applied during cluster making. These corrections depend on  $|\eta|$ , cluster energy and the cluster depth in the calorimeter.

Dead material (DM) corrections are applied to compensate for energy deposits in materials outside of the calorimeters. For deposits in upstream material like the inner wall of the cryostat the presampler

signals are found to be highly correlated with the lost energy and the corrections are derived from the sum of calibration hit energies in the upstream regions and the presampler signal.

The correction for energy deposited in the outer cryostat wall between the electromagnetic and hadronic barrel calorimeters is based on the geometrical mean of the energies in the samplings just before and just beyond the cryostat wall. Corrections for other energy deposits without clear correlations to cluster observables are obtained from lookup tables binned in cluster energy,  $|\eta|$ , and shower depth.

### 5.3 Performance for jets

The aim in this section is to evaluate the degree of completeness of the local hadron calibration when applied to jets. The performance of the local hadronic calibration scheme was evaluated using the dijet samples listed in Table 2 and two methods: by comparison to particle jets as described above in section 3.1, and by comparison to the calibration hits in the GEANT4 record. Since no truth matching occurs in the derivation of the calibration constants genuine jet-level effects are expected to be visible once the reconstructed jet is compared to the matching jet made of stable truth particles. The main sources of remaining energy corrections are:

**Misclassification** Hadronic energy deposits which are treated as electromagnetic lead to a lower energy response, while electromagnetic energy deposits wrongly treated as hadronic lead to a higher energy response. The effect of energy underestimation dominates and is roughly 3% for  $p_\perp \simeq 150$  GeV.

**Lost Particles** Low energetic particles might be bent outside the acceptance cone of the reconstructed jet or reach the calorimeter inside the acceptance cone but leaving a signal below threshold for the clustering. Both effects are estimated to add up to 5% for  $p_\perp \simeq 150$  GeV, with 3% stemming from low energy deposits not included in the clusters and 2% from particles bent outside the acceptance cone.

Jets formed from topological clusters, calibrated using the local hadronic calibration scheme, were compared to the truth jets as done with the previous calibration methods. Figure 15 shows the linearity for Cone  $R_{\text{cone}} = 0.7$  and  $k_T R = 0.6$  dijets for 3 different  $|\eta|$  regions as a function of the jet energy. The performance in the forward region is especially low because of a scale error of 10% introduced in the simulations<sup>1</sup>. The forward scale error highlights another strength of the calibration hits – they can in fact reveal that there is a problem in the predicted reconstructed energy. All calibration methods discussed in this note would yield an overestimation of the jet energy in the forward region in real data if this simulation problem would not be fixed in the samples needed to derive the calibration constants.

In the other pseudo-rapidity regions the linearity is rising from 80% at 30 GeV to over 95% at 1 TeV. Figure 16 shows the linearity as a function of the true jet  $|\eta|$  for 4 different jet energies. Dips in the linearity are clearly visible for the transition regions between the calorimeter systems at the gap region ( $1.3 < |\eta| < 1.5$ ) and the crack region ( $3.0 < |\eta| < 3.5$ ). For the forward region, the mentioned scale error is very clearly visible: the linearity cannot be recovered and the scale is off by 10%. The dependency of the linearity on the jet energies can also be observed in these plots: while the linearity for jets with about 100 GeV can be recovered up to about 90% (85% in the gap region), high energy jets (of about 1 TeV) show a linearity of about 95 – 97% which is compatible with the 3% loss due to misclassification as discussed above. Although a simple scale function, such as given in Eq. (5) on the jet level, would restore the linearity and give a comparable performance as the global calibration, our goal is to understand and correct for these effects in order to recover the linearity instead by correction functions based on the jet constituents.

<sup>1</sup>The assumed sampling fraction did not correspond to the actual sampling fraction in the FCal region and thus the assumption that electromagnetic showers can remain un-scaled leads to an underestimation of the energy.

Figure 15: Linearity for Cone jets with  $R_{\text{cone}} = 0.7$  (left) and Kt jets with  $R = 0.6$  (right), both calibrated with the local hadron calibration method (LC), using truth particle jets (MC) as reference. The linearity is shown as a function of the matched truth jet energy.

Figure 16: Linearity for Cone jets with  $R_{\text{cone}} = 0.7$  (left) and Kt jets with  $R = 0.6$  (right), both calibrated with the local hadron calibration method, using truth particle jets as reference. The linearity is shown as a function of the matched truth jet  $|\eta|$ .

The jet energy resolution is shown in Fig. 17 as a function of the true jet energy. Table 4 shows the parameterised resolution obtained using this method as a function of energy and rapidity. Its performance is typically 20% or more above that obtained using the global calibration method. We discuss some possible improvements to the local hadronic calibration method below.

Figure 17: Resolution for Cone jets normalized to the reconstructed jet energy with  $R_{\text{cone}} = 0.7$  (left) and Kt jets with  $R = 0.6$  (right), both calibrated with the local hadron calibration method, using truth particle jets as reference. The resolution is shown as a function of the matched truth jet energy.

Table 4: Resolution as function of  $E_{\text{true}}$  for jet with the local hadron calibration applied.

Reconstruction Algorithm	$0 <  \eta  < 0.5$			$1.5 <  \eta  < 2.0$		
	a (%)	b (%)	c (GeV)	a (%)	b (%)	c (GeV)
Cone $R_{\text{cone}} = 0.7$ LC	$78 \pm 8$	$3.5 \pm 0.8$	$2.3 \pm 0.9$	$98 \pm 14$	$7.7 \pm 1.7$	$3.3 \pm 0.7$
$k_T$ $R = 0.6$ LC	$79 \pm 8$	$4.7 \pm 0.7$	$2.4 \pm 0.6$	$117 \pm 15$	$9.7 \pm 1.9$	$1.2 \pm 2.3$

A detailed analysis of the performance of the local calibration when applied to jets is also presented in Ref. [19], where different local calibration approaches are compared to the performance of the H1 global calibration.

## 5.4 Further Improvement

As seen in the previous section several jet-level corrections need to be applied in order to bring jets made of local hadron calibrated topological clusters to the truth particle scale. However, the global method is seen to exhibit somewhat superior performance indicating that further improvements should be possible since both methods use shower development as their fundamental basis.

Figure 18 (left) shows the ratio of the corrected energy as obtained from the reconstructed calorimeter cells to the energy obtained from the GEANT4 calibration hits in the clusters and in dead material. A significant deficit is seen at low energy. Figure 18 (right) shows the ratio of the the energy obtained from the GEANT4 calibration hits in the clusters and in dead material to the energy of the nearest truth particle jet. In this case we see roughly unity at high energy and only a 10% deficit at low energy. Since this comparison is to the truth particle jet, we attribute this deficit to out of cone energy. We therefore conclude that the dominant effects on the non-linearity at low energies seen in Fig. 18 stem from particles lost in the dead material upstream of the calorimeters. These low energy pions deposit most of their energy in upstream materials and often do not leave a sufficiently large signal in the calorimeters to cause a cluster to be formed. At present, no good observable on the local cluster level aids in recovering

Figure 18:  $E_{\text{weighted}} + \text{DM corrected} / E_{\text{in cluster truth} + \text{DM truth}}$ , the reconstructed weighted and dead-material corrected energy over the the predicted true energy inside clusters and associated dead material regions (left) and  $E_{\text{in cluster truth} + \text{DM truth}} / E_{\text{truth}}$ , the ratio of the predicted true energy inside clusters and associated dead material regions (the denominator in the left plot) over the energy of the matched truth particle jet (right) as function of the matched truth jet energy for cone jets with  $R_{\text{cone}} = 0.7$ .

this lost energy and the local calibration method can not account for it. Corrections for these effects are currently being studied. A scaling function like Eq. (5) which is used in the global method would help to restore the linearity in Fig. 15 but would not improve the resolution. The generalization of cluster shape variables to the jet level (number of low energetic constituent clusters, energy distribution of the constituent clusters, etc.) might help in order to obtain correction procedures that depend only indirectly on the used jet algorithm, restore the linearity and improve the resolution. The missing energy content can for example be estimated by extrapolating the actual distribution of constituent cluster energies to zero GeV to recover the lost contributions from low energetic particles. The in-situ methods as discussed in Ref. [20] can be used to validate the corrections obtained and to possibly compensate residual non-linearities.

## 6 Track-based improvement in the jet energy resolution

We present a track-based method for improving the jet energy resolution in ATLAS. Unlike energy-flow techniques reference, information is added to the reconstructed jet, after the global jet energy scale corrections have been implemented, and the track-based correction is applied based on the fraction of jet momentum carried by charged tracks associated with the jet. Using this correction, a  $\sim 20\%$  improvement in jet energy resolution at low energy is achieved.

In this chapter we describe a technique that uses tracks in jets to extract information from the jet topology and fragmentation in order to improve the jet energy resolution. The approach is conceptually different from more traditional energy flow methods, where precise track momentum measurements replace calorimeter clusters. In the proposed technique, tracks are used to correct the response of jets as a function of the jet particle composition, specifically using the ratio of track to calorimeter transverse momentum ( $f_{\text{trk}} = \frac{p_{\text{T}}^{\text{tracks}}}{p_{\text{T}}^{\text{calorimeter}}}$ ). Using  $f_{\text{trk}}$  provides an improvement in jet energy resolution without changing the jet energy scale applied during reconstruction.

In general, jets are composed primarily of neutral and charged pions. Charged particles leave tracks in the detectors, and so one might naively expect that approximately two-thirds of the jet energy will be carried by tracks associated with that jet. Monte Carlo QCD dijet samples show Gaussian  $f_{\text{trk}}$  distributions centered around 0.66, with small tails extending above 1. The tails are more prominent at low

energies and include, for example, jets with a true  $f_{\text{trk}}$  near one and one or more tracks with incorrectly measured momenta.

The fractional jet energy resolution,  $\frac{\sigma(p_T^{\text{reco}} - p_T^{\text{true}})}{p_T^{\text{true}}}$ , is proportional to the width of the jet energy response in bins of transverse energy, normalized to the average jet energy in a bin. If the response of these jets varies significantly with  $f_{\text{trk}}$ , the transverse jet energy resolution will be artificially broadened, as shown in Fig. 19. One sees that the total measured transverse jet energy resolution is considerably wider than either of the constituents corresponding to jets with different charged particle fractions. By correcting the jet response as a function of jet  $p_T$  and  $f_{\text{trk}}$  we reduce the overall broadening of the energy distribution and, hence, improve the jet energy resolution.

Figure 19: Black: difference between reconstructed and truth jet transverse energy for jets with  $0 < |\eta| < 0.7$  and  $40 \text{ GeV} < p_T < 200 \text{ GeV}$ . The mean (width) of this distribution is proportional to the jet energy response (resolution). Since jets with different  $f_{\text{trk}}$  have different responses, the transverse energy resolution is artificially broadened because of the offset of the distributions for each  $f_{\text{trk}}$  bin. The normalization is arbitrary.

## 6.1 Monte Carlo samples and event selection

Track based jet corrections were determined using QCD dijet events. The MC events used are the same J1-J4 samples described in Table 2. The reconstructed jets in the samples ranged in  $p_T$  from 7 GeV to 280 GeV. Only jets with energies above 45 GeV were used in the fits.

Reconstructed 0.4 cone, tower-seeded jets were selected from the event and separated into bins of pseudorapidity. Fits were formed for the central ( $|\eta| < 1.2$ ), transition ( $1.5 < |\eta| < 1.8$ ) and end cap ( $1.9 < |\eta| < 2.2$ ) regions of the calorimeters. Because the ATLAS tracker acceptance ends at  $|\eta| = 2.5$ , jets beyond  $|\eta| = 2.0$  were not considered for fits.

Tracks within a cone of radius 0.4 in  $\eta - \phi$  around a jet axis were included in the calculation of  $f_{\text{trk}}$ . In order to remove jets with a single poorly measured track, jets were required to be associated with at least two tracks, and each track was required to have  $\chi^2/\text{DoF} < 3.0$ . Less than 1% of the tracks and jets were rejected by these cuts. The requirement of two tracks was only applied to derive the correction and not to evaluate the performance. In order to be as inclusive as possible, all calorimeter jets were considered. To find the track-based energy corrections, jets were also required to be isolated in a cone of

0.8 in  $\eta - \phi$  space, to avoid jet-jet contamination which skew  $f_{\text{trk}}$  considerably for low energy jets. After cuts, each jet contained typically 5 to 8 tracks.

Jets were also required to have a truth jet matched within 0.1 in  $\eta - \phi$  space, and were required not to be matched to a truth  $b$ -quark. Jets with  $b$ -quarks could have different energy responses compared to light quark jets and were excluded from the fits. Incorporating a track-based  $b$ -jet energy correction is a topic for future studies.

## 6.2 Track-based jet energy response parameterization

Fits to the jet energy response are made as functions of  $f_{\text{trk}}$  and  $p_T$ . The fits were also binned in regions with flat response as a function of pseudorapidity. Three such regions were identified: one in the barrel calorimeter, one in the endcap calorimeter, and one in the transition region between the two. The fits are then extended to nearby regions so that all jets are eventually corrected. Since the transitions between the calorimeters are discontinuous, the transitions between the corrections were discontinuous for this first version of track corrections.

One dimensional fits of the response as a function of jet  $p_T$  were performed in bins of  $f_{\text{trk}}$  with the function  $R^{f_{\text{trk}}}(p_T) = E_T^{\text{jet}}/E_T^{\text{true}} = a(1 - e^{b-c*p_T})$ . Sample fits are shown in Fig. 20 (left). The bins in  $f_{\text{trk}}$  were adjusted so that each bin contained approximately the same number of jets, and no single bin spanned a large range of  $f_{\text{trk}}$ . The  $p_T$  used for each point of the fit was taken to be the average  $p_T$  of jets in that bin, and the  $f_{\text{trk}}$  recorded for the bin was the average  $f_{\text{trk}}$  of all jets in that bin.

Figure 20: On the left, fits as a function of reconstructed jet  $p_T$  for central ( $|\eta| < 0.7$ ) jets in bins of  $f_{\text{trk}}$ . On the right, straight line fit of one of the parameters determined by  $p_T$  fits, as a function of  $f_{\text{trk}}$ .

The jet  $p_T$  fit parameters were then extracted and fitted with a straight line function of  $f_{\text{trk}}$ , as shown in Fig. 20 (right) for parameter  $a$ . The 2-dimensional track-jet energy corrections,  $R(p_T, f_{\text{trk}})$  can be applied to reconstructed jets to improve their average response.

## 6.3 Algorithm performance

The track-jet response correction  $R(p_T, f_{\text{trk}})$  described previously was first applied to jets selected for determining the parameterization. The jet energy response was then checked as a function of  $f_{\text{trk}}$ . Figure 21 (left) shows the dependence of the response on  $f_{\text{trk}}$  before and after applying the track-jet correction. Track-jet corrections flatten the response,  $R^{f_{\text{trk}}}(p_T) = E_T^{\text{jet}}/E_T^{\text{true}}$ , to a mean value of 1 for all  $f_{\text{trk}}$ . An overcorrection at high  $f_{\text{trk}}$  appears. As the overlaid distribution of  $f_{\text{trk}}$  demonstrates, very few jets lie in this region and so the total energy resolution is not altered.

As described earlier and shown in Fig. 19, the jet resolution before the  $R(p_T, f_{\text{trk}})$  correction can be thought of as a convolution of distributions consisting of the sum of several offset Gaussians with different  $f_{\text{trk}}$ . By re-centering the underlying distributions we improve the jet transverse energy resolution. Fig. 21 (right) shows the overlapping distributions after re-centering.

Figure 21: On the left: absolute jet energy response as a function of  $f_{\text{trk}}$ , before and after applying the track-jet response correction. The distribution of  $f_{\text{trk}}$  has been overlaid to show the jet distribution. All jets used in the fits are included. On the right: jet transverse energy response after the track-jet response correction for jets with  $0 < |\eta| < 0.7$  and  $40 \text{ GeV} < p_T < 200 \text{ GeV}$ . The underlying Gaussian distributions are now overlapping, and the measured jet transverse energy resolution has been reduced.

The fitted corrections were applied to all jets above 40 GeV in the dijet samples. The following studies show the improvement of jet transverse energy resolution and  $E_T^{\text{miss}}$  distributions after the corrections are applied.

### Jet transverse energy resolution

The transverse jet energy resolution is considerably improved at low jet  $p_T$ , as demonstrated in Fig. 22. Fits are shown both before and after the corrections are applied. A  $\sim 15\%$  improvement in energy resolution is achieved at 60 GeV.

### $E_T^{\text{miss}}$ resolution

Track-based jet corrections can also be used to improve the scale of the missing transverse energy. The track-corrected  $E_T^{\text{miss}}$  is computed as

$$\vec{E}_T^{\text{corr}} = \vec{E}_T - \sum (\vec{p}_T^{\text{trk,corr}} - \vec{p}_T) \quad (14)$$

where the sum refers to the two leading jets, and  $\vec{p}_T^{\text{trk,corr}} = p_T/R(p_T, f_{\text{trk}})$  is the jet transverse momentum corrected as described in Section 6.2.

Figure 23 (left) shows the mean value of the  $E_T^{\text{miss}}$  as a function of the  $f_{\text{trk}}$  difference between the two leading jets in a dijet sample. Both leading jets were required to have  $|\eta| < 1.2$  for this study. Figure 23 (left) shows a large imbalance of energy when the two jets have large differences in  $f_{\text{trk}}$ . When  $\Delta f_{\text{trk}} < 0$ ,

Figure 22: Jet transverse momentum resolution as a function of jet  $p_T$  before and after correcting for  $f_{\text{trk}}$ .

Figure 23: Average missing transverse energy as a function of the  $f_{\text{trk}}$  difference between the two leading jets in a dijet sample before (left) and after (right) track-based jet energy corrections. The width and tails are improved.

$f_{\text{trk}}^2 > f_{\text{trk}}^1$  and  $p_T^2$  is underestimated resulting in a positive bias on  $E_T^{\text{miss}}$ . Similar argument explains a negative  $E_T^{\text{miss}}$  bias for  $\Delta f_{\text{trk}} > 0$ .

Figure 23 (right) shows that the  $E_T^{\text{miss}}$  scale is properly corrected after applying the track-based response correction to the leading two jets, and the  $E_T^{\text{miss}}$  bias has been removed.

## 6.4 Conclusions and future studies

Although the corrections in this section were calculated only for cone jets with  $\Delta R = 0.4$ , they can be trivially extended to any other jet collection, including  $k_T$  jets.

We introduced a track-based method for correcting the response of jets in ATLAS that provides a  $\sim 20\%$  improvement in jet energy resolution at 50 GeV. The corrections also improve missing energy distributions. These corrections do not require new jet energy scale corrections and can be applied after the standard reconstruction. By systematically adding information from the tracker to jets already reconstructed based on calorimeter information, considerable improvements can be made.

There are several additions being explored to further improve the jet energy resolution using this technique and other similar track-based variable methods. This technique will be expanded to correct

Figure 24: Fraction of  $p_T$  carried by the neutrino in  $b$  jets decaying semileptonically ( $b \rightarrow \mu X$  or  $b \rightarrow c \rightarrow \mu X$ ). The abscissa corresponds to the total transverse component for the jet (all interacting particles except muons), muon and neutrino momenta. We use  $b$  jets from QCD dijet samples as described in Section 7.1.

$b$ -jets in the same way that light quark jets have already been corrected. The radius used for track-jet association may be adjusted to improve the performance. Track-based response corrections will be expanded to include additional variables such as the fraction of transverse momentum carried by the leading track ( $f_{\text{trk}}^1$ ) and track multiplicity ( $n_{\text{trk}}$ ).

## 7 Jet energy scale corrections to semileptonic $b$ jets

In this section, we discuss a possible strategy to correct the  $b$ -jet energy in case of semileptonic decays of the  $b$  quark.

The decay of  $b$  quarks usually produces a  $c$  quark, which subsequently decays to a  $d$  quark. The  $b$  quark decays into a muon and a neutrino  $\approx 10\%$  of the time. As a result, a  $b$  jet is accompanied by a neutrino and a muon  $\approx 19\%$  of the time and by two neutrinos and two muons  $\approx 1\%$  of the time. These neutrinos carry away a fraction of the jet energy, introducing a systematic underestimation of the energy of such jets. In this document, we concentrate on  $b$  jets that contain only one neutrino inside. The neutrino from the semileptonic  $b$  jet decay carries over 10% of the total jet  $p_T$ .

However, these jets can be tagged by the presence of a muon, if the muon is energetic enough to reach the Muon Spectrometer. Upon a successful tag, the jet energy scale can be corrected through a parameterization of the energy carried by the neutrino. In the following sections, a correction of the jet energy scale as a function of jet and muon  $p_T$  for semileptonic  $b$  jets is presented and validated.

### 7.1 Monte Carlo event selection

For the studies in this document, two data samples were used (250 k  $t\bar{t}$  and the dijet samples described in Table 2)

In addition, for the present studies, semileptonic  $b$  jets were required to be tagged by the soft- $b$  tagger [21] and be contained within  $|\eta| < 1.2$ . The  $\eta$  cut is required because the jet response changes for higher  $\eta$ . Studies in larger  $\eta$  regions were not possible due to a lack of statistics. For the dijet sample, only events that had two  $b$  jets with  $\Delta\phi > 1.0$  were used. This provides a sample composed mostly of  $b\bar{b}$  events as well as a few  $g\bar{g}$  events where one of the gluons decays to  $b\bar{b}$ .

Figure 25: Left: Jet response as a function of jet  $p_T$  for semileptonic  $b$  jets containing one muon for different values of  $x$  (equation 15). Here  $p_{T,\text{true}}^{\text{jet}+\mu+\nu}$  refers to the transverse component of the vector addition of the true jet momentum (all interacting particles except muons included), the true muon momentum and the neutrino momentum. Right: Value of the results from straight line fits to the points in the left plot as a function of  $x$ . The fit function  $C(x) = a + be^{-cx}$  is also shown.

## 7.2 Derivation of the jet energy scale correction

The jet energy scale correction was derived using semileptonic  $b$  jets from the  $t\bar{t}$  sample. The jet response was studied as a function of jet and muon  $p_T$ . In particular, it was found that a correlation exists between the jet response and the quantity

$$x = p_{T,\text{reco}}^\mu/p_{T,\text{reco}}^{\text{jet}}, \quad (15)$$

where  $p_{T,\text{reco}}^\mu$  is the reconstructed muon  $p_T$ , and  $p_{T,\text{reco}}^{\text{jet}}$  is the reconstructed jet  $p_T$ , which does not include the muon contribution. The jet responses for samples with different values of  $x$  are shown in the left plot of Figure 25. The responses are shown together with the constant fits used to determine the correlation between the jet response and the quantity  $x$ . The fits do well in correcting for the missing neutrino energy, and, therefore, no further dependence on jet  $p_T$  has been considered so far. A better modeling of the dependence of the response as a function of jet  $p_T$  in the different samples could help improve the correction. The values of the constant fits ( $R$ , in the figure above) were then used to parameterize the jet response as a function of  $x$ . The values of  $R$  for samples with different values of  $x$  are shown on the right plot of Figure 25. These values were fit to the function  $C(x) = a + be^{-cx}$ . This fit is shown on the same plot and resulted in the following values for the parameters:  $a = 0.846$ ,  $b = 0.11$  and  $c = 6$ .

This function was used to correct the jet energy scale. In particular, the corrected  $p_T$  of the jet was calculated as:

$$p_{T,\text{corr}}^{\text{jet}+\mu} = [C(x)]^{-1} p_{T,\text{reco}}^{\text{jet}+\mu}. \quad (16)$$

The momentum of the jet was increased accordingly along the direction of the vector addition of the muon and jet momenta.

## 7.3 Validation

The jet response before and after applying the correction for the  $t\bar{t}$  sample is shown in the left plot of Figure 26. The jet response is corrected appropriately with an uncertainty of  $\approx 2\%$  on the correction. The right plot shows the jet response in the dijet samples. The performance of the correction on this sample is comparable to that shown in the  $t\bar{t}$  sample. The relative jet  $p_T$  resolution,  $\sigma_r/r$  where  $r = p_{T,\text{reco}}^{\text{jet}+\mu}/p_{T,\text{reco}}^{\text{jet}+\mu+\nu}$ , was also studied for these two samples before and after the correction, but it is not

Figure 26: Response of semileptonic  $b$  jets before and after applying the neutrino correction to jets from a  $t\bar{t}$  sample (left) and a  $b\bar{b}$  sample (right).

shown. The effect of the correction on this quantity is not noticeable within the statistical uncertainties of these studies.

#### 7.4 Conclusion on the corrections to semileptonic $b$ jets

In this section, a procedure for correcting the jet energy scale of semileptonic  $b$  jets decaying to a muon has been presented. The procedure has been validated on semileptonic  $b$  jets from two data samples showing a noticeable improvement in the jet response, while the relative  $p_T$  resolution remains unchanged. To conclude, it should be emphasized that the correction of semileptonic  $b$  jets is strongly coupled to our ability to tag them. For this reason, studies in specific physics analyses need to be done to set the operating point of the soft- $b$  tagger. For example, in a  $b\bar{b}$  sample, where there are no light jets, we can benefit from this correction the most, while in a  $t\bar{t}$  sample the operating point of the soft  $b$ -tagger might need to be adjusted and could have too low an efficiency for the correction to be noticeable. Further studies on this subject are required in order to determine when the correction is desirable.

## Conclusion

In the first part of the article, we discussed two different ways of using the full ATLAS simulation to calibrate jets. The global method is proven to recover the linearity of the energy measurement while improving the resolution in a wide energy range on Monte Carlo samples. We proved its robustness over different quark content, shower model, and event complexity. The local hadron calibration has been shown to almost fully recover the linearity with respect to the jet calorimeter energy deposits. Even though a correction step to go back to the truth jet scale is missing, the method is promising. In the last part of the article, we discussed the possible use of the tracker information of the jet to improve the jet resolution. After the application of the global calibration, the method is able to further improve the jet energy resolution especially at low  $E_T$ . Finally we discussed a possible way of recovering the neutrino energy in semileptonic  $b$ -quark decays.

The calibration methods discussed in this note will be used to provide jet corrections for the ATLAS detector. We stress that the validation of the corrections heavily relies on in-situ measurements as discussed in [20].

# $E/p$ Performance for Charged Hadrons

## Abstract

The precise measurement of the momentum of hadrons in the tracking detectors, compared to the energy  $E$  measured in the calorimeters can provide a validation of the hadronic calibration of the response of the calorimeter to pions at the percent level. The  $E/p$  ratio allows the validation of the absolute energy scale calibration over the pseudorapidity range covered by the tracking detectors. Since the selected hadrons are mainly pions, the results obtained for pion response from test beam data are almost directly comparable. The single hadron  $E/p$  performances are studied using minimum bias events.

## 1 Introduction

The tracking system can be used to verify the hadronic calorimeter calibration in the energy range between 400 MeV and 200 GeV. The inner tracking will be able to reach a 1% precision on the transverse momentum,  $p_T$ , with a few months of data taking at low luminosity. The energy over momentum,  $E/p$ , ratio allows the validation of the absolute energy scale calibration over the pseudorapidity range of the tracking detectors which covers the Barrel Tile Calorimeter ( $|\eta| < 1$ ), the Extended Barrel Tile Calorimeter ( $1 < |\eta| < 1.7$ ) and the Liquid Argon Hadronic Endcap Calorimeter up to  $|\eta|=2.5$ . Furthermore, since the selected hadrons are almost exclusively pions, the results obtained for pion response from test beam data are almost directly comparable.

The energy range for which the hadronic calibration must be checked can be determined by jet fragmentation studies at the generator level. It is instructive to investigate the lowest energy needed to obtain a given fraction of the jet energy, denoted  $x$ . For this reason, it is useful to define the lowest energy jet particles (LEJPs). Using the highest  $p_T$  jet in QCD dijet events, the lowest energy jet particles (LEJPs) are determined by ordering in energy the stable particles ( $c\tau > 10$  mm) in the jet. Starting with the highest energy, the particle energies are summed up until a fraction  $x$  of the jet energy is reached. The particle that pushes this sum over the threshold is the LEJP. Figure 1 shows the mean LEJP energy for a value of  $x = 0.95$  as a function of the jet energy for central ( $|\eta| < 1.5$ ) and endcap ( $1.5 < |\eta| < 3.2$ ) jets. To reconstruct 95% of the jet energy in the central region we have to measure particle energies down to 800 MeV. To reconstruct 99% of the jet energy we need to reach energies down to 200 MeV. The energy of the highest energy particle in the jet ranges from 10 GeV to 550 GeV.

Any hadronic calibration scheme is required to be robust over the energy range 200 MeV to 550 GeV to ensure the correct jet energies scale. Furthermore a large fraction of particles in jets have energy below 10 GeV and a large proportion of them are charged pions. Hence it is important to check the hadronic calibration at low particle energies using the  $E/p$  method. The robustness of the hadronic calibration, the validity of the hadronic shower model in Monte Carlo, and the single charged hadron  $E/p$  performance can be studied in several data samples which cover different energy ranges. The minimum bias sample can reach down to a momentum of 400 MeV and the remainder of this note deals with studies of  $E/p$  in the minimum bias sample.

## 2 Study of $E/p$ using Minimum Bias events

As discussed above, low energy hadrons carry a large portion of the energy in a jet. It is therefore important to study the  $E/p$  performance at low energies to obtain an ultimate calibration of the jet energy scale to 1% precision. In early data, when a precise hadronic calibration will not be available, this study will be performed using the electromagnetic scale. Subsequently, each step of the local hadronic

calibration can be cross-checked and improved. These steps include removal of noise via the use of topological clusters, cluster classification as electromagnetic or hadronic, and calibration of hadronic clusters to the local hadronic energy scale.

Minimum bias samples were used to determine the feasibility of using charged hadrons in the  $p_T$  range between 1 to 10 GeV to cross-check the single hadron energy scale for topological clusters calibrated to the local hadronic energy scale [1]. The simulation used for this study replicates data collected over only a few days at a trigger bandwidth of 10Hz. A year of data-taking at low luminosity will reduce the statistical uncertainty to less than 1%. The data collected in one year should allow the local hadronic calibration to be checked as a function of both  $\eta$  and  $\phi$ .

The calibration of topological clusters calibrated to the local hadronic energy includes corrections for invisible and escaped energy in the hadronic shower as well as energy lost in dead material, such as the material of the inner detector. It does not include corrections for energy lost in cells outside the cluster (out-of-cluster). In the very low energy regime considered by this study, there are significant energy losses in dead material and from out-of-cluster effects. Even with cluster calibration, it is not possible to completely recover these losses, since many low energy particles do not leave sufficient energy in the calorimeter to meet the cluster reconstruction thresholds. As a consequence, we expect the calibrated value of  $\langle E/p \rangle$  to be below 1. However, as  $p_T$  increases, these energy losses diminish and therefore  $\langle E/p \rangle$  approaches 1. Measuring the  $E/p$  distributions for single hadrons can provide a way of determining the size of these energy losses in-situ. It can also be directly compared to the single pion Monte Carlo used to derive the weights and cluster classification used as part of the local hadronic calibration.

## 2.1 Isolated pions in Minimum Bias events

To eliminate fake tracks and ensure an accurate momentum measurement, only tracks satisfying the following criteria were considered in this study:

- At least one hit in the B Layer of the pixel detector.
- No more than one missing hit in the other pixel and SCT layers.
- Good quality track fit satisfying  $\chi^2/\text{ndof} < 1.5$ .

Approximately 76% of all reconstructed tracks pass these criteria. The  $p_T$  range for pions surviving the track quality constraints is given by the dashed curve in Fig. 2. This shows that minimum bias events can

Figure 1: Mean LEJP energy ( $x = 0.95$ ) as a function of the jet energy for jets in central (left) and endcap (right) regions. The error bars represent the Full-Width-Half-Maximum of the LEJP energy spectrum.

Figure 2: Distribution of  $p_T$  of all tracks (solid line) and selected tracks (dashed line) in minimum bias events, scaled to  $1 \mu\text{b}^{-1}$ .

provide a source of pions to check the hadronic energy scale from 500 MeV, the nominal lower energy required for a reconstructed track, up to energies of the order 10 GeV.

The pion energy deposited in the calorimeter is found by extrapolating the track direction to the second sampling layer of the EM calorimeter. From this position a cone is defined,  $\Delta R_{\text{cone}} = 1.0$ , and the energy of each charged hadron is calculated as the sum of all topological clusters within this cone. A topological cluster is considered to be inside the cone if its barycenter is within this  $\Delta R_{\text{cone}} = 1.0$  around the extrapolated track position.

In minimum bias events, energy from the underlying event inside the region defined by  $\Delta R_{\text{cone}}$  considerably biases the measured pion energies. Photons originating from the decay of neutral pions are the predominant source of background. Charged particles also contribute to the background as the reconstruction efficiency of tracks below 5 GeV can be lower than 80% [2]. Selection criteria were used to reduce the contamination from the underlying event. These criteria differ slightly for charged hadrons with  $p_T \leq 3 \text{ GeV}$  and  $p_T > 3 \text{ GeV}$  due to the low multiplicity of higher  $p_T$  tracks in the event and the different hadronic shower shapes in the calorimeter. The selection criteria used to minimise the amount of energy from the underlying event are:

- Isolated from other tracks by at least  $\Delta R = 0.4$ . The track positions were taken at the second layer of the EM calorimeter.
- The charged hadron must be one of the harder particles in the event.
  - $p_T / \sum_{\text{all tracks}} p_T > 0.1$  for  $p_T \leq 3 \text{ GeV}$ .
  - $p_T / \sum_{\text{all tracks}} p_T > 0.3$  for  $p_T > 3 \text{ GeV}$ .
- The energy in the hadronic calorimeter must be isolated by requiring the energy in the outer region  $0.4 < \Delta R_{\text{cone}} < 1.0$  of the cone to be small.
  - $E_{\text{HAD}_{1.0-0.4}} < 0.01 \times p_{\text{track}}$  for  $p_T \leq 3 \text{ GeV}$ .
  - $E_{\text{HAD}_{1.0-0.4}} < 0.05 \times p_{\text{track}}$  for  $p_T > 3 \text{ GeV}$ .

Figure 3: The  $E/p$  distributions for pions from minimum bias events before cuts (dotted line), after cuts (dark solid line) and for a reference sample of single particles (dashed line) for tracks in the  $p_T$  range 0.8 – 1.2 GeV (top left), 1.6 – 2.4 GeV (top right), 4 – 6 GeV (bottom left) and 8 – 12 GeV (bottom right). All distributions are normalised to unity. The negative  $E/p$  ratios are a consequence of clusters with negative energy resulting from noise.

Figure 3 shows the  $E/p$  distribution in minimum bias events before and after cuts, and compares it to single pions. All results shown here and in Section 2.2 are for tracks associated with real pions (studies of the impact of non-pion tracks are in progress). These selection criteria approximately halve the shift in  $\langle E/p \rangle$  caused by other particles in the cone.

The shift of  $\langle E/p \rangle$  caused by the selection is primarily due to the isolation cut in the hadronic calorimeter. The shift was estimated using the pion from single particle Monte Carlo and was found to change  $\langle E/p \rangle$  by 0.006 for 1 GeV pions, 0.002 for 2 GeV pions, negligible for 5 GeV pions and 0.001 for 10 GeV pions. The remaining background, due to energy from the underlying event, cannot be removed with cuts. This is justified by the absence of isolated charged hadrons in minimum bias events.

## 2.2 Data-driven unfolding procedure

The remaining background, present inside the region defined by  $\Delta R_{\text{cone}}$ , was estimated using a data-driven method described in Ref. [3]. This was then unfolded from the pion  $E/p$  distribution. Most of the energy coming from the underlying event is deposited in the electromagnetic calorimeter. Charged pions which deposit most of their energy in the hadronic calorimeter were therefore selected in order to estimate the energy contamination in the electromagnetic calorimeter. These are labelled as late showering pions.

The energy from the underlying event was studied by dividing  $\Delta R_{\text{cone}}$  into the following two regions:

- A region where very little background energy is deposited, consisting of:
  - The hadronic calorimeter and

Figure 4: The total,  $(E/p)^{\text{meas}}$ , (left) and underlying event,  $(E/p)^{\text{contam}}$ , (right) distributions used to extract the  $E/p$  of isolated charged hadrons in the range 0.8 - 1.2 GeV. Error bars show the statistical error on the distribution before fitting (solid line).

- A core region close to the track:
  - \*  $\Delta R_{\text{core}} = 0.1$  for  $p_T \leq 3$  GeV.
  - \*  $\Delta R_{\text{core}} = 0.05$  for  $p_T > 3$  GeV.
- A ring surrounding the assumed trajectory of the pion through the electromagnetic calorimeter contains energy of the underlying event,  $E_{\text{outer-cone}}$ , defined to be  $\Delta R_{\text{core}} < \Delta R < 1$  in the electromagnetic calorimeter.

We use the energy in the  $E_{\text{outer-cone}}$  of late-showering pions to estimate the underlying event energy. For this study we assume that the energy in  $E_{\text{outer-cone}}$  for late-showering charged particles is zero as they act as minimum ionising particles (mips) in the electromagnetic calorimeter.<sup>1</sup>

Late-showering charged pions were identified by two criteria based on the energy in a narrow cone of  $\Delta R < 0.05$  around the track:

- Energy in the electromagnetic calorimeter  $< 0.5 \times p_{\text{track}}$ .
- Energy in the hadronic calorimeter  $> 0.5 \times p_{\text{track}}$ .

The background estimated using late-showering pions is applied to all pions (late and early showering ones). Figure 4 shows the underlying event energy obtained by this method for tracks in the  $p_T$  range 0.8 – 1.2 GeV. The underlying event energy divided by the track momentum is defined as  $(E/p)^{\text{contam}}$ .

The  $(E/p)^{\text{meas}}$  distributions shown by the solid curves in Fig. 3 are a convolution of the  $E/p$  distributions for isolated pions,  $(E/p)^{\text{iso}}$ , and the underlying event energy. By deconvoluting the background from the measured  $E/p$ , we recovered  $(E/p)^{\text{iso}}$ .

The convolution can be written in terms of the number of entries in each bin  $i$  in the measured  $E/p$  histogram:

$$(E/p)_i^{\text{meas}} = \sum_j P_{ij} \times (E/p)_j^{\text{iso}}, \quad (1)$$

where the elements of the matrix  $P_{ij}$  represent the probability of background contamination shifting the energy from bin  $j$  to bin  $i$ .

Each element of  $P_{ij}$  is taken from the energy deposited in  $E_{\text{outer-cone}}$  (shown in Fig. 4 for  $p_T = 1$  GeV pions). The matrix elements are defined as  $P_{ij} = (E/p)_{(i-j)}^{\text{contam}}$ , i.e.  $P_{ij}$  is given by the  $i^{\text{th}} - j^{\text{th}}$  bin content of the normalised histogram in the region  $E_{\text{outer-cone}}$ . The probability that each bin contributes to

<sup>1</sup>We assumed that the mips penetrating depth was uncorrelated with the background.

the  $(E/p)^{\text{meas}}$  value is given by  $P_{ij}/\det(P_{ij})$ . The diagonal elements of the normalised matrix give the probability that a measurement is free from contaminating energy.

The distribution  $(E/p)^{\text{iso}}$  is derived by solving the set of linear equations described above via matrix inversion. The unfolding method is described in Ref. [4] and Ref. [5]. The background is fitted with two exponential functions: one above zero and one below. The measured  $E/p$  is fitted with an exponential function below zero, a 7th order polynomial function above zero up to half the maximum height, and an exponential function for the high  $E/p$  tail. The result of these fits for 1 GeV pions is shown in Fig. 4. The final distributions obtained for  $(E/p)^{\text{iso}}$  are shown in Fig. 5. The subtraction:

$$\langle E/p \rangle^{\text{iso}} = \langle E/p \rangle^{\text{meas}} - \langle E/p \rangle^{\text{contam}} \quad (2)$$

is used to examine the shift caused by any remaining contamination or by the method itself. Results are shown in Table 1. The  $E/p$  values are consistent with the single particle mean, showing that this procedure is promising. However, larger statistics are required to properly assess the ultimate precision of this method.

We compared charged hadrons in minimum bias Monte Carlo events of  $p_T = 0.8 - 1.2$  GeV,  $1.6 - 2.4$  GeV,  $4 - 6$  GeV and  $8 - 12$  GeV with single pion samples of 50000 events generated with  $p_T = 1$  GeV, 2 GeV, 5 GeV and 10 GeV. As both minimum bias and single particle simulations are done with the same detector geometry and showering model, the  $E/p$  distributions are identical, providing a way to test how well we can retrieve the single pion  $E/p$  distribution in minimum bias events.

Both positive and negative pions were used, and the results were combined to improve the statistical

Figure 5:  $E/p$  distributions obtained from deconvolution for pions in minimum bias events (solid line) and single pions (dashed line) for the track momentum ranges  $0.8 \text{ GeV} < p_T < 1.2 \text{ GeV}$  (top left),  $1.6 \text{ GeV} < p_T < 2.4 \text{ GeV}$  (top right),  $4 \text{ GeV} < p_T < 6 \text{ GeV}$  (bottom left) and  $8 \text{ GeV} < p_T < 12 \text{ GeV}$  (bottom right). The deconvolution also removes the effect of ‘fake’ clusters in  $E_{\text{outer-cone}}$ , reconstructed from electronics noise.

Table 1:  $\langle E/p \rangle$  for pions at  $p_T = 1, 2, 5$  and  $10$  GeV compared to pions in single particle events.

Pion $p_T$ Range	Minimum Bias	Single Particles
$0.8 - 1.2$ GeV	$0.429 \pm 0.052$	$0.449 \pm 0.003$
$1.6 - 2.4$ GeV	$0.622 \pm 0.043$	$0.609 \pm 0.003$
$4 - 6$ GeV	$0.818 \pm 0.015$	$0.786 \pm 0.002$
$8 - 12$ GeV	$0.870 \pm 0.036$	$0.869 \pm 0.001$

precision. Due to limited Monte Carlo statistics, here we bin only in  $p_T$ . Ultimately, the  $E/p$  response will be studied in bins of both energy and pseudorapidity, because the dead material distribution varies dramatically across  $|\eta|$ . In minimum bias events, the mean charged particle multiplicity is relatively flat in  $\eta$  for a given  $p_T$ . Single particle samples are weighted to have the same  $|\eta|$  distribution as minimum bias tracks.

### 2.3 Sources of systematic uncertainties

We studied a number of effects which biased the  $E/p$  distribution. In our study we assumed that all charged hadrons were pions. In minimum bias events, about 75% of all charged particles are pions, with a small number of kaons and protons. Less than 2% of the tracks are due to heavier hadrons, electrons, muons or are fake. However, the mix of particle types is different for late-showering hadrons. Biases arising from this different particle mixture were studied by comparing the  $\langle E/p \rangle$  calculated using all track types with the  $\langle E/p \rangle$  derived from pion tracks alone. Within the available statistical precision, we can put an upper limit of 10% on the shift. We use the energy in the  $E_{\text{outer-cone}}$  of late-showering pions to estimate the contaminating energy. For this study we assume that the energy in  $E_{\text{outer-cone}}$  for late-showering charged particles is zero as they act as mips through the electromagnetic calorimeter. This assumption translates to a shift on  $\langle E/p \rangle$  of less than 4%. The energy from the underlying event in the hadron calorimeter and in the  $\Delta R_{\text{core}}$  region cannot be measured by this in-situ method. The shift of the  $\langle E/p \rangle$  due to this background is estimated using single pions and was found to be less than 4%. The uncertainty in the energy scale is dominated by the unmeasured contaminating energy and the effect of non-pion tracks. All the above systematic uncertainties are statistically dominated.

## 3 Conclusions

Jet fragmentation studies show that low energy hadrons carry a large portion of the energy in a jet. This study shows that isolated charged hadrons produced in minimum bias events can be used to study the  $E/p$  performance in the  $p_T$  range from 1 to 10 GeV to obtain an ultimate calibration of the jet energy scale. This sample will provide an in-situ test of the cluster level hadronic calibration down to 1 GeV. Within a year at low luminosity, it will be possible to reduce the statistical uncertainty to less than 1%.

With the available Monte Carlo statistics we obtained a statistical uncertainty of 10% at 2 GeV which goes down to 3% at 10 GeV, mostly dominated by the statistics of the late showering pion control sample. Systematic biases from several sources have been studied. Effects, such as unpredicted detector inhomogeneities, will be studied once data are available.

# Jet Energy Scale: In-situ Calibration Strategies

## Abstract

This note outlines procedures for the in-situ determination of the jet energy scale and resolution of the ATLAS calorimeters. The jet energy scale is evaluated using energy-balanced processes:  $\gamma/Z$  + jet, dijet, and multijet events. The jet energy resolution is obtained from dijet events. Generators using leading-order multiparton matrix element calculations merged with parton showers along with leading-logarithmic Monte Carlo models are compared. Effects on the energy-balance due to hadronization effects are also studied.

## 1 Introduction

Precise reconstruction of the jet energy is a fundamental ingredient of many physics analyses at the LHC, such as the determination of the top quark mass, the reconstruction of dijet resonances, and the measurement of the inclusive jet cross-section. Moreover the performance obtained on jet reconstruction has a direct impact on the quality of the measurement of the missing transverse energy which will play a decisive role in many searches for new physics at the LHC.

The ultimate goal of the jet energy measurement is, in most cases, the reconstruction of the initial parton momentum. On the other hand, the measurement in the ATLAS detector starts from signals recorded in the calorimeter cells which have been calibrated at the *electromagnetic* (EM) scale. This scale is set in test beams and is defined to reproduce correctly the electron energy in the beams.

A subsequent software jet calibration procedure is performed in two major steps. First, corrections are made for detector effects, in particular calorimeter non-compensation, noise, losses in dead material and cracks, longitudinal leakage and particle deflection in the magnetic field. The procedure is described in Ref. [1]. After this step the *hadronic scale* which provides the jet energy at the *particle level* is obtained, i.e. it should correspond to the jet energy obtained after running the same jet algorithm over all true momenta of the final state particles in the event. Throughout this note, we will refer to these jets as “particle-level jets” or “truth jets”. At the second step physics effects, such as clustering, fragmentation, initial and final state radiation (ISR and FSR), underlying event (UE) and pile-up are considered. After that the *final scale* is reached which corresponds to the energy at the *parton level*. These effects can depend on the type of interaction, e.g. they can differ for quark and gluon jets, can depend on the parton momentum scales and multiparton interactions, so that an individual study may be necessary for each data analysis involving jets.

The validation of the whole jet calibration has to be performed *in-situ* using suitable physics processes. In the course of in-situ validation (also called in-situ calibration) the systematic uncertainty of the hadronic energy scale is determined, and the final tuning of this scale is possibly performed. Furthermore, the level of physics effects affecting the final scale is estimated. In addition, the jet energy resolution can be determined in-situ.

The validation procedure will start with QCD dijet events, which allow us to check the uniformity of the calibration as a function of azimuth  $\phi$  and of pseudo-rapidity  $\eta$ . The uniformity in  $\phi$  can be checked by studying jet rates; the uniformity in  $\eta$  can be validated using  $p_T$  balance between the jets. The dijet events also open two ways of determining the jet energy resolution.

After a uniform detector response is obtained, the absolute hadronic energy scale will be studied using  $\gamma$  or  $Z$  + jet events, in which the  $Z$  boson is reconstructed via the  $Z \rightarrow e^+e^-$  or  $\mu^+\mu^-$  decay. The  $p_T$  balance between the jet and the boson in such events will be used to relate the hadronic scale of the jets to the well understood energy of electromagnetic objects.

At very high jet energies, the statistics of  $\gamma/Z$  + jet events vanishes. After the validation of the absolute jet energy scale (JES) with these events in a limited  $p_T$  range, the scale at higher  $p_T$  will be validated using QCD multijet events by balancing the momentum of the leading jet to the momentum sum of the other jets. Alternatively, it can be inferred from the opening angle between the two leading charged particle tracks associated with the jet.

These methods are discussed in the present note. Expectations of several Monte Carlo programs are compared for various jet algorithms. The statistical and systematic uncertainties of the methods are assessed with an emphasis on the first  $100\text{pb}^{-1}$  and  $1\text{fb}^{-1}$  of ATLAS data. It is important to note that one missing contribution is the precision with which the Monte Carlo is tuned to and reproduces the data. This, naturally, can only be determined once data are available.

Several related studies are covered in other notes. The determination of JES from the invariant mass of the  $W$  boson in  $W \rightarrow qq$  decays is covered in Ref. [2]. The study of jet fragmentation and of the underlying event using tracks associated with the jets and in the complete event is discussed in Ref. [3]. The measurement of  $E/p$  for isolated charged particle tracks in order to study the response of the calorimeter is considered in [4].

This note is organized as follows. First, the Monte Carlo programs used for the present studies are briefly described. Then, the standard ATLAS jet reconstruction and calibration procedure is outlined. Afterward, we discuss the basic features of  $\gamma$  and  $Z$  + jet events and of the  $p_T$  balance calibration technique, the physics effects influencing the calibration procedure, the limitations of the underlying models and the expected systematic and statistical uncertainties of the jet energy scale. Subsequently, we consider the calibration techniques in QCD dijet and multijet events, followed by the methods of determination of the jet energy resolution. A summary is given at the end of the note.

## 2 Monte Carlo event generators

The general-purpose Monte Carlo programs HERWIG, PYTHIA and ALPGEN are used here to model the final states at the LHC energies. The event generation relies on phenomenological approaches to describe the processes which occur at all levels apart from calculation of the matrix elements. This is done by factorizing the event generation into several stages:

- hard subprocess at a fixed order of perturbation theory,
- initial and final state QCD radiation using parton shower models,
- multiple parton interactions (MI) contributing to the underlying event (UE),
- hadronization (fragmentation).

PYTHIA and HERWIG include leading order ( $2 \rightarrow 2$ ) matrix elements for generating  $\gamma/Z$  + jet and QCD dijet events. Higher order QCD effects are modeled using parton showers, which can be insufficient to describe hard QCD radiation. These effects may significantly affect the event kinematics and thus spoil the determination of the jet energy scale and resolution. They are checked using ALPGEN which includes leading order matrix elements for generating multiparton final states. ALPGEN simulations are also used in addition to PYTHIA to study multijet events at very high transverse momenta, where such events provide the main means to determine the jet energy scale.

### 2.1 PYTHIA

PYTHIA 6.4 [5] is used with the on-shell leading order (LO) matrix element to model the final states. Higher-order QCD effects are simulated in the leading-logarithmic approximation with initial- and final-state radiation following the DGLAP evolution [6]. Coherence effects from soft-gluon interference are

included. The underlying event has been tuned to reproduce the CDF data. The parton density functions (PDF) CTEQ6ll [7] are used for the proton.

The initial-state shower is based on backward evolution to the shower initiators. Initial and final state showers are matched to each other by maximum emission cones. The Lund string fragmentation model is used to produce the final state hadrons. The string model is based on linear confinement, where (anti-)quarks or other color (anti-)triplets are located at the ends of the string, and gluons are energy momentum carrying kinks on the string. When the invariant mass of a string piece gets small enough, it is identified as a hadron, thus the whole system eventually evolves into hadrons.

## 2.2 HERWIG

HERWIG 6.510 [8] is used in conjunction with the underlying event generator JIMMY 4.31 [9]. As with PYTHIA, the CTEQ6ll set is used for the proton PDFs. HERWIG uses the parton shower approach for initial and final state QCD radiation, including color coherence effects and azimuthal correlations both within and between the jets. It includes the angular ordered parton shower algorithm which re-sums both soft and collinear singularities. HERWIG uses the cluster fragmentation model [10, 11], where all the outgoing gluons are first split into quark/anti-quark or diquark/anti-diquark pairs. Then, quarks are combined with their nearest neighbor (in the color field) anti-quark or diquark to form color singlet clusters. These clusters have mass and spatial distributions peaked at relatively low values. For large cluster masses, the  $q$ -distributions fall rapidly and are asymptotically independent of the hard subprocess scale. If a cluster is too light to decay into two hadrons, it is allowed to become the lightest hadron of the relevant flavor. A similar cluster model is also used to model soft and underlying hadronic events.

## 2.3 ALPGEN

ALPGEN 2.06 [12] is used with the HERWIG parton shower and the JIMMY underlying event model and with the subsequent HERWIG cluster fragmentation. Similarly to PYTHIA and HERWIG simulations, the CTEQ6ll set is used for the proton PDFs. Each final state parton multiplicity is generated individually by ALPGEN. A matching using a given scheme between a generated parton with the parton shower is performed in order to avoid double counting of the jet multiplicity. We use the MLM matching scheme.

# 3 Jet reconstruction in ATLAS

Several jet collections are built during event reconstruction in ATLAS, varying the input to the jet finder and the jet finding algorithm. The inputs considered for the jet finder are “calorimeter towers” (calo-towers) and “topological clusters” (topoclusters). In addition, “truth particles” are used for simulated events. Calorimeter towers are built from all calorimeter cells contained in a region of ( $d\eta \times d\phi$ ) of size ( $0.1 \times 0.1$ ). The initial cell energy is calibrated at the EM scale. Topological clusters are built according to criteria that identify significant energy deposits in topologically connected cells. Three different levels of signal significance are applied to the seed, the neighboring and peripheral cells. Currently, the settings of (4, 2, 0) in units of sigma of noise are used [1].

The jet finder methods used are cone and  $k_T$  algorithms. The seeded cone algorithm is used with radii of  $R = 0.4$  or  $0.7$ ,  $p_T$  of seeds = 1 GeV, and a split/merge fraction of 0.5. The inclusive  $k_T$  algorithm (fast version) is run with a  $D$  parameter of 0.4, 0.6 or 1.0 [3].

Two calibration approaches are developed in ATLAS, the “global” and the “local” schemes [1]. The global scheme uses H1-style weights [1] to correct calorimeter cells after jet finding. The weights are based on the energy density in a cell. This calibration is specific to each type of jet finder. In the local

scheme, jets are built from pre-calibrated topoclusters, which already include hadronic calibration, as well as dead material and out-of-cluster corrections. In this note, we report on the "global" scheme<sup>1</sup>.

For most of the studies, a minimum transverse momentum  $p_T$  of at least 10 GeV is required for a jet to be considered in the data analysis.

## 4 In-situ studies using $\gamma/Z$ + jet events

### 4.1 Electromagnetic final state in $\gamma/Z$ + jet events

The Z boson is observed via its  $Z \rightarrow ee$  or  $Z \rightarrow \mu\mu$  decay products. The good lepton identification capability of the ATLAS detector allows reconstruction of Z decays with very low background [13].

Before comparing the jet energy scales in data and in simulation using  $\gamma/Z$  + jet events, basic  $p_T$  and  $\eta$  spectra of the vector bosons have to be checked. These spectra are affected mainly by the efficiency of photon or lepton identification, and by the trigger efficiency. In the case of  $\gamma$  production, significant background due to misidentified jets in QCD dijet events remains despite the rejection power of the detector and of the reconstruction algorithms. The theoretical systematic uncertainties associated with the vector bosons are expected to be small at all levels. The effects on transverse momentum due to additional photon radiation at the hadron level are predicted to be negligible.

### 4.2 Use of $p_T$ balance

In leading order of perturbation theory the final state of  $\gamma/Z$  + jet events can be considered as a two-body system in which the transverse momentum of the jet  $p_{T,\text{jet}}$  is exactly balanced by the transverse momentum of the vector boson  $p_{T,\gamma}$  or  $p_{T,Z}$ . The  $p_T$  balance can thus be defined as

$$B_1 = \frac{p_{T,\text{jet}}}{p_{T,\gamma/Z}} - 1. \quad (1)$$

<sup>1</sup>The local scheme approach was not yet fully developed when studies reported here were done; this approach will be studied and compared to the global scheme in the future.

Figure 1: Mean jet multiplicity for jets with  $p_T > 10$  GeV as a function of  $p_T$  of the Z boson in Z + jet events.

Figure 2:  $\Delta\phi$  between the photon and the jet for a) cone algorithm with  $R = 0.4$ , and b)  $k_T$  algorithm with  $D = 1$ .

However in reality, these events contain more than one jet in the final state at parton, particle and detector level, so that considering only the leading (highest  $p_T$ ) jet is in general too crude an approximation of the event kinematics. This is one of the major issues in this study and requires a detailed understanding of jet multiplicities, as well as their  $p_T$  and angular spectra. The Monte Carlo models will have to be tuned to reproduce these jet properties and their energy dependence as observed with the data. A striking example of the current uncertainty in modeling these quantities is shown in Fig. 1, in which the average multiplicity of jets in  $Z$ +jet events, generated using PYTHIA and HERWIG, is depicted as a function of the transverse momentum of the  $Z$  boson. Cone jets reconstructed with  $R = 0.7$  at the particle level with  $p_T > 10$  GeV in the pseudorapidity range  $|\eta| < 5$  are used. HERWIG predicts a larger number of jets than PYTHIA mainly due to its mechanism of cluster formation and the assumptions used to model soft and underlying hadronic events. Further extensive studies have been performed in order to understand the differences in the basic jet distributions at the parton and the particle level for various jet algorithms, and to quantify the influence of initial and final state radiation and of the underlying event model.

A very useful quantity to consider is the azimuthal angular difference  $\Delta\phi$  between the boson and the leading jet. It provides information about the event topology and is sensitive to additional physics effects, like initial state radiation and final state radiation. Figure 2 shows the  $\Delta\phi$  distribution at parton and at hadron level for three jet algorithms in  $\gamma$ +jet events with multiple interactions switched on and off, respectively. Although the hadronization effects are apparent for cone jets with  $R = 0.4$ , the resulting leading jet in most cases is in a back-to-back topology with the photon. In order to reduce the topological bias due to additional radiation, the boson and jets in both  $\gamma$  and  $Z$ +jet events are typically required in our studies to be back-to-back within  $\Delta\phi$  of  $\pm 0.2$ .

In principle, one can consider two extreme ways of taking the physics effects into account:

- Select only those events where the  $Z$  or  $\gamma$  is back-to-back to only one jet in the event. Require any other jet to have a small transverse momentum. The jet energy correction factors can then be determined from the requirement  $B_1 = 0$  as a function of energy and pseudorapidity. The strong back-to-back cut and the requirement against other jets in the event will severely cut the statistics in such an analysis.
- The other extreme is to take all jets in the event that pass loose selection cuts and balance the sum of their momenta to the  $Z$  or  $\gamma$  momentum. The  $p_T$  balance can then be defined as

$$B_\Sigma = \frac{|\sum_{\text{jets}} \vec{p}_T|}{p_{T,\gamma/Z}} - 1, \quad (2)$$

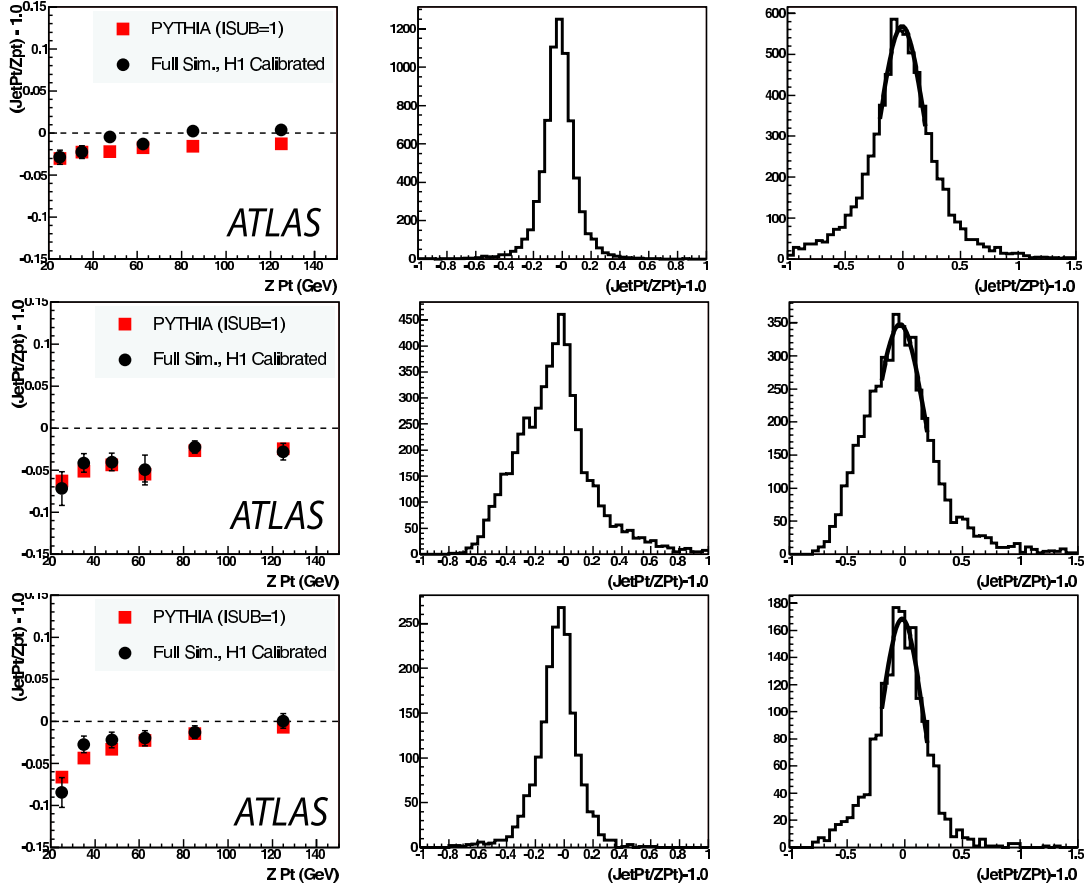

Figure 3: Left in all rows: the mean value of the fitted  $p_T$  balance  $B_\Sigma$  as a function of  $p_{T,Z}$  in  $Z$ +jet events. Particle level jets (squares) and jets reconstructed from detector signals (circles) are shown. Middle in all rows:  $B_\Sigma$  distribution for  $p_{T,Z} \sim 50$  GeV for truth jets. Right in all rows:  $B_\Sigma$  distribution for  $p_{T,Z} \sim 50$  GeV for reconstructed jets. Upper row: all jets with  $p_T > 1$  GeV are taken into account. Middle row: only jets with  $p_T > 10$  GeV are used and the requirement  $|\pi - \Delta\phi| < 0.2$  is imposed. Lower row: in addition, no further jet with  $p_T > 10$  GeV is allowed.

This approach should be less sensitive to issues related to physics modeling. However, it is more difficult in this case to relate directly the measured balance to the energy scales of specific jets.

Any kinematic selection cut will affect the global  $p_T$  balance between the boson and the hadronic system. This is illustrated in Fig. 3. The central figure in the upper row shows the momentum balance  $B_\Sigma$  obtained by summing all particle level jets with  $p_T > 1$  GeV for events with  $p_{T,Z} \sim 50$  GeV. The actual balance fluctuates around a mean value close to zero. The right plot shows the corresponding distribution for reconstructed (H1) jets which is broader due to the detector resolution effects.

The left plot shows the  $p_T$  balance obtained by fitting a Gaussian to the  $p_T$  balance distribution in the various  $p_{T,Z}$  bins<sup>2</sup>. The fitted mean shows a small negative bias (of the order of 1-3%) which decreases with increasing  $p_{T,Z}$ . Adding the  $p_T$  of neutrinos and muons to that of the jets reduces the bias by about 1%, so this cannot be the origin of this systematic effect, which is further discussed later on.

The effect of selection cuts is studied further, as shown in the middle row of Fig. 3, which presents the

<sup>2</sup>Throughout this note we use the mean value of a Gaussian distribution fitted within a limited sigma range (typically  $\pm 1\sigma$ ) to characterize the  $p_T$  balance. We refer to it also as the most probable value.

$p_T$  balance for particle jets with  $p_T > 10$  GeV. In addition, the leading jet is required to be back-to-back with the Z within  $|\Delta\phi| = (\pi \pm 0.2)$ . The bias increases and the spread deteriorates after increasing the  $p_T$  threshold for jets. The effects are still strong even though the  $\Delta\phi$  cut is imposed. They become less significant as  $p_{T,Z}$  increases. The main effect is due to fluctuations of the fragmentation combined with out-of-cone losses and with jet splitting. In addition, residual ISR/FSR contributes significantly to the spread. The underlying event may also contribute particles to the clustered jet. Studies performed with PYTHIA  $\gamma$ +jet events [14, 15] indicate that the underlying event contributes  $\sim 20$  MeV on average to the transverse energy  $E_T$  at truth particle level in each  $(\Delta\eta \times \Delta\phi)$  region of  $(0.1 \times 0.1)$  which corresponds to one calorimeter tower. This results in  $\sim 1$  GeV contribution per cone jet with  $R = 0.4$  and  $\sim 3$  GeV per cone jet with  $R = 0.7$ . The lower row of Fig. 3 shows the same distributions after an additional requirement to have no further jet with  $p_T > 10$  GeV in the event. The spread of the  $p_T$  balance distributions is reduced. The negative bias is also reduced but remains significant, especially at low  $p_{T,Z}$  values.

Furthermore, these effects strongly depend on the chosen jet algorithm. In Fig. 4 the  $p_T$  balance for the leading jet relative to the photon is depicted as a function of photon  $p_T$  for cone jets with  $R = 0.4$ ,  $R = 0.7$  and for  $k_T$  jets with  $D = 1$ . The jets are reconstructed at the truth particle level and at the parton level after parton showering in HERWIG  $\gamma$ +jet events and after applying the  $\Delta\phi$  cut. The  $k_T$  jets on parton level reveal an essentially perfect balance, as expected from theory. Cone jets are subject to out-of-cone losses due to parton showering. The relative losses increase with decreasing  $p_T$ , and are bigger for cone jets with smaller radii. They are much larger for particle level cone jets due to the lateral spread of the fragmentation. On the contrary, the  $k_T$  algorithm tends to include particles originating from other partons, which leads to a significant positive bias at low  $p_T$ .

A further important issue in the use of the  $p_T$  balance is the quantity used as a reference to define the  $p_T$  ranges. This is illustrated in Fig. 5 in which PYTHIA  $\gamma$ +jet events are used which were generated with a minimum  $p_T$  of 30 GeV for the hard scattering process. The scatter plot shows the photon  $p_T$  versus the  $p_T$  of the parton as produced in the hard interaction. The events are distributed around the diagonal as a result of ISR. The cut at the generator stage is visible. If we choose  $p_{T,\gamma}$  bins to study  $p_T$  balance distributions (e.g. the set of events with  $30 \text{ GeV} < p_{T,\gamma} < 40 \text{ GeV}$  contained between the two horizontal

Figure 4: Mean value of the fitted  $p_T$  balance ( $B_1 + 1$ ) as a function of  $p_{T,\gamma}$  in  $\gamma$ +jet HERWIG events for various jet algorithms. The points correspond to particle level and parton level jets.

Figure 5: The  $p_T$  of the parton versus the  $p_T$  of the photon as produced in the hard interaction in  $\gamma$ +jet events.

dashed lines), we will observe a bias towards lower  $p_T$  balance values, since in this case we populate the distribution with significantly more events from the left side of the diagonal than from the right side. The events on the left side are generated on average in interactions with smaller center-of-mass energy, hence with higher cross-section. The cross-section decreases quickly with energy and the negative bias of the  $p_T$  balance is significant<sup>3</sup>. One should note also that the bias is proportional to the spread around the diagonal. Hence it decreases with  $p_T$ . It also decreases if one requires the parton and the  $\gamma$  to be back-to-back in azimuth within some  $\Delta\phi$  limit, since the ISR spread is then reduced [14]. If we were able to select events according to  $(p_{T,\gamma} + p_{T,\text{parton}})/2$  (with lines perpendicular to the diagonal), then the symmetry would be restored.

This can be seen in Fig. 6. The  $p_T$  balance  $B_1$  for events with  $101 < p_T < 152$  GeV is shown in the

<sup>3</sup>Throughout this note, we will generically refer to such bias as “bin migration effect”.

Figure 6: Left:  $p_T$  balance at particle level for events with  $101 < p_T < 152$  GeV. The solid line shows the balance when the  $p_T$  reference for binning is taken as the average  $p_T$  of the photon and the jet; the triangles when it is taken as the photon  $p_T$ . The circles show the balance when the photon  $p_T$  is used and the photon and the jet are required to be back-to-back within 0.2. Right: the  $p_T$  dependence of the most probable value of the particle level jet balance for these three cases.

left panel of the figure. The solid line shows the balance when the  $p_T$  is taken as the average  $p_T$  of the photon and the jet<sup>4</sup> and the triangles when it is taken as the photon  $p_T$ . The difference in the shape is clearly visible with a more pronounced low tail for the  $p_{T,\gamma}$  reference, because the cross-section favors the case when ISR has reduced the leading jet  $p_T$ , as discussed above. The circles show the balance with the photon  $p_T$  reference when the photon and the jet are required to be back-to-back within 0.2 to reduce ISR. The resulting distribution is indeed more symmetric.

The right panel of the figure shows the most probable value of the particle level jet balance for these three cases. The effect of varying the quantity used to define the  $p_T$  bins can be as large as 3% for low  $p_T$ . The  $\Delta\phi$  cut helps reducing the effect to the percent level. More details on this issue can be found in Ref. [14]. A disadvantage of using the average  $p_T$  to define the energy bins is to introduce a coupling with the jet energy scale that one is trying to measure. Hence, we decided to use  $p_{T,\gamma}$  and  $p_{T,Z}$  in the baseline study. The average  $p_T$  will be used as a cross-check.

The above studies show that the level of imbalance is determined in first order by “out-of-cone” losses related to the jet algorithm under consideration. In addition ISR/FSR and UE influence the measured balance. ISR/FSR effects can be reduced by suitable cuts like a “back-to-back” requirement. UE can be estimated separately by looking at the energy outside jets and can be subtracted, if necessary. The imbalance, depending on the algorithm and on the choice of the reference scale, is up to 5 – 10% at 20 GeV and becomes smaller than 1% around 100 – 200 GeV. A careful tuning of Monte Carlo simulations will be necessary to reproduce and disentangle the effects that cause the residual imbalance.

In the following, the specific issues of  $\gamma$ +jet and Z+jet data analyses are discussed. In particular, backgrounds, event rates and the kinematic reach for each channel are considered.

### 4.3 Analysis of $\gamma$ +jet events

The data used in this section are  $\gamma$ +jet events generated using PYTHIA. They are generated in intervals of  $p_T$  of the hard scattered partons to provide adequate statistical coverage over a wide range of  $p_T$ . The signal has been generated via the annihilation process  $q\bar{q} \rightarrow g\gamma$  (ISUB = 15) [5], and the QCD Compton process  $qg \rightarrow q\gamma$  (ISUB = 30). The Compton process dominates over the whole  $p_T$  range.

The main background comes from QCD dijet events, where one of the jets is misidentified as a photon in the calorimeter. For background estimation, QCD jets are simulated with the same version of PYTHIA and similar intervals of  $p_T$ . Table 1 gives the cross-sections for the various  $p_T$  intervals for  $\gamma$ +jet and QCD dijet events.

In this study, the leading jet  $p_T$  balance method is used, which consists of first selecting the leading photon in the event and then selecting the leading jet in the opposite hemisphere. The balance is investigated at the reconstruction level using full detector simulation. The cone jet algorithm with  $R = 0.7$  is

<sup>4</sup>The jet  $p_T$  is used as an approximation to the parton  $p_T$ .

Table 1:  $\gamma$ +jet and QCD dijet cross-sections for the various  $p_T$  intervals. The total inelastic cross-section is  $8 \times 10^{11}$  pb.

$p_T$ interval	$\gamma$ +jet $\sigma$ (pb)	Dijet $\sigma$ (pb)	$\sigma$ ratio (Dijet / $\gamma$ +jet)
$17 < p_T < 35$ GeV	$2.61 \times 10^5$	$1.38 \times 10^9$	$5.29 \times 10^3$
$35 < p_T < 70$ GeV	$2.76 \times 10^4$	$9.33 \times 10^7$	$3.38 \times 10^3$
$70 < p_T < 140$ GeV	$2.59 \times 10^3$	$5.88 \times 10^6$	$2.27 \times 10^3$
$140 < p_T < 280$ GeV	$1.99 \times 10^2$	$3.08 \times 10^5$	$1.55 \times 10^3$
$280 < p_T < 560$ GeV	$1.17 \times 10^1$	$1.25 \times 10^4$	$1.07 \times 10^3$
$560 < p_T < 1120$ GeV	$4.90 \times 10^{-1}$	$3.60 \times 10^2$	$7.35 \times 10^2$

Figure 7: The most probable value of the balance at reconstruction level for cone jets with  $R = 0.7$ . Black and dots are for default and tight selection, respectively, and the points show the truth level balance. The back-to-back  $\Delta\phi$  cut is applied.

used. Only jets with  $|\eta| < 2.5$  are considered.

Two different photon selections have been considered. The tight photon selection adds isolation criteria in the calorimeter and tracker to provide further jet rejection, as discussed later in this section. A calorimeter isolation criterion is applied on the relative transverse isolation energy in a cone with half-opening angle 0.2, requiring that  $E_T(\text{cone})/p_{T,\gamma} < 0.05$ . The track isolation criterion requires that the number of tracks pointing to any jet around the photon is less than three. Here, track parameters are measured at the origin. The tight selection maintains a good efficiency of  $> 60\%$  above 100 GeV while it is significantly reduced at low  $p_T$ . These tight selection cuts have not been optimized. Their purpose in this note is to show that additional purity can be obtained, without too much loss of efficiency, at least for the higher  $p_T$  range. The photon energy calibration,  $p_T(\text{reconstructed})/p_T(\text{truth})$ , has been checked and is between 0.995 and 1 over most of the  $p_T$  range. No photons impinging in the calorimeter crack regions with  $1.37 < |\eta| < 1.52$  are used.

The average response of jets over the various calorimeter regions was checked and a residual miscalibration of about 1% was found for all  $p_T$  values. Jets close to the crack regions are not well calibrated, therefore jets with  $1.3 < |\eta| < 1.8$  are excluded from further analysis. Eventually we will rely on dijet balance to correct for such  $\eta$ -dependent effects in the calibration (see Section 5).

Figure 7 shows the measured  $p_T$  balance. The photon  $p_T$  is used as the reference and the standard back-to-back  $\Delta\phi$  cut is applied. Table 2 shows the fitted mean, the statistical uncertainty and the integrated luminosity for each  $p_T$  interval for the tight photon selection. The  $p_T$  balance above 80 GeV is flattening at the level of -0.02. At low  $p_T$  the balance with the tight photon selection is a few percent below the balance measured with the default cuts. The photon reconstruction efficiency is low, and the stringent isolation cuts likely bias the sample composition rejecting events with strong ISR or underlying event. The match between the leading reconstructed jet and the leading truth jet is better than 98.5% for jets above 70 GeV; it degrades to 85% for jets above 17 GeV. The reconstruction level  $p_T$  balance is one percent below the truth level  $p_T$  balance. This is the result of the residual miscalibration of the jets in the particular release of the ATLAS event reconstruction software, as checked by comparing the reconstructed jet  $p_T$  with the truth particle level jet  $p_T$ .

The PYTHIA QCD jet samples described in Table 1 were used to estimate the influence of the dijet background. The jet rejection factors for the standard photon selection and the tight photon selection were studied as a function of jet  $p_T$ . With the default photon selection criteria, the probability of identifying a jet as the leading photon is of the order of  $10^{-3}$  and has some  $p_T$  dependence. The resulting signal to

Table 2: Fitted mean  $p_T$  balance, error and integrated luminosity of the analysed samples for the various  $p_T$  intervals for the tight photon selection. The last column shows the precision expected for  $10 \text{ pb}^{-1}$  obtained by scaling the error according to recorded integrated luminosity.

$p_{T,\text{low edge}}$	Bin width	Fitted balance	Integrated luminosity, $\text{pb}^{-1}$	Error for $10 \text{ pb}^{-1}$
20 GeV	10 GeV	$-0.052 \pm 0.007$	0.67	0.2%
30 GeV	15 GeV	$-0.042 \pm 0.005$	0.67	0.2%
45 GeV	22.5 GeV	$-0.047 \pm 0.005$	9.1	0.4%
67.5 GeV	33.5 GeV	$-0.027 \pm 0.003$	9.1	0.4%
101 GeV	51 GeV	$-0.026 \pm 0.003$	47	0.7%
152 GeV	76 GeV	$-0.018 \pm 0.002$	47	0.4%
228 GeV	114 GeV	$-0.016 \pm 0.002$	535	1.7%
342 GeV	171 GeV	$-0.021 \pm 0.005$	535	4%
513 GeV	256 GeV	$-0.006 \pm 0.026$	535	19%

background ratio is estimated to be of the order of 1 above 100 GeV and degrades to about 0.1 for lower  $p_T$ . The tight photon selection improves the signal to background reduced by a factor of three or more.

Figure 8 left shows the  $p_T$  balance distribution for QCD background events passing the default photon selection in the interval  $140 < p_{T,\gamma} < 280 \text{ GeV}$ . The back-to-back  $\Delta\phi$  cut has been applied. The fitted most probable value of the distribution with the default photon selection and the  $\Delta\phi$  cut is 0.13. Applying the tight selection reduces the number of background events, but a few events still remain in the tail. It will thus be desirable to maintain a good signal to background ratio to avoid a bias that would be difficult to control. For the tight photon selection, the mean of the Gaussian fit to the signal shown in Fig. 8 (right) for the interval  $140 < p_{T,\gamma} < 280 \text{ GeV}$  changes by less than 1% when the background is added in.

Thus, the background studies have shown that above  $\sim 80 \text{ GeV}$ , the signal to background ratio is good enough to avoid bias. A more detailed and higher statistics study of the background rejection at lower  $p_T$  should be carried out, to understand if the range of high precision could be extended to lower  $p_T$ .

Table 2 shows that a good statistical precision is obtained for a relatively small integrated luminosity. For example,  $100 \text{ pb}^{-1}$  is sufficient to reach a precision of 1 – 2% for jets in the range

Figure 8: Left:  $p_T$  balance for the background sample of  $140 < p_T < 280 \text{ GeV}$  for the default and tight photon selection. Right:  $p_T$  balance for the signal and background sample in the interval  $96 < p_{T,\gamma} < 224 \text{ GeV}$  for tight photon selection.

$300 < E_T < 500$  GeV. We expect that the threshold of the un-prescaled photon trigger will be 60 GeV for early running. Hence above that value the full statistics should be recorded while prescale factors will have to be applied for lower  $p_T$ .

#### 4.4 Analysis of $Z$ + jet events

A sample of inclusive  $Z$  boson events corresponding to an integrated luminosity of  $500 \text{ pb}^{-1}$  has been produced using ALPGEN. The MLM matching cut is imposed at  $p_T > 20$  GeV and  $|\eta| < 6$ , and the factorization scale is set at  $m_Z^2 + p_{T,Z}^2$  where  $m_Z$  is the  $Z$  boson mass. The invariant mass is required to lie between 40 and 200 GeV. A generator-level filter requires one truth cone jet with  $R = 0.4$ , with  $p_T > 20$  GeV and  $|\eta| < 5.0$  and two electrons/muons with  $p_T > 10$  GeV and  $|\eta| < 2.7$  in the event.

Another sample of inclusive  $Z$  events corresponding to  $120 \text{ pb}^{-1}$ , as well as the relevant background samples have been generated using PYTHIA. The signal has been generated via the Drell-Yan process (ISUB = 1) [5]. As for  $\gamma$ +jet events, the  $qg$  Compton process dominates over the whole  $p_T$  range. The Drell-Yan process contributes due to higher order QCD radiation which may reproduce the leading jet.

The  $Z \rightarrow ee$  and  $W \rightarrow e\nu$  events are produced with a generator-level filter requiring one truth electron with  $p_T > 10$  GeV and  $|\eta| < 2.7$ . The  $Z \rightarrow \tau\tau$  events are generated with a filter requiring two electrons/muons with  $p_T > 5$  GeV and  $|\eta| < 2.8$ . For  $Z \rightarrow \tau\tau$  and  $Z \rightarrow ee$  the dilepton mass is required to be larger than 60 GeV. For more details on the data samples see Ref. [16].

The fully simulated events are required to pass the isolated single-electron trigger with a  $p_T$  threshold of 25 GeV or the isolated di-electron trigger with the  $p_T$  threshold of 15 GeV at trigger level 1 and 2. Electrons are required to have  $p_T > 25$  GeV,  $|\eta| < 2.5$  and to be outside the calorimeter cracks defined as  $1.37 < |\eta| < 1.52$ . Jets are reconstructed with the cone tower algorithm with  $R = 0.7$ . They are required to have a distance of  $\Delta R > 0.4$  from a reconstructed electron and  $p_T > 30$  GeV.

The  $Z$  bosons are selected by requiring two reconstructed electrons with invariant mass in the range  $m_Z \pm 20$  GeV. If more than two electrons are reconstructed, the pair with the invariant mass closest to  $m_Z$  is chosen. The combined distribution of the invariant mass for the signal and background events is shown in the left panel of Fig. 9 for ALPGEN  $Z$ +jet events where jets with  $p_T > 40$  GeV are reconstructed using the cone tower algorithm with  $R = 0.7$ . The main backgrounds are from QCD multijets and from top production, while  $Z \rightarrow \tau\tau$  and  $W \rightarrow e\nu$  events are an order of magnitude smaller. The background level is reasonably low. Requiring the jet and the  $Z$  to be back-to-back in azimuth within 0.2 reduces the background to a negligible level.

The right panel of Fig. 9 shows the measured balance for cone jets with  $R = 0.7$  as predicted by ALPGEN for  $500 \text{ pb}^{-1}$ . The precision with which the  $p_T$  balance can be measured experimentally depends on the efficiency for reconstructing the  $Z$  in its electron or muon decay channels, on the trigger efficiency and on the experimental width of the  $p_T$  balance distribution. Table 3 shows the fitted most probable value of the  $p_T$  balance and the statistical precision for an integrated luminosity of  $500 \text{ pb}^{-1}$  obtained with the  $Z \rightarrow ee$  sample. Below 200 GeV, the precision is of the order of 0.8%, while above 200 GeV, it gets worse. The  $Z \rightarrow \mu\mu$  decay mode can also be used. A similar efficiency and background level can be achieved as shown in [16] doubling the available statistics. A statistical precision of 1% can be achieved below 200 GeV with an integrated luminosity of  $100 \text{ pb}^{-1}$ , while above the precision is at the level of 2%. This assumes also that the complete  $\eta$  range can be used for the measurement, relying on techniques like dijet balancing to ensure uniformity across  $\eta$  to the desired precision.

The measurement is also affected by systematic uncertainties. The balance is sensitive to the correct modeling of higher order radiation. Comparing the predictions from different Monte Carlo simulation programs gives an indication of the size of such effects. This is illustrated in Fig. 10, in which ALPGEN and PYTHIA samples of  $Z$ +jet events corresponding to  $120 \text{ pb}^{-1}$  and  $500 \text{ pb}^{-1}$  (ALPGEN only) are compared after applying the  $\Delta\phi$  cut, for cone jets with  $R = 0.7$ . PYTHIA predicts a more negative average  $p_T$  balance at low  $p_T$  than ALPGEN. This effect is related to broader distributions and larger tails in the

Figure 9: Left: Distribution of the dielectron mass for  $Z \rightarrow ee + \geq 1\text{jet}$  events and the relevant background in a simulated event sample corresponding to an integrated luminosity of  $200\text{ pb}^{-1}$  with cone jets with  $R = 0.7$ . Right: The  $p_T$  balance for an integrated luminosity of  $500\text{ pb}^{-1}$  of cone jets with  $R = 0.7$  in events generated with ALPGEN in 5 bins of  $p_{T,Z}$ . balance distributions resulting from low  $p_T$  activity in PYTHIA induced by higher order radiation. The differences between the two generators can be tested with  $\sim 100\text{pb}^{-1}$  of data for  $p_T < 100\text{ GeV}$ .

#### 4.5 The missing $E_T$ projection method

The missing  $\vec{E}_T$  projection method is an alternative approach to test the jet energy scale and has been used successfully by the D0 experiment to determine the response of their calorimeter to hadronic jets [17]. It is explained here for the example of  $\gamma$ +jet events, but it can also be used for Z+jet events. Details about the study presented in this section can be found in Ref. [15].

At leading order, momentum conservation between the photon and the jet gives

$$\vec{E}_{T,\gamma} + \vec{p}_{T,\text{parton}} = 0. \quad (3)$$

Neglecting parton showering and hadronization effects, this can be rewritten at particle level as

$$\vec{E}_{T,\gamma} + \vec{E}_{T,\text{jet}} \approx 0, \quad (4)$$

where momentum has been replaced by energy, which is a good approximation for light quark jets.

The systematic effects of parton showering and hadronization, including initial state radiation (ISR) and final state radiation (FSR), can be reduced by requiring that the leading jet and the photon are back-to-back within 0.2 in azimuth in a similar way to what was shown in Fig. 2.

At the calorimeter level, the balance equation is modified to

$$e\vec{E}_{T,\gamma} + j(E_{\text{jet}})\vec{E}_{T,\text{jet}} = -\vec{E}_T^{\text{miss}}. \quad (5)$$

where  $e, j$  are the electromagnetic and hadronic responses,  $E_{\text{calo}}/E_{\text{particle}}$ , of the calorimeters, respectively. It is implicit in Eq. 5 that energy deposited in the calorimeters by the underlying event and pileup is

symmetric in  $\phi$ . These assumptions have been tested and their effect is small. Anticipating that the electromagnetic scale will be well calibrated, for example by using the electrons from the decay of a  $Z$  boson, we can assume that  $e \approx 1$ . The quantities can then be projected in the direction of the photon, yielding

$$E_{T,\gamma} + j(E_{\text{jet}}) \vec{E}_{T,\text{jet}} \cdot \hat{n}_\gamma = -\hat{n}_\gamma \cdot \vec{E}_T^{\text{miss}}, \quad (6)$$

where  $\hat{n}_\gamma$  is the unit vector in the direction of the photon. Using the relation

$$\vec{E}_T^{\text{miss}} = -\vec{E}_{T,\gamma} - \sum' \vec{E}_T, \quad (7)$$

where  $\sum'$  indicates a sum over all activity in the calorimeter other than the  $\gamma$ , the response can be further simplified as

$$j = \frac{\sum' \vec{E}_T \cdot \hat{n}_\gamma}{\vec{E}_{T,\text{jet}} \cdot \hat{n}_\gamma} = \frac{\sum' \vec{E}_T \cdot \hat{n}_\gamma}{E_{T,\gamma}}, \quad (8)$$

where Eq. 4 was used in the last step. In this form it is clear that this method of measuring the response is independent of the underlying event, since the hadronic activity outside the  $\gamma$ +jet system is approximately  $\phi$ -symmetric and its contribution to the sum cancels out. It is also (mostly) independent of the jet algorithm.

However, the jet response depends on the jet energy because the relative fraction of EM energy in the calorimeter level jet increases with increasing energy, hence a correction for non-compensation must be applied. Thus, the response has to be measured as a function of the jet energy. If we bin the response as a function of the measured jet energy ( $E_{\text{jet}}$ ), it would be biased towards lower  $E_{T,\gamma}$  due to the bin migration described in Section 4.2. Instead, the jet energy is taken as  $E' = E_{T,\gamma} \cdot \cosh(\eta_{\text{jet}})$ , which uses the much better measured energy of the photon and projects it in the jet direction; this procedure is based on the momentum balance of Eq. 4. The EM scale jet energy distribution is fitted with a Gaussian in each bin of reference energy  $E'$ , and the jet energy scale is then calculated. The correspondence between  $E'$  and the measured jet energy is also determined. The resulting jet energy scale can then be plotted as a function of  $E_{\text{jet}}$ .

The response function is then plotted for each algorithm as a function of the corresponding mean jet energy and parameterized by

$$j(E) = b_0 + b_1 \ln \frac{E}{E_{\text{scale}}} + b_2 \ln^2 \frac{E}{E_{\text{scale}}} \quad (9)$$

with  $E_{\text{scale}}$  set to 200 GeV and the  $b$  parameters fitted, as shown in Fig. 11.

The fit function is used to correct the jet energy at the EM scale  $E_T^{\text{meas}}$ . The corrected energy  $E_T^{\text{calib}} = E_T^{\text{meas}} / j(E)$  is then compared to the truth information  $E_T^{\text{MC}}$  in the Monte Carlo simulation. Figure 12 is a plot of the ratio  $E_T^{\text{MC}} / E_T^{\text{calib}}$  as a function of jet energy, which shows a linear response within  $\approx 2\%$  over the range 50 – 900 GeV.

This procedure accounts for the fact that the ATLAS calorimeters are non-compensating and that the electromagnetic content of a hadronic shower is energy dependent. Further adjustments, such as out-of-cone corrections, must be made to obtain the final jet energy scale. It is only at this point that jet algorithm dependent corrections are made and is therefore a useful method as a cross-check of our understanding of the energy scale with different sensitivity to systematic effects.

#### 4.6 Conclusions of the studies of $\gamma/Z$ + jet events

The use of the in-situ  $\gamma/Z$  + jet processes allows us to propagate the knowledge of the electromagnetic scale characteristic of the  $\gamma$  or the  $Z \rightarrow \ell\ell$  decay to the hadronic recoil system. Typically the leading jet

Figure 11: The energy dependence of the jet response for cone jets with  $R = 0.4$ . The solid line corresponds to the fit using Eq. 9.

Figure 12: The ratios  $E_T^{\text{MC}}/E_T^{\text{calib}}$  (triangles) and  $E_T^{\text{MC}}/E_T^{\text{meas}}$  (squares) for jets reconstructed using the cone algorithm with  $R = 0.4$ . See the text for an explanation of the symbols.

is required to be back-to-back in azimuth with the  $\gamma$  or the  $Z$  boson, and the  $p_T$  balance between them is used to connect the two scales.

The balance is affected by various physics effects which systematically limit the precision of the in-situ validation procedure. These effects can be as large as 5 – 10% at 20 GeV and tend to decrease to the percent level at about 100 GeV.

The  $\gamma$ +jet process has the advantage of higher statistics compared to  $Z$ +jet. However, at low  $p_T$  it may be seriously affected by background from QCD jets. Hence it may turn out to be most useful above  $\sim 50 - 100$  GeV where the signal to background ratio is more favorable and where an inclusive single photon trigger is available. A statistical precision better than a percent is achieved already with  $10\text{pb}^{-1}$  at 100 GeV, and in the range 300 – 500 GeV the percent level is reached with about  $100\text{pb}^{-1}$ . The  $Z$ +jet

Figure 13: The jet response  $p_T(\text{reconstructed})/p_T(\text{truth})$  at the EM scale versus the jet pseudorapidity  $\eta$

process allows us to measure the absolute energy scale in the low  $p_T$  range with a statistical precision of 1% with  $\sim 300\text{pb}^{-1}$  of data. It provides also the highest  $p_T$  reach with percent level precision in the range 300 – 500 GeV with  $\sim 200\text{pb}^{-1}$ . Above  $\sim 500$  GeV, other methods will be used as discussed further on.

## 5 In-situ studies using QCD jet events

### 5.1 Calorimeter intercalibration in QCD dijet samples

The calorimeter response  $p_T(\text{reconstructed})/p_T(\text{truth})$  for jets at the EM scale reveals significant variations with pseudorapidity  $\eta$ , as shown in Fig. 13. The dips correspond to known cracks and dead material regions. The response may also be non-uniform in azimuth  $\phi$  for the same  $\eta$  due to the variations in the basic calorimeter response and due to the non-uniform distribution of the dead material. The response in  $\phi$  and  $\eta$  should become flat at the hadronic scale. This has to be checked in-situ with high precision, and if necessary, an intercalibration of different regions of the calorimeter has to be performed. For this study we use PYTHIA QCD jet events, generated in intervals of  $p_T$  of the hard scattered partons, as described in Section 4.3.

#### 5.1.1 Intercalibration in azimuth

The intercalibration in  $\phi$  can be checked using the high rates of QCD jet events. As the scattering cross section is constant in  $\phi$ , the jet rates above a fixed  $p_T$  threshold have to be nearly equal in different  $\phi$  sectors, as shown in Fig. 14 (left) for 64  $\phi$  sectors in the  $\eta$  range  $|\eta| < 0.1$  which corresponds to the segmentation of the ATLAS hadronic calorimeter in one calorimeter wheel. Strongly deviating rates in particular sectors would point to dead calorimeter cells, losses in dead material, or noise.

For a perfectly calibrated calorimeter the spread of rates around the mean rate value  $N$  should be  $\sqrt{N}$  following the Poissonian distribution. Thus, collecting on average e.g.  $\sim 1000$  events per sector, one would expect the spread of  $\sim 30$  events, i.e. 3% of the average rate. A significantly larger spread would point to a relative miscalibration of different sectors. The spread can be obtained by filling a histogram with the rates and fitting it with a gaussian. Due to the strongly falling jet  $p_T$  distribution the rates are

Figure 14: Left: The jet rate as a function of  $\phi$  for jets with the transverse momentum above a certain threshold. Right: Integrated luminosity required to collect 1000 events with jets above the given  $p_T$  thresholds in each of the 64  $\phi$  sectors in the region  $|\eta| < 0.1$ .

extremely sensitive to the jet energy scale: a 1.5 – 2% shift in the energy scale would result in  $\sim 6 - 9\%$  change of the rate, which is a 2 – 3 $\sigma$  effect for the above example with 1000 events per sector. Thus, the statistics of 1000 events per sector should allow us to control the jet energy scale to within 1.5 – 2%. The luminosity necessary to collect such statistics in 64  $\phi$  sectors within the  $\eta$  interval  $|\eta| < 0.1$  is shown for different  $p_T$  thresholds in Fig. 14 (right). A study of the systematics for this method is on the way.

The trigger menu for the initial running period at the luminosity of  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  is currently under development, and the effect of trigger prescaling has not yet been taken into account in this plot. The highest  $p_T$  threshold for the inclusive jet trigger is expected to be at 100 – 150 GeV, above which no prescaling will be applied. The prescale factors will steeply rise for lower thresholds, such that the recorded event rate should be roughly flat in  $p_T$ . Scaling the shown luminosity values for the lowest two  $p_T$  bins down with the currently foreseen prescale factors shows that the rate of recorded events will be still sufficient to reach the statistical precision of 1.5 – 2% with  $\lesssim 10 \text{ pb}^{-1}$  of data.

However, the rates may be affected by the calibration of the level 1 calorimeter trigger. To avoid a bias, the  $p_T$  thresholds chosen for this analysis should be significantly higher than the respective trigger thresholds. This will lead to a loss of statistics, and thus a higher integrated luminosity will be necessary for the same statistical precision.

### 5.1.2 Intercalibration in pseudorapidity

The intercalibration in  $\eta$  can be done based on the  $p_T$  balance in QCD dijet events. The roughly three orders of magnitude higher cross section of dijet events, as compared to  $Z/\gamma$ +jet events, allows an intercalibration of the calorimeter with higher granularity, higher precision and for higher energy ranges than can be achieved in  $Z/\gamma$ +jet events for the same integrated luminosity. Applying the calibration based on the  $p_T$  balance, one corrects for the relative difference in calorimeter response for jets, the noise and pile-up in different regions of pseudorapidity  $\eta$ . The goal is to achieve a flat response in  $\eta$  and to extend the previous calibrations for  $|\eta| < 2.5$  to higher pseudorapidities.

The method is straightforward: one calorimeter region in pseudorapidity  $\eta$  is chosen as the reference region and jets in other  $\eta$  regions are calibrated relative to jets in this region. Normally, one calorimeter  $\eta$  wheel in the central range, far from the crack regions, will be chosen as the reference region. Other considerations are the existence of dead or noisy cells in a particular part of the calorimeter, the uniformity of the response in  $\phi$  within one wheel etc. The width of the region will also depend on the available statistics.

Figure 15: Left: The asymmetry  $A$  as measured with both jets in the central region  $|\eta| < 0.7$  as defined in Eq. 10. Right: The mean asymmetry obtained from gaussian fits, plotted as a function of the half scalar sum of  $p_T$  of both jets at the reconstruction level (closed circles) and at the truth particle level (stars).

We choose to characterize the  $p_T$ -balance in dijet events by the asymmetry  $A$  given by

$$A = \frac{p_T^{\text{probe}} - p_T^{\text{ref}}}{(p_T^{\text{probe}} + p_T^{\text{ref}})/2}, \quad (10)$$

where  $p_T^{\text{ref}}$  is the transverse momentum of the jet in the reference region, and  $p_T^{\text{probe}}$  is that of the jet in the region to be calibrated. Using this form, the  $p_T$  balance is symmetric, as shown in Fig. 15 (left) for reconstructed cone jets with  $R = 0.7$ . It thus provides better properties than the simple definition  $p_T^{\text{probe}}/p_T^{\text{ref}}$  which is intrinsically asymmetric.

To limit ISR/FSR and thereby reduce the width of the asymmetry distribution, a cut on the azimuthal angle between the two jets,  $\Delta\phi > 3$ , is applied. The fitted mean value of the asymmetry as a function of  $p_T$  is displayed in the right panel of Fig. 15 and shows that for this definition there is very little bias both for truth particle jets and for reconstructed jets at the hadronic scale.

Further cuts can be applied to obtain a cleaner dijet sample and thus reduce further the width of the  $p_T$  balance distributions. For example, the total number of reconstructed jets with  $p_T > 10$  GeV can be limited to  $N_{\text{jet}} < 4$  or even more strongly to  $N_{\text{jet}} = 2$ . However, these additional cuts reduce the statistics of the sample, as demonstrated in Fig. 16, which shows the integrated luminosity required to reach a statistical precision of 0.5% of the  $p_T$  balance fit mean value in the probe range  $0.7 < \eta < 0.8$ , where  $0 < |\eta| < 0.7$  is taken as the reference region. The luminosity values are shown for different sets of cuts. For the case of applying only the back-to-back cut on the angle between the two leading jets, 0.5% precision can be reached in this  $\eta$  region with  $10 \text{ pb}^{-1}$  of data for  $p_T \lesssim 300$  GeV, and with  $100 \text{ pb}^{-1}$  for  $p_T \lesssim 500$  GeV.

Similar plots were produced for the other  $\eta$  regions, which show that an order of magnitude more luminosity is necessary for  $|\eta| > 2.5$ , compared to the central region. On the other hand, the size of the reference region can be increased sequentially, i.e. as soon as one  $\eta$  has been checked or recalibrated, it can be added to the reference region to study the next  $\eta$  range.

As in the luminosity estimation for the  $\phi$  intercalibration in Section 5.1.1, the trigger prescaling has not yet been taken into account in Fig. 16. As in Sect. 5.1.1, scaling the shown luminosity values for the lowest two  $p_T$  bins down with the currently foreseen prescale factors shows that the rate of recorded events will be sufficient to reach 0.5% precision with  $\lesssim 10 \text{ pb}^{-1}$  of data.

The calibration method is further tested in the full  $\eta$  region for different  $p_T$  ranges. For each  $\eta$  region  $i$  in each  $p_T$  range  $j$ , the asymmetry  $A$  defined in Eq. 10 is fitted and the mean value  $A_{ij}$  is used to

calculate a correction factor  $c_{ij}$  via

$$c_{ij} = \frac{2 - A_{ij}}{2 + A_{ij}}. \quad (11)$$

In the case of an imperfect original calibration, factors deviating from 1 are obtained. Each jet  $p_T$  can then be multiplied by the appropriate factor to restore the balance of fully simulated jets. More details of this study can be found in Ref. [18].

## 5.2 High $p_T$ jet calibration

The calibration of the jet energy scale for high  $p_T$  jets (with  $p_T \gtrsim 500$  GeV) is a challenge at hadron collider experiments. In this energy range, methods developed for lower  $p_T$  jets, normally using well defined objects as reference, start to fail. This difficulty will be further increased at the early stage of data taking, where both our understanding of the detectors and the statistics of such high  $p_T$  jets are usually limited. Our goal is to develop a calibration technique for jets with  $p_T > 500$  GeV based on data collected with an integrated luminosity of  $0.1\text{--}1\text{ fb}^{-1}$ . The basic idea is to determine the energy scale of high  $p_T$  jets from lower  $p_T$  jets, for which the energy scale will be obtained by the techniques described earlier in this note. Two calibration techniques are discussed in the following sections: 1) the correlation between different  $p_T$  jets in momentum balance in the transverse plane, and 2) the angle between particles in the jets.

### 5.2.1 Multijet $p_T$ balance method

This method is based on selecting events with multiple ( $> 2$ ) jets and calibrating the energy scale of the highest  $p_T$  jet by requiring a  $p_T$  balance between the leading jet and the system of remaining lower  $p_T$  jets. The absolute jet energy scale of the non-leading jets, which is expected to be obtained from photon+jets, Z+jets and/or  $W \rightarrow \text{jet jet}$  studies, is thus propagated to the JES of the higher  $p_T$  jets using  $p_T$  balance methods. The large QCD jet cross-section allows for a very high reach in  $p_T$ . This method has been studied with samples generated with both ALPGEN and PYTHIA using the fast and full detector simulation. Two different analysis techniques were applied as described in the following.

Figure 16: Integrated luminosity required to reach 0.5% precision for various  $p_T$  ranges in the region  $0.7 < \eta < 0.8$  with different sets of selection cuts: all PYTHIA dijet events (circles), requiring  $\Delta\phi > 3$  between the two leading jets (triangles), requiring in addition less than 4 reconstructed jets in an event (squares), requiring exactly two reconstructed jets (stars). The reference region is  $0 < |\eta| < 0.7$ .

Figure 17: Energy scale (left) and energy scale uncertainty (right) of high  $p_T$  jets relative to lower  $p_T$  remnant jets as a function of jet  $p_T$ , obtained by multijet  $p_T$  balance method at an integrated luminosity of  $1 \text{ fb}^{-1}$ . The error bars shown are statistical only.

### ALPGEN study

For this study QCD multijet samples with 4, 5 and 6 partons were generated using ALPGEN interfaced with JIMMY. Four data samples were formed by requiring the leading parton  $p_T$  to be larger than 400, 600, 800, or 1000 GeV, while the  $p_T$  of the next-to-leading parton was required to be smaller than 200, 300, 400, or 500 GeV, respectively. The total number of partons ( $p_T > 40$  GeV) can be 4, 5 and 6 in each of the above samples. All the partons are required to be in the range  $|\eta| < 3$ . These samples, referred to as PT400, PT600, PT800, and PT1000 hereafter, were processed through the full detector simulation.

At least four cone jets with  $R = 0.7$  with  $p_T > 40$  GeV must be reconstructed in each event. The leading jet  $p_T$  in the samples PT400, 600, 800, and 1000 must be in the interval  $400 < p_T^{\text{jet1}} < 460$  GeV,  $600 < p_T^{\text{jet1}} < 700$  GeV,  $800 < p_T^{\text{jet1}} < 920$  GeV, and  $1000 < p_T^{\text{jet1}} < 1140$  GeV, respectively, while the  $p_T$  of the next-to-leading jet must correspondingly respect the bound  $p_T^{\text{jet2}} < 190$  GeV,  $p_T^{\text{jet2}} < 280$  GeV,  $p_T^{\text{jet2}} < 370$  GeV, and  $p_T^{\text{jet2}} < 470$  GeV. In addition the leading jet and the vector sum of the remaining lower  $p_T$  jets with  $p_T > 40$  GeV (called remnant jets) are required to be back-to-back in azimuth within  $\pm 20^\circ$ . After all the cuts, about 3200, 310, 40, and 11 events remain in the PT400, 600, 800, and 1000 samples, respectively, for an integrated luminosity of  $1 \text{ fb}^{-1}$ .

The distribution of the  $p_T$  balance, defined as

$$B'_\Sigma = \frac{p_T^{\text{jet1}}}{\text{non-leading jets } |\Sigma p_T|}, \quad (12)$$

is plotted for each sample and fitted by a Gaussian. The mean values of the Gaussian fits with their uncertainties for  $1 \text{ fb}^{-1}$  are shown in Fig. 17 as a function of  $p_T^{\text{jet1}}$ . The figure indicates that  $B'_\Sigma$  could be determined with a statistical accuracy of 2% or better for high  $p_T$  jets with  $400 < p_T < 1100$  GeV and that it shows a constant offset of 2-3% over the  $p_T^{\text{jet1}}$  range, as also observed in the PYTHIA study.

Various potential sources of systematic effect have been studied. Low  $p_T$  jets will not contribute to remnant jet system because of the 40 GeV  $p_T$  threshold applied to the jets. If the threshold is varied by  $\pm 20$  GeV,  $B'_\Sigma$  varies by  $\pm 1\%$  at most. The effect is smaller, for the same range of thresholds, than in the PYTHIA analysis because of the back-to-back requirement imposed on the system. A sizable fraction of the soft radiation is still missed in the event. This is the main cause of the positive  $B'_\Sigma$  offset. It could be reduced by requiring the overall event  $p_T$  to be balanced, e.g. by requiring that  $E_T^{\text{miss}} < 40$  GeV. In that case,  $B'_\Sigma$  decreases by 1–2% and becomes close to 1. However, an  $E_T^{\text{miss}}$  cut should be used with caution as fake  $E_T^{\text{miss}}$  could cause biases. The effect of the underlying event on  $B'_\Sigma$  has also been

evaluated by subtracting the  $E_T$  measured in a cone ( $R = 0.7$ ) placed randomly in a region of azimuth within  $60^\circ < \Delta\phi < 120^\circ$  from the leading jet and not overlapping with any of the remnant jets. After subtraction,  $B'_\Sigma$  increases by 1–2%.

The precision on the JES for high  $p_T$  jets is affected by the JES uncertainty of the remnant jets. If we assume the uncertainty to be  $\pm 7\%$  for low  $p_T$  jets with  $|\eta| < 3.2$ , which is the current linearity performance of the H1 weight calibration method used in this analysis [1], vary the scale of the remnant jets by  $\pm 7\%$ , and apply again all the event selection,  $B'_\Sigma$  changes by  $\pm 7\%$  independently of  $p_T^{\text{jet1}}$ . This provides an estimate of the JES uncertainty for high  $p_T$  jets. The uncertainty on  $B'_\Sigma$  is increased since more events fail the next-to-leading jet  $p_T$  cut that is included in the overall JES uncertainty.

Adding the statistical and above systematic uncertainties in quadrature, the JES uncertainty obtained from multijet balance method is estimated to be about 8% in the  $p_T$  range of  $400 < p_T < 1100$  GeV and is totally dominated by the absolute JES uncertainty for lower  $p_T$  remnant jets. If the absolute JES uncertainty is not included in the systematics, the relative JES uncertainty is 3%.

### PYTHIA study

In this study, PYTHIA samples with full and fast detector simulation were used. The fully simulated sample was generated with kinematic cuts of  $280 < p_T < 560$  GeV for the hard scattering process. It corresponds to an integrated luminosity of about  $25 \text{ pb}^{-1}$ . Cone jets with  $R = 0.7$  were reconstructed based on calorimeter towers, topoclusters and on Monte Carlo truth particles.

The fast simulation package ATLFAST was used for a high statistics study. A cut on the hard scattered parton at  $p_T > 280$  GeV was applied. The sample represents an integrated luminosity of about  $0.8 \text{ fb}^{-1}$ . Cone jets with  $R = 0.4$  were used for this study.

Events are selected with a minimum of three reconstructed jets, the leading jet being above a fixed  $p_T$  threshold, up to which the JES is assumed to be calibrated. All non-leading jets are required to be below that value. A further event selection cut is  $|\eta| < 2$  for the leading jet. Generally non-leading jets have been reconstructed up to  $|\eta| < 5$  and down to  $p_T > 10$  GeV. For specific studies of their systematic influences all these cuts have been varied.

Figure 18 presents results of the method for the sample using full detector simulation. The event selection cut on non-leading jets is  $p_T < 300$  GeV. On the left, the  $p_T$  balance  $B'_\Sigma$  is shown for leading jets with  $370 < p_T < 380$  GeV, together with a Gaussian fit. While non-Gaussian tails are visible, which could be partly reduced by a stricter event selection, they do not influence the fit and it was thus decided to use the maximum statistics.

To reduce the bias of the  $p_T$  balance due to migration effects, the division of the  $p_T$  region into bins is done based on the average  $p_T$  of the sum of the non-leading jets and the leading jet of each event. This reduces the bias to about 1% at truth level. This is similar to what is studied in the  $Z/\gamma + \text{jet}$  analyses (Section 4.2), where the average  $(p_{T,\gamma/Z} + p_{T,\text{jet}})/2$  is an option for the binning.

On the right of Fig. 18 the JES was studied from 350 GeV to 550 GeV. The result is reasonably flat but shows a systematic offset of about 2%, as also observed in the ALPGEN study. There are various effects contributing to this imbalance, mostly originating from soft radiation affecting the low  $p_T$  jets in the hemisphere opposite the leading jet. At truth jet level, changing the minimum jet  $p_T$  from 5 to 10/20/40 GeV introduces a negative bias of 0.2/1/3%, respectively. The  $p_T$  threshold value for real data should be chosen taking the noise, pile-up conditions and jet finding efficiency at low  $p_T$  into account. Out of cone losses also play a role: changing the cone size from 0.7 to 0.4 at truth level, affects the measured balance by  $\sim 1\%$ . Furthermore, imperfect calibration of low  $p_T$  jets at the level of few percent [1] may be a cause of bias.

In a high statistics study, based on ATLFAST, the non-leading jets were restricted to a  $p_T$  value below 350 GeV during event selection. Figure 19 shows the result on the left. The  $p_T$  balance distribution is

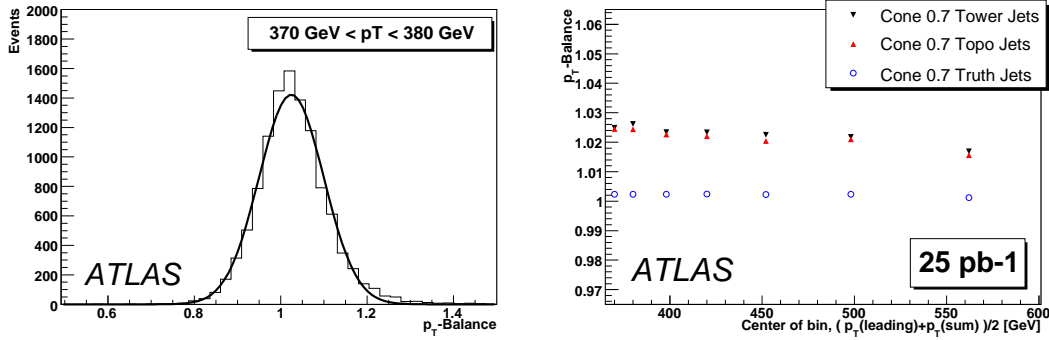

Figure 18: Left: the ratio of the absolute value of the vector sum of the non-leading jet  $p_T$  to the leading jet  $p_T$  for the  $p_T$  bin 370–380 GeV fitted by a Gaussian. Right: this ratio as a function of jet  $p_T$ . The mean and the error of the mean of the Gaussian fits are shown. The average of the leading jet  $p_T$  and of the total  $p_T$  of the non-leading jets is used for the binning.

Figure 19: Results using ATLFast with cone jets with  $R = 0.4$ . Left: The fitted balance as a function of the average leading and non-leading jets  $p_T$ . Right: Iterations of the method using the  $p_T$  range checked by one iteration as the reference region for the next.

lower than for cone jets with  $R = 0.7$ , as discussed above. Truth and ATLFast jets give closer results in this case, since the latter are truth jets smeared for resolution effects.

The reach in  $p_T$  of the method can be further increased by iterating the procedure. Apart from the QCD jet cross-section, the statistics are mainly limited by the cut on the  $p_T$  of the non-leading jets during event selection, essentially requiring that one parton in the hard scattering lost a significant part of its energy due to gluon radiation. For higher  $p_T$  ranges this cut should be moved to higher values to obtain sufficient statistics. The procedure is thus, after applying the method once, up to a certain  $p_T$ , to use the range up to this  $p_T$  as reference region for a next iteration. Results using this approach based on the ATLFast sample are shown in Fig. 19 on the right hand side. For the studied high  $p_T$  region, the multijet statistics predicted by PYTHIA may be an underestimation, as the PYTHIA parton shower model is not perfectly tuned for this  $p_T$  range.

A crucial feature for this method, as observed in PYTHIA simulations, is that the imbalance value remains essentially constant for one iteration if the tested JES is correct. The balance can differ between the iterations. In general, it is slightly closer to 1 for higher  $p_T$  ranges, as the system of non-leading jets becomes harder and thus less sensitive to low energy effects. To ensure that the JES is correct, we require that the beginning of the test region for a given iteration overlaps with the end of the region verified in the previous iteration, or at the very beginning verified by another method.

A complete understanding of the feature that the balance should remain constant for all  $p_T$  within one iteration, is necessary in order to rely on it in data. In this case, in addition to the absolute JES uncertainty of the non-leading jets, the systematic uncertainty of this method is given by deviations of the balance from a constant value as a function of  $p_T$ .

To determine this additional systematic uncertainty, the deviations are split into a global slope of a linear fit and into local deviations around this fit. As possible sources of systematic effects, the absolute JES of the remnant system, the choice of the  $p_T$  binning, the lower and upper  $p_T$  thresholds for the non-leading jets, the effect of the underlying event and of the noise, and the effect of the varying jet multiplicity in the remnant system are studied. To estimate the deviations quantitatively, the absolute JES is varied by 10%; the lower jet  $p_T$  threshold is varied between 10 and 50 GeV; the upper threshold for each iteration is varied by 100 GeV; the effect of the underlying event and of the noise is estimated by adding  $\pm 5$  GeV to each jet in the event; and the analysis is performed separately for events with exactly 4, 5 and 6 jets.

The slope of the fit is compatible with zero within statistical uncertainties for all variations of the sources. The corresponding systematic uncertainties for each source is estimated to be  $\lesssim 0.1\%$ . The estimation is limited by the available statistics. All local deviations from a linear fit are of the order of the statistical uncertainties. The width of their distribution is found to be less than 0.2% above the statistical expectation for each of the above influences. Adding all uncertainties quadratically results in a very small total systematic uncertainty of 0.5%. Thus, the main contribution to the JES uncertainty is expected to be the accuracy of the calibration in the reference region. The JES can then be calibrated up to  $p_T \gtrsim 1.5$  TeV, with the specific uncertainties introduced by this method being below 1% and requiring less than  $1\text{fb}^{-1}$  of integrated luminosity.

### 5.2.2 Track angle method

The idea behind this method is that the invariant mass of two particles in a jet is approximately constant (given by the scale of  $\Lambda_{\text{QCD}}$ ), which leads to a  $p_T^{-1}$  behavior of the  $\eta$ - $\phi$  distance between two particles in a jet  $\Delta R$ , where  $p_T$  is the transverse momentum of the jet. The dependence of  $\Delta R$  on  $p_T^{-1}$  of the jet could provide a means of determining the energy scale of high  $p_T$  jets once the JES of lower  $p_T$  jets is calibrated with some accuracy using other in-situ techniques. The procedure to determine the JES of high  $p_T$  jets is as follows: 1) measure  $\Delta R$  for low  $p_T$  jets with the calibrated JES in both data and Monte Carlo samples, 2) calibrate the simulation so that  $\Delta R$  in the simulation matches  $\Delta R$  in data in the low  $p_T$  range, then 3) measure the  $\Delta R$  for a sample of given high  $p_T$  jets in data, and look for the Monte Carlo jet  $p_T$  scale corresponding to the measured  $\Delta R$  value on the curve of  $\Delta R(p_T^{-1})$ .

The studies were performed on PYTHIA dijet samples generated in intervals of  $p_T$ . The jets selected have to have  $p_T > 20$  GeV and should not overlap with other physics objects within  $R < 0.4$ . Afterward all tracks are selected which fall in a cone of  $R = 0.4$  around reconstructed jet axis of the jet with the highest  $p_T$ . If fewer than two tracks are found for the jet, the event is rejected. The  $\Delta R$  of two tracks is then calculated for all combinations from two up to the five highest  $p_T$  tracks in the jet. Figure 20 shows the mean of the  $\Delta R$  values (one entry per event), normalized to an integrated luminosity of  $1\text{fb}^{-1}$ , for leading jets with  $140 < p_T^{\text{truth}} < 160$  GeV (top-left) and  $1120 < p_T^{\text{truth}} < 1280$  GeV (top-right). The two histograms correspond to the  $\Delta R$  obtained from leading two and five tracks. When more low  $p_T$  tracks are involved, the  $\Delta R$  distribution broadens as a result of jet fragmentation.

The bottom plots in Fig. 20 show the mean (left) and most probable value (MPV) obtained from a Landau fit to the peak (right) of the  $\Delta R$  distributions as a function of the leading jet truth  $p_T$ . Both mean and MPV are well fit by a function of the form  $p_0/x + p_1$  as shown by the curves. Figure 21 (top-left) shows the uncertainty of the jet  $p_T$  scale obtained by evaluating the jet  $p_T$  range on the curves covered by the statistical uncertainties of the data points in the bottom of Fig. 20 and dividing the  $p_T$  range by the jet truth  $p_T$ . The  $p_T$  scale uncertainty varies significantly at high  $p_T$  with different choices of  $\Delta R$

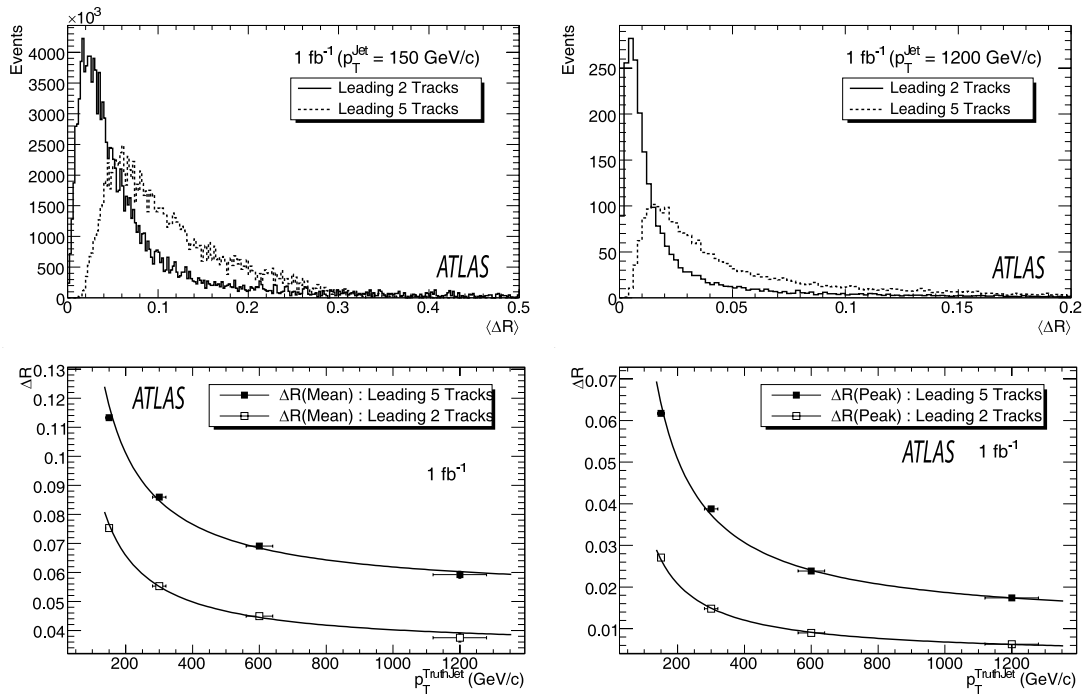

Figure 20: Top: Distributions of the mean of the  $\Delta R$  values for the leading two (solid histogram) and five (dashed histogram) tracks in jets with  $140 < p_T^{\text{truth}} < 160$  GeV (left) and  $1120 < p_T^{\text{truth}} < 1280$  GeV (right) for an integrated luminosity of  $1\text{fb}^{-1}$ . Bottom: Mean (left) and most probable value obtained from a Landau fit to the peak (right) of the  $\Delta R$  distributions as a function of the leading jet truth  $p_T$  for the leading two (solid points) and five (open points) tracks. The curves represent fits with a function of the form  $p_0/x + p_1$ .

values. In general, the MPV is more stable than the mean value as it suffers less from fluctuations in jet hadronization. The MPV-based scale uncertainty seems less dependent on the leading track multiplicity in PYTHIA-only comparisons, but the situation changes when PYTHIA is compared with HERWIG as in Fig. 21 (top-right). Apparently the choice of the leading two tracks is more robust against different jet fragmentation models, and therefore the  $\Delta R$  obtained from the MPV of leading two tracks is used hereafter as a central value.

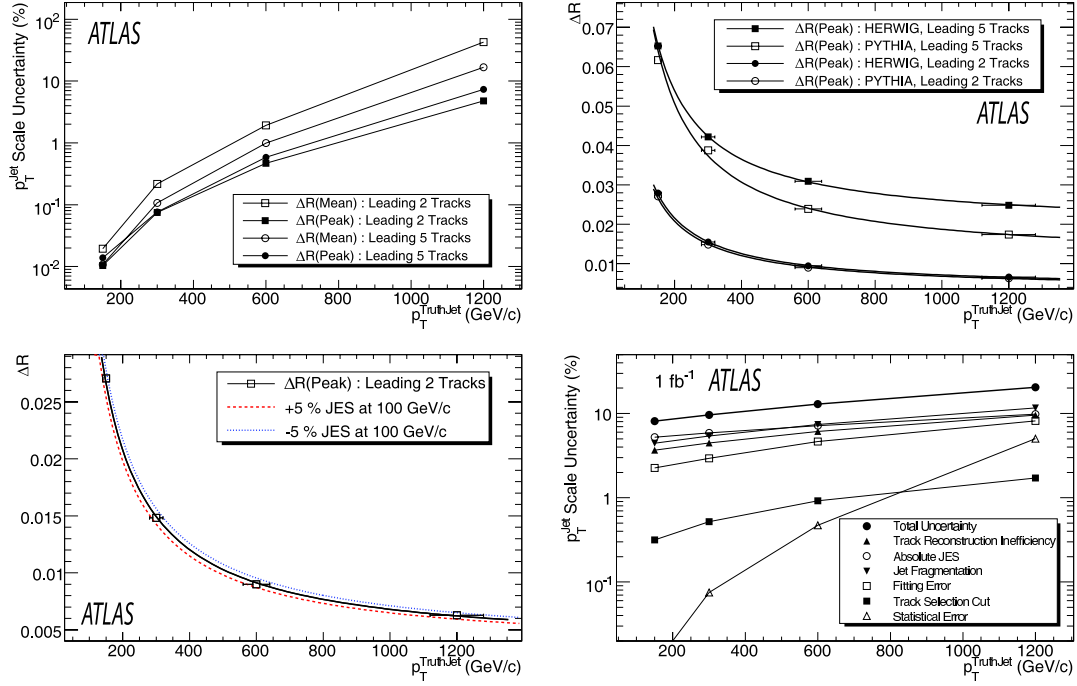

Figure 21: Top-Left: Jet  $p_T$  scale uncertainty (statistical uncertainty only) as a function of jet truth  $p_T$  obtained for different choices of  $\Delta R$  values and track multiplicities. Top-Right: The most probable  $\Delta R$  of the leading two and five tracks as a function of the jet truth  $p_T$  in PYTHIA (open points) and HERWIG (solid points). Bottom-Left: Default fit (solid curve) to the most probable  $\Delta R$  of the leading two tracks as a function of the truth jet  $p_T$  and the curves corresponding to  $\pm 5\%$  JES variations at  $p_T^{\text{jet}} = 5$  GeV (dashed and dotted). Bottom-Right: Total and individual systematic and statistical uncertainties as a function of the truth jet  $p_T$  expected to be obtained from the track angle method for an integrated luminosity of 1fb $^{-1}$ .

The following sources of systematic uncertainties are considered: 1) the jet fragmentation model as discussed above, 2) the track selection cuts and reconstruction inefficiencies, 3) absolute JES at low energies, and 4) the uncertainty associated with the fit. The systematic uncertainty on the jet  $p_T$  scale is evaluated by obtaining the  $\Delta R$  versus jet  $p_T$  distributions shifted by  $\pm 1\sigma$  (or the equivalent amount specified) of the source, and looking at the variation in the jet  $p_T$  at the measured  $\Delta R$  values. For 1), the difference between PYTHIA and HERWIG is assigned. For 2), the deviated distributions are obtained by applying different selection cuts on tracks and assuming an extra 5% reconstruction inefficiency for tracks in jets. The JES uncertainty for low  $p_T$  jets is assumed to be  $\pm 5\%$  at  $p_T^{\text{jet}} = 100$  GeV, and the deviated distributions are obtained by estimating the corresponding variations in  $\Delta R$  at  $p_T^{\text{jet}} = 100$  GeV using the default fit function and transferring the variations to uncertainties on the parameters of the function. The JES deviated and default distributions are shown in Fig. 21 bottom-left. The total uncertainty obtained by adding all the systematic uncertainties and the statistical uncertainty in quadrature, and individual

systematic uncertainties as a function of the jet truth  $p_T$  are shown in the bottom-right of the figure. With the assumption of  $\pm 5\%$  JES uncertainty at  $p_T^{\text{jet}} = 100$  GeV, the JES of 150, 300, 600, and 1200 GeV  $p_T$  jets can be potentially measured with an accuracy of 8, 10, 13, and 21%, respectively, with an integrated luminosity of  $1\text{fb}^{-1}$ .

### 5.3 Obtaining jet energy resolution in QCD dijet sample

A precise measurement of the jet energy resolution is necessary to model and control the systematic effects associated with it on jet observables and the quantities used in physics measurements. A key issue in estimating the jet energy and momentum resolution is the need to disentangle detector effects from those associated with physics such as the underlying event, and initial and final state radiation.

Two data-based techniques are presented which allow the jet energy resolution to be estimated, and they were compared where appropriate to the resolution obtained using particle jets: the dijet balance method, used by the DØ collaboration, and the  $k_T$  balance technique, developed by UA2 and used by CDF.

The QCD dijet events for this analysis were generated using PYTHIA in the  $p_T$  range from 17 GeV up to 1120 GeV. Jets were reconstructed using the cone algorithm with  $R = 0.7$ .

To select dijet events the following basic cuts are applied:

- One primary vertex;
- Exactly two back-to-back leading jets with  $|\Delta\phi| < 0.3$  and  $p_T > 10$  GeV;
- Both jets in the same  $\eta$  region  $|\eta| < 1.2$ .

The  $\Delta\phi$  and minimum  $p_T$  cuts are varied for some systematic studies.

#### 5.3.1 Dijet balance method

The determination of the jet  $p_T$  resolution in the dijet balance technique is based on energy conservation in the transverse plane. It assumes that there are only two jets in the event which have similar  $p_T$ . If one defines the asymmetry distribution  $A$  for the two jets as:

$$A \equiv \frac{p_{T,1} - p_{T,2}}{p_{T,1} + p_{T,2}}, \quad (13)$$

then for jets in the same rapidity region, which therefore have the same resolution, the fractional transverse jet energy resolution can be expressed as a function of  $\sigma_A$ :

$$\frac{\sigma_{p_T}}{p_T} = \sqrt{2}\sigma_A, \quad (14)$$

where  $p_T = (p_{T,1} + p_{T,2})/2$ .

The asymmetry distribution  $A$  for two representative  $p_T$  bins obtained by using cone jets with  $R = 0.7$  are shown in Fig. 22. The distributions have been symmetrized by computing either  $p_{T,1} - p_{T,2}$  or  $p_{T,2} - p_{T,1}$  randomly for each event. The resolution function is well described by a Gaussian fit, although it is worth mentioning that previous studies done by the DØ Collaboration suggest using a double Gaussian fit for large  $p_T$  bins, to absorb effects of non-Gaussian tails.

The simple dijet balance method does not return the true fractional transverse energy resolution associated purely with detector effects, since the two leading jets of an event could be imbalanced due to undetected jets in the event with  $p_T < 10$  GeV such as from soft radiation. This radiation will broaden the resolution function and a correction may be derived by studying the effect of the cut on the  $p_T$  of any third jet in the event as described in the next section.

Figure 22: Asymmetry distributions of two jets for two representative  $p_T$  bins. Cone jets with  $R = 0.7$  in the pseudorapidity region  $|\eta| < 1.2$  are used. The distributions were fitted with a single Gaussian function.

### 5.3.2 Soft radiation correction

In our basic event selection, both the  $\Delta\phi$  cut and the cut requiring exactly two jets with  $p_T > 10$  GeV are implemented in order to reduce the broadening of the  $p_T$  balance distribution due to soft radiation effects. However, the effects are not fully suppressed, as further jets with  $p_T < 10$  GeV may remain in the selected events. To account for this effect, the jet resolution is computed by allowing a third jet with transverse momentum  $p_{T,3}$  up to some threshold  $\varepsilon$ , and varying the threshold values between  $\varepsilon = 12.5$  and 27.5 GeV. As before, the resolution distributions in the jet  $p_T$  bins are fitted using single Gaussian functions. For each jet  $p_T$  bin, the set of resolutions obtained from the different  $p_{T,3}$  thresholds are fitted with a straight line and extrapolated to  $\varepsilon = 0$ . We define this value as:

$$\left( \frac{\sigma_{p_T}}{p_T} \right)^{p_{T,3} \rightarrow 0}, \quad (15)$$

which would be the resolution that we would have measured from an ideal dijet sample with  $\varepsilon = 0$ . Examples of the linear fits and the extrapolations for two  $p_T$  bins are presented in Fig. 23.

After fitting the resolution for the different third jet thresholds, we calculate a correction factor,  $K(p_T)$ , as follows:

$$K(p_T) = \left( \frac{\sigma_{p_T}}{p_T} \right)^{p_{T,3} \rightarrow 0} / \left( \frac{\sigma_{p_T}}{p_T} \right)^{\varepsilon=10 \text{ GeV}}. \quad (16)$$

Finally, correcting by this factor, the unbiased fractional transverse energy resolution is obtained via

$$\left( \frac{\sigma_{p_T}}{p_T} \right)_{\text{corrected}} = K(p_T) \times \left( \frac{\sigma_{p_T}}{p_T} \right)_{\text{uncorrected}}^{\varepsilon=10 \text{ GeV}}. \quad (17)$$

Since the soft radiation bias should be larger at small transverse energies, and negligible at high  $p_T$  we parametrize  $K(p_T)$ , with the function:

$$K(p_T) = 1 - \exp(a - bp_T). \quad (18)$$

This parametrization can be used to correct the resolution for each  $p_T$  bin and determine the unbiased resolution associated purely with detector effects. The jet energy resolutions with and without the soft

Figure 23: Resolution versus the  $p_{T,3}$  threshold cut for different  $p_T$  bins. The line corresponds to the linear fit applied while the dashed-line shows the extrapolation to  $p_{T,3} = 0$ , which corresponds to an ideal dijet sample ( $\varepsilon = 0$ ).

radiation correction are shown in Fig. 24. As we will see below, by comparing this result to that obtained by other approaches we can establish an estimate of the systematic uncertainty of the jet energy resolution.

Figure 24: Jet energy resolution for cone jets with  $R=0.7$  in the pseudorapidity range  $|\eta| < 1.2$ . The results are obtained by using dijet balance techniques with and without applying the soft radiation correction.

Figure 25: Sketch of the  $k_T$  balance technique. The  $\eta$  axis corresponds to the azimuthal angular bisector of the dijet system while the  $\psi$  axis is defined as being orthogonal to the  $\eta$  axis.

### 5.3.3 The $k_T$ balance technique

The  $k_T$  balance technique was developed by UA2 and studied at CDF. To extract the contributions of detector effects on to the jet energy resolution, the imbalance vector  $\vec{K}_T = \vec{p}_{T,1} + \vec{p}_{T,2}$  is projected onto two components ( $\psi, \eta$ ) as shown in Fig. 25.

The  $\eta$  axis corresponds to the azimuthal angular bisector of the dijet system while the  $\psi$  axis is

defined as being orthogonal to the  $\eta$  axis. The two components,  $K_{T,\psi}$  and  $K_{T,\eta}$ , are sensitive to different effects. The calorimeter energy resolution represents the main source for  $\sigma_\psi$ , the spread of  $K_{T,\psi}$ . Gluon radiation effects are smaller but affect this component as well. On the other hand,  $\sigma_\eta$ , the spread of  $K_{T,\eta}$ , is significantly affected by gluon radiation. In addition, there are other smaller effects such as jet angular resolution, underlying event and out-of-cone fluctuations. In order to reduce the hard gluon radiation effects, events with  $p_{T,3} > 11$  GeV are rejected. If we define the contributions from the calorimeter resolution,  $\sigma_{\text{res}}$ , and from soft radiation,  $\sigma_{\text{SR}\parallel}$  and  $\sigma_{\text{SR}\perp}$ , then we can write

$$\begin{aligned}\sigma_\psi^2 &= \sigma_{\text{res}}^2 + \sigma_{\text{SR}\parallel}^2 \\ \sigma_\eta^2 &= \sigma_{\text{SR}\perp}^2.\end{aligned}$$

Assuming

$$\sigma_{\text{SR}\parallel}^2 = \sigma_{\text{SR}\perp}^2, \quad (19)$$

the soft radiation effects are removed by subtracting in quadrature  $\sigma_\eta$  from  $\sigma_\psi$ :

$$\sigma_{\text{res}} = \sqrt{\sigma_\psi^2 - \sigma_\eta^2}. \quad (20)$$

The data sample was divided into six  $p_T$  regions, and the distributions  $K_{T,\eta}$  and  $K_{T,\psi}$  were fitted with single Gaussians. Since in this method the measured resolution comes from the convolution of the single jet resolution, to obtain the single jet energy resolution,  $\sigma_{\text{res}}$  must be scaled by a factor  $\frac{1}{\sqrt{2}}$ .

Figure 26 shows the resulting  $\frac{1}{\sqrt{2}}\sigma_\psi$  and  $\frac{1}{\sqrt{2}}\sigma_\eta$  as a function of the square root of the average  $p_T$  of both jets.  $\sigma_\psi$  has an approximately linear dependence with  $\sqrt{\langle p_{T,1,2} \rangle}$ , while  $\sigma_\eta$  has a flat dependence, especially at high  $p_T$ , as expected. The effective jet energy resolution after removing soft radiation effects by subtracting in quadrature  $\sigma_\eta$  from  $\sigma_\psi$  is shown in Fig. 27.

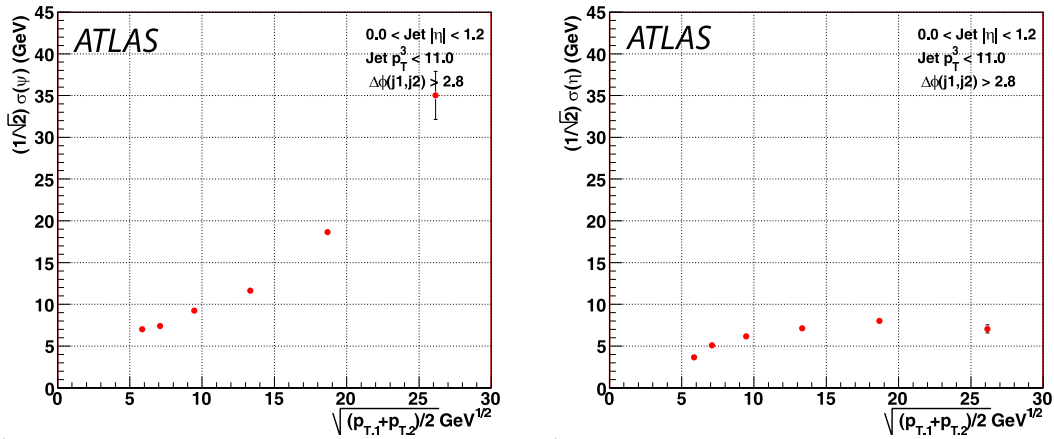

Figure 26:  $\frac{1}{\sqrt{2}}\sigma_\psi$  and  $\frac{1}{\sqrt{2}}\sigma_\eta$  in dijet events as a function of the square root of the average  $p_T$  of both jets.

### 5.3.4 Comparison of dijet and $k_T$ balance techniques

A comparison of the two methods, the dijet balance and the  $k_T$  balance technique, allows an estimate of the systematic uncertainty associated with the determination of the resolution associated with detector response. By comparing the reconstructed jets with the jets from Monte Carlo truth we obtain information on its dependence on the jet algorithm and the jet matching. Each of the first two leading calorimeter

Figure 27: The effective jet energy resolution for cone 0.7 jets after removing soft radiation effects by subtracting in quadrature  $\sigma_\eta$  from  $\sigma_\psi$ .

Figure 28: True jet energy resolution for cone 0.7 compared with those obtained using dijet and  $k_T$  balance techniques.

jets is matched to particle jets, which lie within  $\Delta R < 0.1$  w.r.t. the reconstructed jet. After matching, the response  $p_T^{\text{calo}}/p_T^{\text{truth}}$  is determined, and the true resolution is obtained by fitting the response with single Gaussians. This is shown in Fig. 28 together with the results from the two data-driven estimates.

The two data-driven approaches agree within uncertainties, though a hint that the  $k_T$  method is underestimating the true detector resolution might be visible. The determination of the resolution using reconstructed jets matched to particle jets gives results in between the two data-driven approaches and together with them provides a reasonable basis from which to estimate the systematic uncertainties in the determination of the noise, stochastic and constant terms in the jet energy resolution.

## 6 Summary and conclusions

Precise reconstruction of the jet energy is required by many physics analyses. In-situ processes provide the platform against which our understanding, based on theory and detector simulation, must be tested in order to achieve maximum precision. From the analyses presented in this paper, we conclude that one can characterize three ranges of jet  $p_T$ , in which the different features of detector response and underlying physics control the precision which can be achieved.

From the reconstruction threshold of 10 GeV up to  $\sim 100 - 200$  GeV, the combination of effects from jet clustering and physics effects like ISR/FSR and underlying event can be as large as 5 – 10% at low  $p_T$ , slowly decreasing to the percent level around 100 – 200 GeV. With QCD dijet events, we will be able to control the uniformity of the response on the percent level with high granularity in  $\phi$  and  $\eta$  already with  $\sim 10\text{pb}^{-1}$ . In turn,  $Z + \text{jet}$  balance is an adequate process to measure the absolute energy scale with a statistical precision of 1% with approximately  $300\text{pb}^{-1}$  of data. Hence the precision will rather quickly be dominated by the systematic uncertainty. Validation of the Monte Carlo simulation to ensure that both physics and detector effects are well modeled will be particularly important to control systematic uncertainties. Differences between currently available Monte Carlo generators are on the level of 5 – 10% in some of the observables, which sets the scale for the challenge in this region of jet  $p_T$ .

The medium  $p_T$  region extends from 100 – 200 GeV to about 500 GeV. Physics effects are at the level of 1 – 2% in this region. The momenta of the particles resulting from jet fragmentation are within the range of the test beam measurement. It will be an important range in which to validate the Monte

Carlo description of the detector response. In addition the dijet balance is still statistically powerful, and 1% precision for an  $\eta$  bin size of 0.1 can be achieved with  $\sim 100\text{pb}^{-1}$ . In  $\gamma$ +jet events the  $p_T$  balance can be measured with negligible bias from QCD background. The statistical precision is better than one percent for  $10\text{pb}^{-1}$  at 100 GeV, and in the range 300 – 500 GeV the percent level is reached with  $\sim 100\text{pb}^{-1}$ .

Above 500 GeV, one enters a regime which is beyond any existing jet measurement and extrapolation of the Monte Carlo modeling and comparison to in-situ data is crucial. A much larger integrated luminosity is required for in-situ measurements of similar precision. In addition, for the highest momentum particles which may be produced in these jets, our simulation of the detector no longer has test beam data available as a basis. Techniques such as multijet balancing or extrapolation based on jet particle properties can be used and should allow us to control the scale at the level of a few percent with  $1\text{fb}^{-1}$  for jets up to 1 TeV.

# Measurement of Missing Transverse Energy

## Abstract

This note discusses the overall ATLAS detector performance for the reconstruction of the missing transverse energy,  $\cancel{E}_T$ . Two reconstruction algorithms are discussed and their performance is evaluated for a variety of simulated physics processes which probe different topologies and different total transverse energy regimes. In addition, effects of fake  $\cancel{E}_T$  resulting from instrumental effects and from false reconstructions are investigated. Finally, studies with first data, corresponding to an integrated luminosity of  $100\text{pb}^{-1}$ , are suggested which can be used to assess and calibrate the  $\cancel{E}_T$  performance at the startup of data taking.

## 1 Introduction

A very good measurement of the missing transverse energy,  $\cancel{E}_T$ , is essential for many physics studies in ATLAS. Events with large  $\cancel{E}_T$  are expected to be the key signature for new physics such as supersymmetry and extra dimensions. A good  $\cancel{E}_T$  measurement in terms of linearity and resolution is also important for the reconstruction of the top-quark mass from  $t\bar{t}$  events with one top quark decaying semi-leptonically. Furthermore, it is crucial for the efficient and accurate reconstruction of the Higgs boson mass when the Higgs boson decays to a pair of  $\tau$ -leptons.

This Note describes the overall performance of the  $\cancel{E}_T$  measurement in ATLAS. The performance is checked using fully simulated Monte Carlo (MC) samples in different physics channels with differences in event topology and kinematics range. Events with no true  $\cancel{E}_T$  as well as events with a true  $\cancel{E}_T$ ,  $\cancel{E}_T^{\text{True}}$ , due to particles unseen in the detector as neutrinos or lightest supersymmetric particles, ranging from  $\sim 20$  to  $\sim 500$  GeV are used.

An important requirement on the measurement of  $\cancel{E}_T$  is to minimize the impact of limited detector coverage, finite detector resolution, presence of dead regions and different sources of noise that produce fake  $\cancel{E}_T$ ,  $\cancel{E}_T^{\text{Fake}}$ . The ATLAS calorimeter coverage extends to large pseudorapidity angles to minimize the impact of high energy particles escaping in the very forward direction. Even so, there are inactive transition regions between different calorimeters that produce  $\cancel{E}_T^{\text{Fake}}$ . Dead and noisy readout channels in the running detector, if present, will also produce  $\cancel{E}_T^{\text{Fake}}$ . Such  $\cancel{E}_T^{\text{Fake}}$  sources can significantly enhance the background from QCD multi-jet events in supersymmetry searches or the background from  $Z \rightarrow \ell\ell$  events accompanied by high- $p_T$  jets in Higgs boson searches when the Higgs boson decays into two leptons and neutrinos.

The calorimeter plays a crucial role in the  $\cancel{E}_T$  measurement and an important first step of the  $\cancel{E}_T$  measurement is the suppression of noise in the calorimeter. Section 2 describes the techniques used for noise suppression in calorimeters. The two  $\cancel{E}_T$  reconstruction algorithms used in ATLAS, Cell-based and Object-based, are described in detail in Sections 2.2 and 2.3. The overall performance of the  $\cancel{E}_T$  measurement in ATLAS is reported in Section 3. Any mis-measurement in the event, due to finite resolution or acceptance of the detector or due to instrumental effects related to dead or noisy channels, will degrade the  $\cancel{E}_T$  measurement. Such sources of  $\cancel{E}_T$ , that can lead to large values of fake  $\cancel{E}_T$ , are studied in Section 4. Section 5 introduces the  $\cancel{E}_T$  algorithm for the ATLAS triggers and describes its performance. Finally, Section 6 describes techniques in different physics channels that can be used with the very first ATLAS data to validate the  $\cancel{E}_T$  measurement and determine the  $\cancel{E}_T$  scale in-situ.

## 2 The algorithms for $\cancel{E}_T$ reconstruction in ATLAS

The transverse missing energy in ATLAS is primarily reconstructed from energy deposits in the calorimeter and reconstructed muon tracks. Apart from the hard scattering process of interest, many other sources, such as the underlying event, multiple interactions, pile-up and coherent electronics noise, lead to energy deposits and/or muon tracks. Classifying the energy deposits into various types (e.g. electrons or jets) and calibrating them accordingly is the essential key for an optimal  $\cancel{E}_T$  measurement. In addition, the loss of energy in dead regions and readout channels make the  $\cancel{E}_T$  measurement a real challenge.

There are two algorithms for  $\cancel{E}_T$  reconstruction in ATLAS that emphasize different aspects of energy classification and calibration.

The Cell-based algorithm starts from the energy deposits in calorimeter cells that survive a noise suppression procedure. The cells can be calibrated using global calibration weights depending on their energy density. This procedure will be robust already at initial data taking because it does not rely on other reconstructed objects. In a subsequent step, the cells can be calibrated according to the reconstructed object they are assigned to. Corrections are applied for the muon energy and for the energy lost in the cryostats.

The Object-based algorithm starts from the reconstructed, calibrated and classified objects in the event. The energy outside these objects is further classified as low  $p_T$  deposit from charged and neutral pions and calibrated accordingly.

The noise suppression in the calorimeter is common for the Cell- and Object-based algorithm and is described below, followed by a detailed description of the algorithms.

### 2.1 Calorimeter noise suppression

The electronics noise alone in the  $\approx 200k$  readout channels of the ATLAS calorimeter contributes about 13 GeV to the width of the  $\cancel{E}_T$  distribution. Especially in events that do not have large  $\cancel{E}_T$ , such as in  $Z \rightarrow \tau\tau$  used for an in-situ determination of the  $\cancel{E}_T$  scale (Section 6.2), the noise suppression is of crucial importance.

For the  $\cancel{E}_T$  measurement, two noise suppression methods have been studied so far. Both require knowledge of the width of the noise distribution,  $\sigma_{\text{noise}}$ , which can be either purely electronics noise or a combination of electronics and pile-up noise.

**Standard Noise Suppression Method.** The first method is based on only using calorimeter cells with energies larger than a threshold, generally corresponding to a certain number of  $\sigma_{\text{noise}}$ . The threshold is optimized for  $\cancel{E}_T$  resolution, the scale of  $\cancel{E}_T$ , the total transverse energy in the calorimeters,  $\Sigma\cancel{E}_T$ , and for the highest  $p_T$  jet to be close to the case without noise simulation. Two cases are studied: a symmetric threshold ( $|E_{\text{cell}}| > n \times \sigma_{\text{noise}}$ ) and an asymmetric one ( $E_{\text{cell}} > n \times \sigma_{\text{noise}}$ ). A symmetric threshold with  $n = 2$  for all calorimeters is generally used.

**Noise Suppression using TopoClusters.** The second method only uses cells in 3-dimensional topological calorimeter clusters [1, 2], hereafter called TopoClusters. A TopoCluster is reconstructed starting from a seed cell with an absolute energy value  $|E_{\text{cell}}| > 4\sigma_{\text{noise}}$  to which neighbors with  $|E_{\text{cell}}| > 2\sigma_{\text{noise}}$  are added. Finally the cells at the boundary are required to have  $|E_{\text{cell}}| > 0\sigma_{\text{noise}}$ . The cells that constitute the TopoCluster are hereafter called TopoCells. This set of thresholds, referred to as 4/2/0, is optimized to suppress electronics noise as well as pile-up from minimum bias events, while keeping the single pion efficiency as high as possible.

As a result of the large energy density of electromagnetic showers, the  $\pi^0$  reconstruction efficiency is high (close to 100% for energies  $> 4$  GeV) for the 4/2/0 configuration. On the other hand, the reconstruction efficiency for charged pions is very sensitive to the parameters of the TopoClusters. For example, changing the cuts on neighbors from 4/2 to 6/3, the  $\pi^\pm$  efficiency significantly decreases for

TopoClusters with  $E < 4$  GeV. This sensitivity highlights the importance of a good modeling of the noise level from first data.

In  $Z \rightarrow \nu\bar{\nu}$  events simulated with electronics noise, the  $\cancel{E}_T$  resolution degrades by only 3 % for the 4/2/0 configuration as compared to the same events without noise added. Also, the TopoCluster algorithm performs better in terms of linearity and resolution of the  $\cancel{E}_T$  measurement, compared to the standard noise suppression method. Therefore Cell- and Object-based  $\cancel{E}_T$  algorithms apply the noise suppression method based on TopoClusters with configuration 4/2/0.

## 2.2 Cell-based $\cancel{E}_T$ reconstruction

The Cell-based  $\cancel{E}_T$  reconstruction includes contributions from transverse energy deposits in the calorimeters, corrections for energy loss in the cryostat and measured muons:

$$\cancel{E}_{x,y}^{\text{Final}} = \cancel{E}_{x,y}^{\text{Calo}} + \cancel{E}_{x,y}^{\text{Cryo}} + \cancel{E}_{x,y}^{\text{Muon}}. \quad (1)$$

In the following, the three terms in the above equation, referred to as calorimeter, cryostat and muon terms, are described in some detail.

### 2.2.1 The $\cancel{E}_T$ calorimeter term

As described in the previous section, the first step is to select calorimeter cells that belong to reconstructed TopoClusters to minimize the impact of noise.

The  $x$  and  $y$  components of the calorimeter  $\cancel{E}_T$  term are calculated from the transverse energies measured in TopoCells:

$$\cancel{E}_{x,y}^{\text{Calo}} = - \sum_{\text{TopoCells}} E_{x,y}. \quad (2)$$

The total transverse energy in the calorimeters,  $\Sigma\cancel{E}_T$ , is calculated from the scalar sum of  $E_T$  of all TopoCells:

$$\Sigma\cancel{E}_T^{\text{Calo}} = \sum_{\text{TopoCells}} E_T. \quad (3)$$

The straightforward result, obtained by using the electromagnetic calibration for all cells, gives a large shift in the  $\cancel{E}_T$  scale of about 30% with respect to  $\cancel{E}_T^{\text{True}}$  (see Section 3).

This result illustrates the necessity of developing a dedicated calibration scheme to reduce the systematic shift of the  $\cancel{E}_T$  scale and optimize its resolution. This goal is achieved in several steps according to the cell classification. The classification depends on whether the energy deposits in the calorimeter are electromagnetic or hadronic in nature and whether they are associated with high  $p_T$  particles.

To classify energy deposits, schemes to calibrate hadronic showers such as ‘H1-like’ calibration or ‘Local-Hadronic’ calibration [3] utilize the energy density in a cell. Electromagnetic showers tend to have higher energy densities as compared to hadronic showers. The ‘Local-Hadronic’ calibration scheme uses further information related to shape and depth of the calorimetric shower to classify a TopoCluster. The next step in the cell-based  $\cancel{E}_T$  reconstruction is to globally calibrate all calorimeter cells using the ‘H1-like’ or ‘Local-Hadronic’ calibration schemes. As can be seen in the performance section, this already gives a very good  $\cancel{E}_T$  performance. The final refinement step of the calibration using the association of cells with reconstructed objects is described in Section 2.2.4. It improves the linearity and the resolution particularly for events containing electrons (Section 3).

### 2.2.2 The $\cancel{E}_T$ muon term

The  $\cancel{E}_T$  muon term is calculated from the momenta of muons measured in a large range of pseudorapidity, defined by  $|\eta| < 2.7$ :

$$\cancel{E}_{x,y}^{\text{Muon}} = - \sum_{\text{RecMuons}} E_{x,y}. \quad (4)$$

In the region  $|\eta| < 2.5$  only good-quality muons in the muon spectrometer with a matched track in the inner detector are considered. The matching requirement reduces considerably contributions from fake muons, sometimes created from high hit multiplicities in the muon spectrometer in events with very energetic jets. For higher values of the pseudorapidity ( $2.5 < |\eta| < 2.7$ ), outside the fiducial volume of the inner detector, there is no matched track required and the muon spectrometer is used alone.

The muon momentum measured by the muon spectrometer is taken in the two cases. Energy lost in the calorimeter is already included in the calorimeter term. No  $p_T$  threshold cut is applied to reconstructed muons. Apart from the loss of muons outside the acceptance of the muon spectrometer ( $|\eta| > 2.7$ ), there is a loss of muons in other regions (see Section 4.1) due to limited coverage of the muon spectrometer. The muons reconstructed from the inner detector and calorimeter energy deposits could be used to recover these events, but they are not yet used here.

As can be seen in the performance section, the  $\cancel{E}_T$  resolution is only marginally affected by the muon term, due to the good identification efficiency and resolution of the ATLAS muon system. However, unmeasured, badly measured or fake muons can be a source of large fake  $\cancel{E}_T$  (see Section 4).

### 2.2.3 $\cancel{E}_T$ cryostat term

The thickness of the cryostat between the LAr barrel electromagnetic calorimeter and the tile barrel hadronic calorimeter is about half an interaction length where hadronic showers can lose energy. The  $\cancel{E}_T$  reconstruction recovers this loss of energy in the cryostat using the correlation of energies between the last layer of the LAr calorimeter and the first layer of the hadronic calorimeter. A similar correction for the end-cap cryostats is applied. This correction is called the cryostat term when used for jet energy correction [3]. It is defined as follows:

$$\cancel{E}_{x,y}^{\text{Cryo}} = - \sum_{\text{recJets}} E_{jet_{x,y}}^{\text{Cryo}}, \quad (5)$$

where all reconstructed jets are summed in the event, and

$$E_{jet}^{\text{Cryo}} = w^{\text{Cryo}} \sqrt{E_{\text{EM3}} \times E_{\text{HAD}}}, \quad (6)$$

where  $w^{\text{Cryo}}$  is a calibration weight (determined together with the cell calibration weights in the H1-like calibration) and  $E_{\text{EM3}}$  and  $E_{\text{HAD}}$  are the jet energies in the third layer of the electromagnetic calorimeter and in the first layer of the hadronic calorimeter, respectively. The cryostat correction turns out to be non-negligible for high- $p_T$  jets. It contributes at the level of  $\sim 5\%$  per jet with  $p_T$  above 500 GeV.

### 2.2.4 Refined calibration of the $\cancel{E}_T$ calorimeter term

The final step is the refinement of the calibration of cells associated with each high- $p_T$  object. Calorimeter cells are associated with a parent reconstructed and identified high- $p_T$  object, in a chosen order: electrons, photons, muons, hadronically decaying  $\tau$ -leptons,  $b$ -jets and light jets. Refined calibration of the object is then used in  $\cancel{E}_T$  to replace the initial global calibration cells. The calibration of these objects is known to higher accuracy than the global calibration, enabling to improve the  $\cancel{E}_T$  reconstruction.

Figure 1: Distribution of the difference between true and reconstructed  $\cancel{E}_T$  for  $Z \rightarrow \tau\tau$  events (left) including and (right) excluding cells in Topoclusters not associated with reconstructed high- $p_T$  objects.

The calorimeter cells are associated with the reconstructed objects through the use of an association map. This map is filled starting from the reconstructed/identified objects in the chosen order, navigating back to their component clusters and back again to their cells. If a cell belongs to several kinds of reconstructed objects, only the first association is included in the map, i.e. the overlap removal is done at cell level. This avoids double counting of cells in the  $\cancel{E}_T$  calculation. If a cell belongs to more than one object of the same kind, all associations are included in the map and the geometrical weight of the cells, accounting for the sharing of energy of cells owned by two different TopoClusters, is also included to avoid double counting.

Attention has to be paid to the calibration of cells inside different objects. For example, for electrons/photons, the final cluster-level calibration (which can be propagated back to the cell-level) corrects for upstream material, longitudinal leakage and out-of-cone energy. The last correction should not be applied in the  $\cancel{E}_T$  calculation because the contribution of cells outside objects already accounts for it. In a similar way, for  $\tau$  lepton decays and for jets, the overall scale factors which correct the energy for physics effects like final state radiation, fragmentation or the underlying event as well as for the effects due to the clustering algorithm are not applied in the calculation of  $\cancel{E}_T$ , because they also contain the out-of-cluster correction.

All TopoCells, even if not associated with any high- $p_T$  reconstructed object, are used in the  $\cancel{E}_T$  calculation. They are calibrated using the global calibration scheme. The importance of the energy deposits of these low energy particles for the  $\cancel{E}_T$  calculation is shown in Fig. 1. The shift in the absolute value of the reconstructed  $\cancel{E}_T$  increases by about 1 GeV while the resolution is degraded by a factor  $\sim 1.25$ .

Once the cells are associated with categories of objects as described above, the contribution to  $\cancel{E}_T$  is calculated as follows:

$$\cancel{E}_{x,y}^{\text{Calo}} = \cancel{E}_{x,y}^{\text{RefCalib}} = -(\cancel{E}_{x,y}^{\text{RefEle}} + \cancel{E}_{x,y}^{\text{RefTau}} + \cancel{E}_{x,y}^{\text{Refbjets}} + \cancel{E}_{x,y}^{\text{RefJets}} + \cancel{E}_{x,y}^{\text{RefMuon}} + \cancel{E}_{x,y}^{\text{RefOut}}), \quad (7)$$

where each term is calculated from the negative of the sum of calibrated cells inside a specific object and  $\cancel{E}_{x,y}^{\text{RefOut}}$  is calculated from the cells in TopoClusters which are not included in the reconstructed objects. In the following the final  $\cancel{E}_T$  calculation obtained from Equation (1) with  $\cancel{E}_{x,y}^{\text{Calo}} = \cancel{E}_{x,y}^{\text{RefCalib}}$  will be referred to as  $\cancel{E}_T^{\text{RefFinal}}$ .

### 2.3 Object-based $\cancel{E}_T$ reconstruction

The motivation of the method is to reliably reconstruct  $\cancel{E}_T$  for analyses that are sensitive to low  $p_T$  deposits coming mostly from neutral and charged pions, from soft jets, from the underlying event and

from pile-up. This is important, for example, in reconstructing the invariant mass of the Standard Model Higgs boson,  $m_H$ , in the  $H \rightarrow \tau^+ \tau^-$  final state for masses in the range  $115 < m_H < 140$  GeV [4].

The object-based method comprises two main steps:

- Establish a classification between two main types of objects: high  $p_T$  ( $e/\gamma, \mu, \tau$ , jets) and low  $p_T$  objects ( $\pi^0, \pi^\pm$ , unclustered deposits) coming from underlying event, pile-up of multiple  $pp$  collisions, initial and final state radiation, and other soft QCD processes.
- Apply the object-based calibration optimized for  $\cancel{E}_T$  calculation.

The  $x$  and  $y$  components of  $\cancel{E}_T$  and  $\sum E_T$  are calculated by adding the contributions from each type of components:

$$\cancel{E}_{x,y} = -E_{x,y}^{\text{High}} - E_{x,y}^{\text{Low}} \quad (8)$$

$$\sum E_T = \sum E_T^{\text{High}} + \sum E_T^{\text{Low}}, \quad (9)$$

where the indices ‘High’ and ‘Low’ correspond to the  $\cancel{E}_T$  and  $\sum E_T$  calculated from high  $p_T$  and low  $p_T$  objects, defined below.

The object-based algorithm uses mostly the calorimeter to reconstruct  $\cancel{E}_T$ . Some objects such as electrons and taus also use the inner detector tracking, while the muons use both, inner detector and muon spectrometer information. Tracking is also used for the low  $p_T$  deposits of soft objects.

The object-based method uses the TopoClusters 4/2/0 (Section 2.1) and first calculates all contributions of high  $p_T$  objects. Each TopoCluster is allowed to be included only once by the first object that is associated with it. The classification starts with the identification of electrons, photons, muons and  $\tau$ ’s. Once the clusters belonging to these objects are removed from the event record, hadronic jets above a certain threshold are identified. TopoCells not part of any of the above high  $p_T$  objects are classified as low  $p_T$  deposit. The next subsections discuss the calibration of these objects.

### 2.3.1 Calorimeter objects: electrons, hadronic $\tau$ -jets, jets

**Electrons:** The electron objects are taken from the standard electron reconstruction and a matched track is always required. The default calibration of an electron is based on the ‘sliding window’ EM clusters [5]. To be consistent with the combined 4/2/0 TopoClustering used for the object-based reconstruction, electrons are reconstructed from TopoClusters and they are calibrated by weighting the energy deposits in the longitudinal calorimeter layers. The electron  $p_T$  is required to be at least 8 GeV.

**Tau Leptons:** The object-based method uses the calo-based reconstructed  $\tau$ -jets [6] and it calibrates them as jets. A cut of 20 GeV on the  $\tau$ -jet  $p_T$  is applied and a  $\tau$  likelihood  $> 4$  is required.

**Jets:** A cone ( $\Delta R = 0.7$ ) jet algorithm running on the TopoClusters is used for calculating the  $\cancel{E}_T$  contribution from jets. Jets not overlapping with the electron and tau jets are chosen. The jet energy calibration is based on the ‘H1-like’ hadronic calibration [3], which corrects for the difference in response for  $e/\gamma$  and hadrons, followed by a scale correction due to the non-uniformity of the reconstruction in  $\eta$ . It is based on the  $\cancel{E}_T$  projection method (used by CDF and D0)[7] using a dijet sample where forward jets are corrected with respect to well measured central jets ( $|\eta| < 0.8$ ). The jet  $p_T$  is required to be at least 20 GeV.

Figure 2: Linearity for single charged  $\pi$  (left) and single  $\pi^0$  (right) as a function of  $\eta$  for the energy bin  $1 < E < 10$  GeV).

### 2.3.2 Muons

In general, the combined muons, reconstructed from the inner detector and the muon spectrometer, are used. In the region where the inner detector has no coverage ( $2.5 < |\eta| < 2.7$ ) muons reconstructed from the spectrometer only are used. To reduce the number of fake muons originating from punch through of high  $p_T$  jets, strong quality requirements are imposed on the combined track from the inner detector and the muon spectrometer. Additionally, if a muon passes inside a jet and the ratio of measured momenta in the inner detector and in the muon spectrometer is below 0.2, the muon is rejected. If the muon is found inside a jet or the total  $p_T$  at the EM scale of the TopoClusters within a cone of 0.2 around the muon is  $> 10$  GeV, either the measured muon energy loss in the calorimeter is subtracted from the combined  $p_T$  or the muon spectrometer  $p_T$  is used. The combined muon  $p_T$  is required to be at least 6 GeV.

Inner detector tracks may be used to improve the  $\cancel{E}_T$  reconstruction. They contain the muons not covered by the combination of inner detector and muon spectrometer, especially in the crack regions of the muon system. Only those tracks are retained which are isolated from others by a cone of size 0.3. Those tracks overlapping with electrons, muons or jets that are already used for  $\cancel{E}_T$  are discarded. The tracks should have  $p_T > 6$  GeV and should satisfy a muon likelihood criterion based on  $E/p$  and the energy in the calorimeter sampling layers. In addition, isolated tracks (mostly pions) with little energy deposits in the calorimeter can be used to improve  $\cancel{E}_T$ . These tracks are used only if  $p_T$  less than 10 GeV, to avoid tracks with spurious high  $p_T$ , which deteriorates the  $\cancel{E}_T$  performance.

### 2.3.3 Low $p_T$ depositions: classification and calibration

Only those TopoClusters that have not been assigned to high  $p_T$  objects are considered for classification as low  $p_T$  objects of either electromagnetic or hadronic nature. For this purpose, clusters are further subdivided into so-called mini-jets. Mini-jets are reconstructed from TopoClusters using a cone algorithm of a relatively small radius of  $\Delta R = 0.2$  and a seed cluster of  $p_T > 0.5$  GeV. A mini-jet is required to have  $p_T > 0.5$  GeV. The mini-jets are next classified as charged and neutral pions.

The separation between charged and neutral pions is done only in  $|\eta| < 3.2$ . A mini-jet is defined to be a  $\pi^0$  if the fractional energy in the hadronic compartments is less than 2% and  $p_T > 10$  GeV. The low  $p_T$  depositions are calibrated under single charged and neutral pion hypotheses in the full  $\eta$  range. A sampling method similar to that used to extract longitudinal weights as implemented for the electron and photon calibration is used. The calorimeter sampling weights are determined separately for neutral and charged pions in different energy and  $\eta$  regions. A good linearity is achieved for both neutral and charged pion hypotheses. Figure 2 shows the linearity for charged and neutral pions in the central region,

which roughly fluctuates within 5%.

Mini-jets will not saturate all the low  $p_T$  calorimeter deposits. There will remain a non-trivial amount of energy left in the calorimeter and clustered in TopoClusters from very low momentum pions, which will not form a mini-jet. These deposits are referred to as unassociated deposits. The energy calibration of these unassociated deposits has been estimated in three  $\eta$  regions, depending on the calorimeter region (barrel, end-cap, forward), and has been added to the  $\cancel{E}_T$  calculation.

### 3 Performance of the reconstructed $\cancel{E}_T$

In this section the performance of the  $\cancel{E}_T$  reconstruction is discussed, focusing on the linearity and resolution of the reconstructed  $\cancel{E}_T$  as a function of the true missing transverse energy,  $\cancel{E}_T^{\text{True}}$ . The measurement of the  $\cancel{E}_T$  direction and the dependence on topology are also discussed. Note that the performance of the two  $\cancel{E}_T$  reconstruction methods is very similar, so it is not specified which method has been used to produce each performance plot.

$\cancel{E}_T^{\text{True}}$  is defined from the sum of all stable and non-interacting particles in the final state (neutrinos and the lightest supersymmetric particles). Comparisons between  $\cancel{E}_T$  and  $\cancel{E}_T^{\text{True}}$  are made for a number of physics processes with different topologies and final states.

The  $\cancel{E}_T$  performance in case of events with large  $\cancel{E}_T^{\text{Fake}}$ , which contribute predominantly to the tails of the  $\cancel{E}_T$  distribution, is described in the next section.

#### 3.1 Linearity and resolution

The  $\cancel{E}_T$  linearity is defined by the following expression:

$$\text{Linearity} = (\cancel{E}_T^{\text{True}} - \cancel{E}_T) / \cancel{E}_T^{\text{True}}, \quad (10)$$

where  $\cancel{E}_T$  and  $\cancel{E}_T^{\text{True}}$  are reconstructed and true  $\cancel{E}_T$ , respectively. This definition of linearity assumes an  $\cancel{E}_T^{\text{True}}$  value above a threshold and an  $\cancel{E}_T^{\text{Fake}}$  value that is small such that the  $\cancel{E}_T$  angle is well measured.

Figure 3 shows the reconstructed linearity as a function of  $\cancel{E}_T^{\text{True}}$  for a number of physics processes. The following statements summarize the behavior of the linearity distributions:

- The uncalibrated  $\cancel{E}_T$  corresponds to the use of cell energies at the electromagnetic scale and shows a large systematic bias of 30%. In  $W \rightarrow e\nu$  and  $W \rightarrow \mu\nu$  decays, the bias is smaller since the hadronic activity on average is smaller.
- The reconstructed  $\cancel{E}_T$  based on globally calibrated cell energies and reconstructed muons gives a linearity to within 5%.
- The reconstructed  $\cancel{E}_T$  including the cryostat correction shows a linearity to within 1% for all processes except for  $W \rightarrow e\nu$ .
- The refined  $\cancel{E}_T$  calibration, which optimizes the calibration with reconstructed object identity, recovers the linearity for  $W \rightarrow e\nu$  events to within 1%. The refined calibration also gives the best resolution when compared with the above steps of calibration (see also Section 6).

The linearity for  $A \rightarrow \tau\tau$  with  $m_A = 800$  GeV is shown in Fig. 3 (right) as a function of  $\cancel{E}_T^{\text{True}}$ . The bias of linearity at low  $\cancel{E}_T^{\text{True}}$  is due to the finite resolution of the  $\cancel{E}_T$  measurement. The reconstructed  $\cancel{E}_T$  is positive by definition, so the linearity is negative when the true  $\cancel{E}_T$  is near to zero. Excluding the events with  $\cancel{E}_T^{\text{True}} < 40$  GeV, which have a small statistics the observed linearity is found to be within 2%.

The resolution is estimated from the width of the  $\cancel{E}_{x,y} - \cancel{E}_{x,y}^{\text{True}}$  distribution in bins of the total transverse energy deposited in the calorimeters ( $\Sigma\cancel{E}_T$ ). The core of each distribution is fitted with a Gaussian shape to estimate the width. Figure 4 shows the  $\sigma$  of the fit plotted as a function of  $\Sigma\cancel{E}_T$  when refined calibration is applied. The  $\cancel{E}_T$  resolution approximately follows a stochastic behaviour as a function of  $\Sigma\cancel{E}_T$ . Deviations from this simple behaviour are expected, and observed for low values of  $\Sigma\cancel{E}_T$  where the contribution of noise is important and for very high values of  $\Sigma\cancel{E}_T$  where the constant term in the resolution of the calorimetric energy measurement dominates.

The  $\cancel{E}_T$  resolution is fitted with a function  $\sigma = a \cdot \sqrt{\Sigma\cancel{E}_T}$  for values of  $\Sigma\cancel{E}_T$  between 20 and 2000 GeV. The parameter  $a$ , which quantifies the  $\cancel{E}_T$  resolution, varies between 0.53 and 0.57 (see Fig. 4 left and right, respectively). Refined  $\cancel{E}_T$  calibration yields the best results when compared to earlier stages of the calibration as described above. For  $W \rightarrow e\nu$  decays the  $a$  parameter is reduced by 88% and for  $Z \rightarrow ee$  events it is reduced by 78% with respect to the global calibration with the cryostat correction applied. Figure 5 shows the resolution in the high  $\Sigma\cancel{E}_T$  region for QCD jet samples. The jet samples used are generated in parton  $p_T$  bins: J1 corresponds to  $17 < p_T < 35$  GeV, J2 to  $35 < p_T < 70$  GeV, J3 to  $70 < p_T < 140$  GeV, J4 to  $140 < p_T < 280$  GeV, J5 to  $280 < p_T < 560$  GeV, J6 to  $560 < p_T < 1120$  GeV, J7 to  $1120 < p_T < 2240$  GeV. There is a clear degradation in the performance for the high  $p_T$  jet samples (J6 and J7), where the linear term dominates.

The effect of angular calorimeter coverage on the  $\cancel{E}_T$  measurement is evaluated by comparing the resolution with and without including the forward calorimeters (FCAL). In  $Z \rightarrow \tau\tau$  events the  $\cancel{E}_T$  resolution is 7.8 and 10.1 GeV, respectively, showing that the ATLAS coverage minimises by design the effect of particles escaping at very large  $\eta$  and that the forward calorimeter is very important to guarantee that.

Projections of  $\cancel{E}_T$  along suitable axes can be used to check calibration problems and understand topology dependences. The quantity  $\cancel{E}_L$  (longitudinal  $\cancel{E}_T$  projection) is the  $\cancel{E}_T$  projection onto the axis pointing in the direction of the genuine  $\cancel{E}_T$  of the event. In events without genuine  $\cancel{E}_T$ , such as  $Z \rightarrow \ell\ell$  events this axis is reconstructed from the direction of flight of the  $Z$  and in dijet events the projection is done along the dijet thrust axis. The quantity  $\cancel{E}_P$  (perpendicular  $\cancel{E}_T$  projection) is defined as a projection orthogonal to the  $\cancel{E}_L$  direction.

A bias of  $\cancel{E}_L$  usually indicates mis-calibration of the object's energy scale (in most cases the hadronic

Figure 3: (left) Linearity of response for reconstructed  $\cancel{E}_T$  as a function of the average true  $\cancel{E}_T$  for different physics processes covering a wide range of true  $\cancel{E}_T$  and for the different steps of  $\cancel{E}_T$  reconstruction (see text). The points at average true  $\cancel{E}_T$  of 20 GeV are from  $Z \rightarrow \tau\tau$  events, those at 35 GeV are from  $W \rightarrow e\nu$  and  $W \rightarrow \mu\nu$  events, those at 68 GeV are from semi-leptonic  $t\bar{t}$  events, those at 124 GeV are from  $A \rightarrow \tau\tau$  events with  $m_A = 800$  GeV, and those at 280 GeV are from events containing supersymmetric particles at a mass scale of 1 TeV. (right) Linearity of response for reconstructed  $\cancel{E}_T$  as a function of the true  $\cancel{E}_T$  for  $A \rightarrow \tau\tau$  events with  $m_A = 800$  GeV.

Figure 4: Resolution of the two  $\cancel{E}_T$  components with refined calibration as a function of the total transverse energy,  $\Sigma E_T$  for low to medium values (left) and for higher values (right). The curves correspond to the best fits of  $\sigma = 0.53\sqrt{\Sigma E_T}$  through the points from  $Z \rightarrow \tau\tau$  events (left) and  $\sigma = 0.57\sqrt{\Sigma E_T}$  through the points from  $A \rightarrow \tau\tau$  events (right). The points from  $A \rightarrow \tau\tau$  events are for masses  $m_A$  ranging from 150 to 800 GeV and the points from QCD jets correspond to dijet events with  $560 < p_T < 1120$  GeV.

Figure 5: Resolution of the two  $\cancel{E}_T$  components with refined calibration as a function of  $\Sigma \cancel{E}_T$  for QCD dijet samples ( $17 < p_T < 2240$  GeV). See text for the definition of samples J1-J7. The curve corresponds to  $\sigma = 0.55\sqrt{\Sigma \cancel{E}_T}$  (combined fit in the low and medium  $\Sigma \cancel{E}_T$  regions).

Figure 6: Linearity of response for  $\cancel{E}_L$  (left) and  $\cancel{E}_P$  (right) as a function of the average true  $\cancel{E}_T$  for different physics processes.  $\cancel{E}_L$  and  $\cancel{E}_P$  are defined in the text.

Figure 7: Resolution of  $\cancel{E}_L$  (left) and  $\cancel{E}_P$  (right) as a function of  $\Sigma \cancel{E}_T$  for QCD jet samples. See text for the definition of samples J1-J7.

scale). For events with significant values of  $\cancel{E}_T^{\text{True}}$ ,  $\cancel{E}_P$  is a measure of the  $\cancel{E}_T$  angular resolution. For dijet events and other back-to-back topologies with similarly defined  $\cancel{E}_P$  usually there is no bias in  $\cancel{E}_P$ , but the resolution of  $\cancel{E}_P$  is sensitive to soft radiation in the event. One possible source of bias in  $\cancel{E}_P$  comes from a bias in the angular measurement of the objects in the event, which will cause a shift in the same direction on both sides of  $\cancel{E}_L$ .

Figure 6 shows the  $\cancel{E}_L$  and  $\cancel{E}_P$  linearity as a function of the true  $\cancel{E}_T$  for different physics channels. The  $\cancel{E}_L$  linearity is within 2% above 100 GeV and deviates by 5-10% at lower  $\cancel{E}_T^{\text{True}}$ . The  $\cancel{E}_P$  bias is consistent with zero throughout. Figure 7 shows the  $\cancel{E}_L$  and  $\cancel{E}_P$  resolution as a function of the true  $\Sigma \cancel{E}_T$  for the QCD jet samples. As the  $\cancel{E}_L$  for jet events is defined as the  $\cancel{E}_T$  projection onto the thrust axis of the two leading jets which are back-to-back, a much larger resolution in absolute terms is expected with respect to  $\cancel{E}_P$ . The discontinuity in J4 ( $140 < p_T < 280$  GeV) and J5 ( $280 < p_T < 560$  GeV)  $\cancel{E}_P$  resolution is a result of dividing the dijet events into samples based on the parton  $p_T$ . Events with the same  $\Sigma \cancel{E}_T$  in J4 and J5 can have different energies in the perpendicular direction due to differences in underlying event, initial or final state radiation. This changes the  $\cancel{E}_P$  resolution in the two samples.

A good performance in terms of linearity and resolution may enhance the ability to reconstruct the mass of final states which involve neutrinos. Despite the presence of several neutrinos in the final state, the invariant mass of the  $\tau$  pair can also be reconstructed in  $Z \rightarrow \tau\tau$  and supersymmetric Higgs boson

Figure 8: Distributions of the reconstructed invariant mass of  $\tau$ -lepton pairs with one  $\tau$ -lepton decaying to a lepton and the other one decaying to hadrons. The results are shown for  $Z \rightarrow \tau\tau$  decays (left) and for  $A \rightarrow \tau\tau$  decays with  $m_A = 450$  GeV (right).

Figure 9: (left) Accuracy of the measurement of the azimuth of the  $\vec{E}_T$  vector as a function of the true  $\vec{E}_T$  for three different physics processes: semi-leptonic  $t\bar{t}$  events,  $Z \rightarrow \tau\tau$  and  $W \rightarrow e\nu$  events. (right)  $\vec{E}_T^{\text{Fake}}$  as a function of the reconstructed  $\phi(\vec{E}_T)$  in  $t\bar{t}$  events, simulated with extra material in  $\phi$ .

decays like  $A \rightarrow \tau\tau$  under simplifying assumptions [8, 9, 10]. Figure 8 shows reconstructed mass peaks of  $Z \rightarrow \tau\tau$  and supersymmetric Higgs boson decays  $A \rightarrow \tau\tau$  with  $m_A = 450$  GeV. The reconstructed masses are correct to  $\sim 2\%$  and the mass resolution is approximately 11%. Nevertheless, significant tails remain in the distributions because of the highly non-Gaussian effects induced by mis-measurements of  $\vec{E}_T$  and by the approximations used.

### 3.2 Measurement of the $\vec{E}_T$ direction

Large energy fluctuations in the calorimeter or muon mis-measurements can produce large  $\vec{E}_T^{\text{Fake}}$ . In general, for events with genuine missing transverse energy, the  $\vec{E}_T$  angular resolution will depend on the relative fraction of  $\vec{E}_T^{\text{Fake}}$  and on the event topology. Figure 9 shows the  $\vec{E}_T$  azimuthal angular resolution as a function of the  $\vec{E}_T^{\text{True}}$  for three different physics processes. The measurement of the  $\vec{E}_T$  azimuth is clearly more accurate for  $W \rightarrow e\nu$  events, which in general contain one high- $p_T$  electron and moderate hadronic activity in addition, compared to  $t\bar{t}$  events. For values of  $\vec{E}_T^{\text{True}}$  below 40 GeV, the accuracy of the measurement of the direction degrades rapidly. In contrast, for high values of  $\vec{E}_T^{\text{True}}$ , azimuthal accuracies below 100 mrad are achieved.

Detector inefficiencies may perturb the radial symmetry of the physics events. Thus, observations of  $\phi$  asymmetries in reconstructed variables may be a hint of instrumental problems. Due to the increased material (of  $\sim 5\%$  to  $10\%$ ) in the upper half of the detector that was added artificially into the simulation, a  $\phi$  asymmetry is observed in  $\vec{E}_T$  as seen in Fig. 9 (right). This  $\phi$  asymmetry can also be observed in the  $\vec{E}_T$  computed at the event filter trigger level.

Similarly, problematic  $\eta$  regions may be spotted by looking at  $\vec{E}_T$  correlations with jet pseudorapidity, in particular in QCD events. In fact, in this kind of events,  $\vec{E}_T$  is mainly due to jet mis-measurements which will affect more the  $\vec{E}_T$  component parallel to the dijet axis than that perpendicular to it. Detector failures or incorrect calibration sets may be revealed as unexpected peaks in such plots.

## 4 Fake $\vec{E}_T$

The reconstructed  $\vec{E}_T$  has two constituents - one that is produced by particles that interact weakly with the detector ( $\vec{E}_T^{\text{True}}$ ) and the other one due to detector inefficiencies and resolution ( $\vec{E}_T^{\text{Fake}}$ ). Figure 10 shows the rate of  $\vec{E}_T^{\text{Fake}}$  and  $\vec{E}_T^{\text{True}}$  for the QCD sample generated with  $560 < p_T < 1120$  GeV, where  $\vec{E}_T^{\text{Fake}}$  dominates at lower values and also has a larger tail. The same figure also shows these distributions

after excluding events with high  $p_T$  jets within  $17^\circ$  of the reconstructed  $\cancel{E}_T$  in the transverse plane. This considerably lowers the  $\cancel{E}_T^{\text{Fake}}$  rate compared to  $\cancel{E}_T^{\text{True}}$ . For an accurate measurement of  $\cancel{E}_T$  it is important to have a good understanding of the sources of  $\cancel{E}_T^{\text{Fake}}$  in data. Since the goal here is to study the performance and not the relative contributions of signal and background, comparisons between different physics samples are made for a common number of events rather than for a common luminosity.

The first two subsections discuss the  $\cancel{E}_T^{\text{Fake}}$  from muons and from the calorimeter under the assumption that all detector readout channels are functional. The impact of dead-regions in the detector is examined in the subsequent subsections.

#### 4.1 Fake $\cancel{E}_T$ from muons

$\cancel{E}_T^{\text{Fake}}$  from muons can be caused either by inefficiencies in reconstructing a high  $p_T$  muon or by reconstructing a fake high  $p_T$  muon. The latter could be present due to a combination of a lower  $p_T$  muon and/or random hits from high  $p_T$  jet punch-throughs from the calorimeter to the muon chambers. It can be argued that for reasonable muon identification efficiencies,  $\cancel{E}_T^{\text{Fake}}$  from missed muons will only be a small fraction of the  $\cancel{E}_T^{\text{True}}$  from neutrinos. For example in QCD samples the neutrino to muon ratio is roughly two. It gets higher in other physics samples depending on the fraction of  $\tau$  candidates in the event. On the other hand fake muons that are reconstructed from random hits in the muon chambers can be arbitrarily hard and strongly contribute to  $\cancel{E}_T^{\text{Fake}}$ . However, the study here shows that  $\cancel{E}_T^{\text{Fake}}$  from muons is dominated by missed muons rather than fake muons.

The total  $\cancel{E}_T^{\text{Fake}}$  in the MC sample can be defined as the vectorial difference of reconstructed  $\cancel{E}_T$  and  $\cancel{E}_T^{\text{True}}$ , as follows:

$$\cancel{E}_T^{\text{Fake}} = \sqrt{\cancel{E}_x^{\text{Fake}2} + \cancel{E}_y^{\text{Fake}2}} \quad \text{where} \quad \cancel{E}_{x,y}^{\text{Fake}} = \cancel{E}_{x,y} - \cancel{E}_{x,y}^{\text{True}}. \quad (11)$$

$\cancel{E}_{x,y}$  and  $\cancel{E}_{x,y}^{\text{True}}$  are the  $x$  and  $y$  components of the final reconstructed  $\cancel{E}_T$  and of the  $\cancel{E}_T^{\text{True}}$  defined in Section 3.

The contribution to the total  $\cancel{E}_T^{\text{Fake}}$  from muon mis-measurements can be defined by

$$\cancel{E}_{x,y}^{\text{FakeMu}} = \cancel{E}_{x,y}^{\text{Mu}} - \cancel{E}_{x,y}^{\text{TrueMu}}, \quad (12)$$

where  $\cancel{E}_{x,y}^{\text{Mu}}$  and  $\cancel{E}_{x,y}^{\text{TrueMu}}$  are calculated by summing the reconstructed and true  $x$  and  $y$  components from muons in the event.

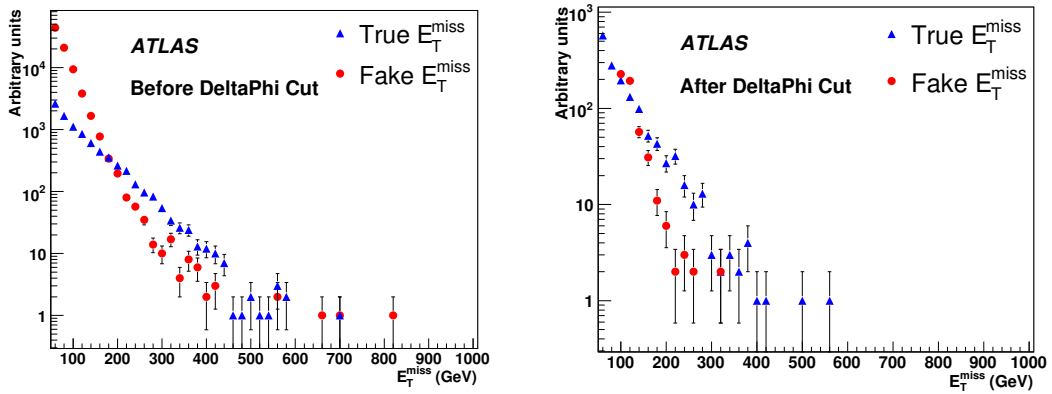

Figure 10: The rates of  $\cancel{E}_T^{\text{Fake}}$  and  $\cancel{E}_T^{\text{True}}$  in the QCD sample with  $560 < p_T < 1120$  GeV: (left) overall rates, (right) requiring a  $\Delta\phi$  separation between  $\cancel{E}_T$  and the leading high- $p_T$  jet in the event. The  $\cancel{E}_T^{\text{Fake}}$  rates can be strongly reduced. It should be noted though that such cuts are very analysis dependent.

Table 1: Number of events with  $\cancel{E}_T^{\text{Fake}}$  above various thresholds from muon (top) and calorimeter (bottom) mis-measurements. The J6 (QCD jets in  $560 < p_T < 1120$  GeV range), SU3,  $t\bar{t}$ , and  $Z \rightarrow \mu\mu$  samples are normalized to the same number of events (25k).

	$\cancel{E}_T^{\text{Fake}} > 60$ GeV	$> 90$ GeV	$> 120$ GeV	$> 150$ GeV
$\cancel{E}_T^{\text{Fake}}$ from Muon				
J6	61	33	20	13
SU3	195	109	57	42
$t\bar{t}$	147	64	33	20
$Z \rightarrow \mu\mu$	436	94	37	20
$\cancel{E}_T^{\text{Fake}}$ from Calorimeter				
J6	4273	1249	351	110
SU3	1005	176	56	53
$t\bar{t}$	104	15	4	2

Figure 11 (left) shows the scatter plot of the two quantities defined in Equations (11) and (12) for the QCD sample with  $560 < p_T < 1120$  GeV. In order to separate the  $\cancel{E}_T^{\text{Fake}}$  from muons with respect to the calorimeter related  $\cancel{E}_T^{\text{Fake}}$  the following cuts can be used: (a)  $\cancel{E}_T^{\text{FakeMuon}} > \cancel{E}_T^{\text{Fake}}/2$  which selects events with fake  $\cancel{E}_T$  coming predominantly from muon mis-measurements, and (b)  $\cancel{E}_T^{\text{FakeMuon}} < \cancel{E}_T^{\text{Fake}}/2$  which selects events with fake  $\cancel{E}_T$  coming predominantly from other sources like jet mis-measurements in the calorimeter. Figure 11 also shows how these cuts separate events with  $\cancel{E}_T^{\text{Fake}}$  from muons and from calorimeter induced effects.

Table 1 shows the number of events above various  $\cancel{E}_T^{\text{Fake}}$  thresholds for physics samples (QCD jets in the range  $560 < p_T < 1120$  GeV, SU3,  $t\bar{t}$  and  $Z \rightarrow \mu\mu$ ) that are predominantly from muons (top rows) or from the calorimeter (bottom rows). It can be seen that the relative rate of  $\cancel{E}_T^{\text{Fake}}$  across samples depends on the muon and calorimeter activities.

In Table 2 different categories of muon mis-measurements and their relative contribution to  $\cancel{E}_T^{\text{Fake}}$  are shown<sup>1</sup>. The first two rows are from missed muons and the last two rows are from fake muons reconstructed from random hits in the muon chambers and with a possible match to soft muon tracks in the inner detector. Table 2 shows a smaller contribution to  $\cancel{E}_T^{\text{Fake}}$  from fake muons compared to missed muons. Therefore the dominant contribution to  $\cancel{E}_T^{\text{Fake}}$  from muons is due to inefficiencies in the muon

<sup>1</sup>Due to technical reasons a small fraction of muon events were not classified in any category.

Figure 11: (left) Total  $\cancel{E}_T^{\text{Fake}}$  as a function of  $\cancel{E}_T^{\text{Fake}}$  from muon mis-measurements. (middle and right) Cuts defined in (b) and (a) (see text) are used to separate calorimeter/jet and muon  $\cancel{E}_T^{\text{Fake}}$  components.

Figure 12: (left) The  $\eta$  distribution of true muons that were missed during reconstruction in a  $Z \rightarrow \mu\mu$  high  $p_T > 100$  GeV sample. (right)  $\cancel{E}_T^{\text{Fake}}$  in  $t\bar{t}$  events in the electron (hatched) and muon channel.

identification.

Figure 12 (left) shows the  $\eta$  distribution of the true muons that were missed at the reconstruction level in the  $Z \rightarrow \mu\mu$  sample with  $p_T > 100$  GeV. There are missed muons around  $\eta = 0$ ,  $|\eta|=1.2$  and at high  $\eta$  ( $|\eta|>2.7$ ) where there is no muon coverage. Muon tracks cannot be reconstructed by the muon system around  $\eta = 0$  ( $-0.05 < \eta < 0.05$ ), because of service holes required for cables and cryogenics passage to the inner detectors and calorimeters. In the region around  $|\eta|=1$  there is a loss of efficiency in muon reconstruction, due to the middle muon station missing for initial data taking. In these studies muons missed due to limitations of muon detector coverage or poor muon reconstruction have not been recovered. In the next software releases algorithms to recover some of these missed muons using energy deposits in the calorimeter and tracks in the inner detector will be used.

Figure 12 (right) shows the  $\cancel{E}_T^{\text{Fake}}$  distributions for events in which the leptonically decaying  $W$  results in an electron and those resulting in a muon, respectively. The latter distribution clearly contains larger non-Gaussian tails. As discussed above, the sources of these large tails are either missed or fake muons.

## 4.2 Fake $\cancel{E}_T$ from the calorimeter

In this section it is assumed that all calorimeter readout channels are functional.  $\cancel{E}_T^{\text{Fake}}$  in the calorimeter is then produced by mis-measurements of hadronic jets, taus, electrons or photons.

The calorimeter has cracks and gaps in the transition regions, which are also used for service outlets. These regions have poorer resolution and are expected to have larger contributions to  $\cancel{E}_T^{\text{Fake}}$  compared to the rest of the calorimeter. There are two gap regions defined in the following  $\eta$  ranges: ( $1.3 < |\eta| < 1.6$ ) and ( $3.1 < |\eta| < 3.3$ ). Figure 13 shows the  $\eta$  distribution of the worst and the second worst measured jet (defined w.r.t. the closest true jet and their energy difference) in the calorimeter for the

Table 2: The sources of mis-measured muons that contribute to  $\cancel{E}_T^{\text{Fake}} > 60$  GeV. The columns are normalized to the same number of events (25k).

Sources	SU3	J6	$t\bar{t}$	$Z \rightarrow \mu\mu$
MC muon not reconstructed	121	17	42	332
Reconstructed muon failed quality cut	30	18	40	18
Muon reconstructed with badly measured $p_T$	29	3	28	28
Reco muon not close to MC muon (“fake muon”)	11	23	0	25

QCD sample generated with  $560 < p_T < 1120$  GeV. It shows that a large number of the worst measured jets have  $\eta$  pointing to  $|\eta|$  in 1.3-1.6. The  $\eta$  distribution of the second worst measured jet is more flat and peaks around  $|\eta|$  in 0.6-0.9, the transition region of the barrel tile calorimeter to the extended barrel tile calorimeter.

The above correlation of worst measured jets and their  $\eta$  suggests a large correlation between the jet  $\eta$  and  $\cancel{E}_T^{\text{Fake}}$ . However, the  $\cancel{E}_T^{\text{Fake}}$  distribution from full simulation samples suggests otherwise. Figure 14 shows the  $\cancel{E}_T^{\text{Fake}}$  distribution in the QCD samples generated with  $560 < p_T < 1120$  GeV and  $140 < p_T < 280$  GeV, when a jet points to the crack/gap region or not. The slope of the distributions suggests no significant correlation between jets pointing to cracks and  $\cancel{E}_T^{\text{Fake}}$ .

This apparent contradiction between Fig. 13 and Fig. 14 can be understood as follows: even though the worst measured jet contributes strongly to the  $\cancel{E}_T^{\text{Fake}}$ , it is not the only source of  $\cancel{E}_T^{\text{Fake}}$  in the event. The worst measured jet contributes on average about 60% and the second worst measured jet contributes about 20% to  $\cancel{E}_T^{\text{Fake}}$ . But not all worst measured jets are along the crack region and each event has many jets. In lower  $\cancel{E}_T^{\text{Fake}}$  regions there is a stronger correlation between  $\cancel{E}_T^{\text{Fake}}$  and jets pointing to cracks. For higher  $\cancel{E}_T^{\text{Fake}}$  ( $> 50$  GeV considered here) there is more than one source contributing to  $\cancel{E}_T^{\text{Fake}}$  and the correlation of jets pointing to cracks is smeared out as can be seen in Fig. 14.

### 4.3 Fake $\cancel{E}_T$ from calorimeter leakage

Jet leakage from the calorimeters or fluctuations in large jet energy deposits in non-instrumented regions such as the cryostat between the liquid argon and tile calorimeters can also be a source of  $\cancel{E}_T^{\text{Fake}}$ . The method used to detect events with potential jet leakage is to look for large energy deposits in the following regions: the outermost layers of the TileCal and the HEC, the outermost LAr barrel layer and the innermost TileCal barrel layer, and in the TileCal gap and crack scintillators.

The following shows an example of selection cuts applied on different variables of the three leading  $p_T$  jets with  $p_T > 100$  GeV:  $E_{\text{Tile2}}/E_{\text{Total}} > 0.05$ ,  $E_{\text{Tile10}}/E_{\text{Total}} > 0.7$ ,  $E_{\text{Cryo}}/E_{\text{Total}} > 0.2$ ,  $E_{\text{Gap}}/E_{\text{Total}} > 0.2$  and  $E_{\text{HEC3}}/E_{\text{Total}} > 0.5$ , where  $E_{\text{Total}}$  is the total jet energy,  $E_{\text{Tile2}}$  is the jet energy in the outermost tile layer,  $E_{\text{Tile10}}$  is the jet energy in the first two innermost tile layer,  $E_{\text{Cryo}}$  is the energy lost by the jet in the cryostat,  $E_{\text{Gap}}$  is the jet energy in the gap scintillators and  $E_{\text{HEC3}}$  is the jet energy in the outermost layer of the HEC calorimeters. If any of these cuts is satisfied the event is rejected.

Furthermore, as the tracks found in the inner detector are not affected by the reconstruction, com-

Figure 13: The  $\eta$  distribution of the worst (left) and second-worst measured jet (right) in the calorimeter in QCD events generated with  $560 < p_T < 1120$  GeV.

Figure 14: The  $\cancel{E}_T^{\text{Fake}}$  rate for QCD sample in  $560 < p_T < 1120$  GeV range (left) and QCD sample in  $140 < p_T < 280$  GeV (right) due to calorimeter mis-measurements.

Figure 15: Fraction of events remaining after the cuts discussed in the text as a function of  $\cancel{E}_T$  (left) and  $\cancel{E}_T^{\text{Fake}}$  (right) for the QCD sample generated with  $560 < p_T < 1120$  GeV.

plementary information on events with fake  $\cancel{E}_T$  can be obtained using  $\cancel{E}_{T\text{trk}}$  from tracks which is the  $\cancel{E}_T$  computed only from tracks. A cut on  $(\cancel{E}_{T\text{trk}} - \cancel{E}_T > 50 \text{ GeV})$  was chosen for the optimization of the signal significance.

Figure 15 shows the percentage of events remaining after the cuts described above are applied on QCD sample generated with  $560 < p_T < 1120$  GeV. The right plot shows suppression of large fake  $\cancel{E}_T$  generated due to high  $p_T$  jet leakage. Larger fake  $\cancel{E}_T$  are suppressed more strongly. It can also be noticed from the left plot that these cuts, although removing a large fraction of the events dominated by fake  $\cancel{E}_T$ , are not sensitive to the overall  $\cancel{E}_T$  in the event and the fraction of remaining events is fairly constant over  $\cancel{E}_T$ . The method is of course analysis dependent and the values of the cuts should be chosen taking into account the signal efficiency.

#### 4.4 Fake $\cancel{E}_T$ from instrumental effects

In real data there will be sources of  $\cancel{E}_T^{\text{Fake}}$  which are not fully modeled in Monte Carlo simulations including, for example, mis-modeling of material distributions and instrumental failures. As the details of these  $\cancel{E}_T^{\text{Fake}}$  sources will be understood with time, increasingly refined analyses will be developed to minimize their associated backgrounds while maintaining high selection efficiencies for signals with genuine missing energy. While it is difficult to predict in advance the exact sources of mis-modeled  $\cancel{E}_T^{\text{Fake}}$ , it is nevertheless possible to insert problems into the Monte Carlo that match potential hardware

Figure 16: Cell-killed QCD sample in  $560 < p_T < 1120$  GeV range: the  $\cancel{E}_T$  distribution (left) and the EM fraction (right). The histograms are normalized by area.

failures. These include trips in high-voltage channels or readout power supplies of the calorimeter or noise in calorimeter channels or regions. The initial studies presented here are based on samples with simulated dead regions of the calorimeter, so called ‘cell-killed’ samples: one dead front-end readout crate in the LAr electromagnetic barrel calorimeter and one dead front-end readout crate affecting LAr electromagnetic and endcap calorimeters. Based on the location of these hardware failures the calorimeter is divided into three regions of  $\phi(\cancel{E}_T)$ : ‘Region 1’ with EM endcap and hadronic endcap problems, ‘Region 2’ with EM barrel problems, and ‘Region 3’ with no problems.

These samples were used as references for the development of cuts that reduce the  $\cancel{E}_T^{\text{Fake}}$  background while maintaining high efficiencies for potential signal events. Since we will not know the precise location and nature of hardware problems in advance, the cuts are not tuned assuming that knowledge. In real data it will be possible to significantly improve the analysis performance by cutting harder when energy deposits are expected near regions with detector hardware problems, but that is not exploited in the studies so far. Future work will also include using these samples to develop data-driven techniques for predicting the  $\cancel{E}_T^{\text{Fake}}$  tails.

The high- $p_T$  ( $560 < p_T < 1120$  GeV)  $\gamma$ +jet MC sample was processed with the cell-killed configuration described above. Events with at least one back-to-back photon-jet pair were selected. Figure 16 shows the  $\cancel{E}_T^{\text{Fake}}$  generated in the three regions. Large  $\cancel{E}_T$  tails are seen in Regions 1 and 2 where the holes in calorimeter coverage have been introduced. The effect of dead regions can also be seen in Table 3. The columns show the number of events above various  $\cancel{E}_T^{\text{Fake}}$  thresholds. The first two rows show the number of events with no dead-regions and with the above dead-regions simulated. A very large increase in high  $\cancel{E}_T^{\text{Fake}}$  is seen.

Several methods have been developed to suppress events with large fake  $\cancel{E}_T$ :

- EM Fraction Method:** The EM fraction method starts by finding the closest calorimeter jet to the  $\cancel{E}_T$  direction vector using  $\Delta\phi$  between the calorimeter jet and  $\cancel{E}_T$ . Figure 16 (right) shows the EM fraction distributions. Small EM fractions are due to a dead LAr EM calorimeter crates, whereas large EM fractions are due to a dead hadron calorimeter crates. The fake  $\cancel{E}_T$  generated this way can be suppressed by requiring the EM fraction to be in a window from 0.40 to 0.96. The effect of this cut can be seen in the third row of Table 3 when compared to the increase in  $\cancel{E}_T^{\text{Fake}}$  due to dead-regions in row 2. A rejection of 1.5 to 4 is seen from low to high  $\cancel{E}_T^{\text{Fake}}$  bins. The selection efficiency can be defined as the ratio of the number of events after and before the cuts when events fall in Region 3 (Region 3 has small  $\cancel{E}_T^{\text{Fake}}$ ). For the EM fraction method the selection efficiency is  $\sim 90\%$ .
- Track-Jet Methods:** jets were reconstructed from inner detector tracks using the cone algorithm

Table 3: The number of events from  $\gamma$ +jet samples above various  $\cancel{E}_T^{\text{Fake}}$  thresholds with no dead-regions, with simulated dead-regions and after applying various suppression techniques (see text). All numbers are normalized to 25k events sample size.

$\cancel{E}_T^{\text{Fake}}$ (GeV)	> 100	> 200	> 300	> 400	> 500
No dead regions	555	18	3	1	0
w/ dead regions	2482	1308	864	501	199
w/ EM fraction method	1651	572	287	122	50
w/ track-jet cluster method	1786	664	313	129	49
w/ comb. track-jet cluster method	1402	392	150	46	14

with  $\Delta R = 0.4$ . A fiducial volume cut of  $|\eta| < 2.5$  is applied due to the tracking coverage. Since track-jets use the inner tracking detectors, they provide a complementary identification of events with fake  $\cancel{E}_T$ . A number of different methods of exploiting the track-jets were studied. An effective method which only uses information present in the Analysis Object Data (AOD) is to sum the  $E_T$  of calorimeter topological clusters within the track-jet  $\eta$ - $\phi$  cone. The distributions of the  $E_T$  ratio of the track-jet to the clusters has tails due to the dead calorimeter regions. A cut is applied requiring  $E_T$  ratios larger than 1.0; the value was chosen to maintain a significant efficiency for signal samples, and could be substantially tightened for different physics analyses. The fourth row of Table 3 shows the effectiveness of this cut. Rejections from  $\eta = 1.4$  to  $\eta = 4$  are achieved from the low to high  $\cancel{E}_T^{\text{Fake}}$  regions, with efficiencies of  $\sim 93\%$ .

Since the EM fraction method and track-jet methods are largely uncorrelated, they can be combined for better suppression of large  $\cancel{E}_T^{\text{Fake}}$ . The last row in Table 3 shows the performance of the combined track-jet method. The selection efficiency for this combined method is  $\sim 84\%$ . It must be emphasized that the results presented in this table represent the worst case since the cuts do not use the detailed information about detector problems that will be known from the detector control and data quality systems. In a final analysis, much harder cuts can be applied in regions with known detector problems. Of course, this will reduce the acceptance of the detector.

## 5 The $\cancel{E}_T$ Trigger algorithm performance

This section briefly describes the  $\cancel{E}_T$  algorithms applied at the first level trigger (L1) and the higher-level trigger (HLT). The HLT is a combination of second level trigger (L2), and a third level trigger (or event filter, EF). The L1 algorithm is based on hardware, while the HLT algorithms are software based.

### 5.1 The $\cancel{E}_T$ at L1

The  $\cancel{E}_T$  L1 calorimeter triggers cover the region  $|\eta| < 4.9$ , which is the limit of the forward calorimeters [11]. The basic units of L1  $\cancel{E}_T$  and  $\Sigma\cancel{E}_T$  trigger algorithms are ‘jet elements’, formed by summing over trigger towers within windows of  $0.2 \times 0.2$  in the  $(\eta, \phi)$  plane.<sup>2</sup> They are processed by the Jet/Energy modules, which compute  $E_x$ ,  $E_y$  and  $\Sigma\cancel{E}_T$  of each jet element. Four thresholds are available on  $\Sigma\cancel{E}_T$  with values up to 2044 counts in steps of 4 (usually, 1 count = 1 GeV). Eight  $\cancel{E}_T$  thresholds are available, up to a maximum threshold value of 504 counts. If an overflow occurs at any point in the  $\cancel{E}_T$  or  $\Sigma\cancel{E}_T$  algorithm, all of the corresponding thresholds are set as passed.

<sup>2</sup>For  $2.4 < |\eta| < 3.2$  the granularity is either  $\Delta\eta = 0.2$  or  $\Delta\eta = 0.3$ , while FCAL jet elements extend from  $|\eta| = 3.2$  to  $|\eta| = 4.9$ . The  $\phi$  granularity of the FCAL jet elements is  $\Delta\phi = 0.4$ .

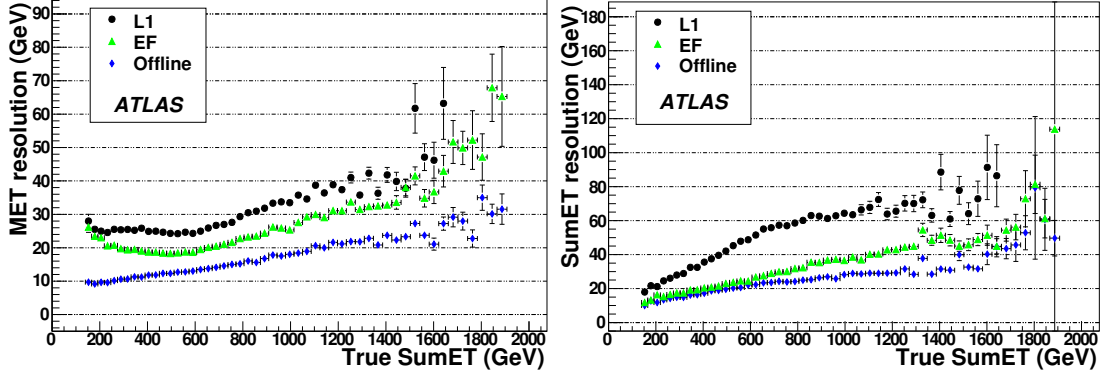

Figure 17: L1, EF and offline results for the  $\cancel{E}_T$  (left) and the  $\Sigma\cancel{E}_T$  (right) resolution as a function of the true  $\Sigma\cancel{E}_T$  in  $t\bar{t}$  events.

For each event, the L1  $E_x$ ,  $E_y$  and  $\Sigma\cancel{E}_T$  are saved into one object of the RecEnergyRoI class, including overflow flags. If any threshold is passed, the JetEnergy RoI is also produced containing the bit pattern of the thresholds passed.

## 5.2 $\cancel{E}_T$ at HLT

The offline algorithm described in Section 2.2 is too resource intensive (both in terms of memory access and calculations to be done) to be applied in the HLT. The following algorithms are ready for the first data taking<sup>3</sup>:

- The L2 algorithm uses the calorimeter information in RecEnergyRoI provided by the L1 trigger and applies a correction for L2 muon objects.
- The default EF algorithm sums all calorimeter cells and applies a 0-th order hadronic calibration by multiplying  $\cancel{E}_T$  and  $\Sigma\cancel{E}_T$  by a constant related to the hadronic/electromagnetic calorimeter energy fraction in a jet. Finally, the EF takes the muon contribution into account.

Both at L2 and EF, the muon correction may be switched off independently for each trigger chain.

The decision taken both at L2 and EF is carried out by the same software package. This hypothesis testing code can be configured to accept events based on  $\cancel{E}_T$ , on  $\Sigma\cancel{E}_T$  or on both.

## 5.3 The $\cancel{E}_T$ and $\Sigma\cancel{E}_T$ resolution at trigger level

Figure 17 shows the  $\cancel{E}_T$  and  $\Sigma\cancel{E}_T$  resolution for the L1, EF and offline algorithms as a function of the true  $\Sigma\cancel{E}_T$  for  $t\bar{t}$  events. Since the L2 algorithm takes the L1 result and applies relatively small corrections, the present L2 resolution is practically the same as for L1 and therefore not shown. At true  $\Sigma\cancel{E}_T$  values of 500 GeV, the L1 resolution on the  $\cancel{E}_T$  measurement is about 25 GeV which is a factor of two larger than what is achieved offline. The EF resolution, for both  $\cancel{E}_T$  and  $\Sigma\cancel{E}_T$  lies in between the values for L1 and offline resolution.

<sup>3</sup>At present, work is in progress to detect fake sources due to detector effects like uninstrumented regions or hardware failure, or physics environment, e.g. beam-halo or cosmic ray tracks.

## 6 $\cancel{E}_T$ in early data

Validation of the  $\cancel{E}_T$  reconstruction described in the previous sections will be performed with the first LHC data accumulated by ATLAS. For the very first data, the two main issues are controlling instrumental failures and calibration of energy deposits in the calorimeter. At this stage, the overwhelming number of minimum bias events will be used to monitor and diagnose  $\cancel{E}_T$  reconstruction problems.

The development of algorithms for data quality checks is being actively pursued to minimize the impact of such failures and will be optimized when the first data is collected. The ‘standard’  $\cancel{E}_T$  calculation, using the calorimeter cells at the electromagnetic scale above a threshold will be always provided as a reference. The  $\cancel{E}_T$  calibration strategy follows the steps described in Section 3. First, a simple global calibration for all the TopoCells will be used. As shown in Section 3 this already gives a good linearity behavior. As the event reconstruction becomes more robust, the event objects (e.g. electrons, jets, taus) will be used to obtain the best  $\cancel{E}_T$  resolution.

Figure 3 already shows how the  $\cancel{E}_T$  linearity improves from a simple to a more refined  $\cancel{E}_T$  calculation. Figure 18 shows how the  $\cancel{E}_T$  resolution improves arriving in steps to the final refined calibration.

Figure 18: The  $\cancel{E}_T$  resolution as a function of true  $\Sigma\cancel{E}_T$  from the uncalibrated to the refined calibration as indicated for the following channels:  $W \rightarrow \mu\nu$  corresponding to true  $\Sigma\cancel{E}_T = 130$  GeV,  $W \rightarrow e\nu$  to 165 GeV,  $Z \rightarrow \tau\tau$  to 210 GeV,  $t\bar{t}$  to 470 GeV,  $A/H \rightarrow \tau\tau$  to 843 GeV, J5 to 800 GeV and SUSY to 906 GeV.

Once data of the order of  $100 \text{ pb}^{-1}$  are collected, the  $\cancel{E}_T$  validation focuses on physics channels with relatively large  $\cancel{E}_T$  and/or  $\Sigma\cancel{E}_T$ . This section briefly describes a few studies that will be performed with the first data.

The  $Z \rightarrow \tau\tau$  process, using the  $Z$  mass constraint, can be used to determine the  $\cancel{E}_T$  scale in-situ to about 8% accuracy. The  $Z \rightarrow \ell\ell$  process with decays to electrons and muons does not have any significant  $\cancel{E}_T^{\text{True}}$  from neutrinos. The small background to these events will help to test possible  $\cancel{E}_T$  biases, expected to be zero, and the resolution in a straightforward manner. The copiously produced  $W \rightarrow e\nu$  and  $W \rightarrow \mu\nu$  events can be used to test the reconstructed  $\cancel{E}_T$  in the (20 – 150) GeV range. Two methods to use these events are discussed. Semileptonic  $t\bar{t}$  events also have genuine  $\cancel{E}_T$  and allow a test of the  $\cancel{E}_T$  reconstruction in an environment relevant for many physics analyses and searches, notably SUSY.

Figure 19: (left) The  $\cancel{E}_{x,y}$  resolution for different  $\Sigma \cancel{E}_T$  regions in minimum bias events. (right) The  $\cancel{E}_T$  resolution in QCD dijet events (J0-J3: see Section 3.1 for definition) is shown together with the  $\cancel{E}_T$  resolution from minimum bias events (black filled circles) as a function of  $\Sigma \cancel{E}_T$ . An integrated luminosity of the order of  $10^{-5} \text{ pb}^{-1}$  is used.

### 6.1 Minimum bias events

Minimum bias interactions at the LHC are dominated by soft collisions of the two interacting protons. These events are useful for  $\cancel{E}_T$  commissioning, especially in the early stages of the experiment, due to their large statistics and their comparatively simple event selection. The main background in minimum bias events will originate from empty, beam gas and beam halo events, especially at the beginning of the experiment. Minimum bias events will be used to verify the  $\cancel{E}_T$  reconstruction procedure and estimate the  $\cancel{E}_T$  resolution for low  $\Sigma \cancel{E}_T$  events.

In the early stages of the experiment, minimum bias events will be selected by three types of triggers: randomly selected bunch crossings (MB1), randomly selected bunch crossings together with a SemiConductor Tracker space point trigger (MB2), and minimum bias trigger scintillator (MBTS2). The details of the triggers are described in Ref. [12].

For the study of  $\cancel{E}_T$  in minimum bias events, high signal efficiency and background rejection are required. The relative fraction of non-diffractive, single diffractive and double diffractive events in the sample is not a concern. The selection criteria require at least 20 semiconductor tracker space points to reject empty events and at least one good reconstructed track to reject beam gas and halo events.

A Monte Carlo study predicts an overall trigger efficiency of 96.8%. The offline track selection efficiency (with respect to events passing the trigger) is 80.6% for a total selection efficiency of 78.0%.

The  $\cancel{E}_T$  in minimum bias events is fairly low with a mean of 4.3 GeV. Fake  $\cancel{E}_T$  is caused mainly by calorimeter energy resolution (82%) and acceptance (18%). The true  $\cancel{E}_T$  is 0.06 GeV on average, originating from  $K/\pi$  decays-in-flight and from the decay of charm and bottom particles. The true  $\Sigma \cancel{E}_T$  in non-diffractive minimum bias events is typically 64 GeV, while the reconstructed  $\Sigma \cancel{E}_T$  is on average 49 GeV due to the loss of low energy particles which do not reach the calorimeters. Since minimum bias events are dominated by soft (low- $p_T$ ) interactions, jets are reconstructed with a rate depending on  $\Sigma \cancel{E}_T$ . When minimum bias events with  $\Sigma \cancel{E}_T$  of 50 GeV are compared to events with  $\Sigma \cancel{E}_T$  of 250 GeV, the average number of reconstructed jets with  $p_T > 7$  GeV increases from below one to about nine with an average jet energy of 10 and 13 GeV, respectively.

The  $\cancel{E}_T$  resolution in minimum bias events is expected to scale as  $\sqrt{\Sigma E_T}$  because the stochastic term

of the calorimeter resolution is dominant in  $\Sigma\cancel{E}_T$  regions as shown in the left plot of Fig. 19. These distributions are well fitted by Gaussian functions with offsets of zero (in the case of no  $\phi$  asymmetry) and resolutions which scale with  $\Sigma\cancel{E}_T$ .

The right plot of Fig. 19 shows the comparison of the  $\cancel{E}_T$  resolution evaluated in this study with the higher  $\Sigma\cancel{E}_T$  region ( $\Sigma\cancel{E}_T > 300$  GeV). The  $\cancel{E}_T$  resolution in QCD dijet events matches well the resolution obtained from minimum bias events.

## 6.2 Determining the $\cancel{E}_T$ scale using $Z \rightarrow \tau\tau$ events

At the beginning of ATLAS operation, about 70k events of type  $Z \rightarrow \tau\tau$  with one leptonic and one hadronic  $\tau$ -decay will be produced in  $100 \text{ pb}^{-1}$  of data. Such events can be selected with a lepton trigger. The  $Z \rightarrow \tau\tau \rightarrow \ell h$  are produced with genuine  $\cancel{E}_T$  of typically 20 GeV and  $\Sigma\cancel{E}_T$  of the order of 200 GeV. In these events the peak position of the  $\tau\tau$  invariant mass distribution is sensitive to  $\cancel{E}_T$  and can be very useful in determining the  $\cancel{E}_T$  scale [10].

The main backgrounds come from  $W \rightarrow \ell\nu$ +jets events, where one jet fakes a  $\tau$  decay, and from QCD events (mainly  $b\bar{b}$ ). The  $t\bar{t}$  background has a much lower cross-section; the  $Z \rightarrow ee$  and  $Z \rightarrow \mu\mu$  backgrounds are also small and the  $WW$  background is negligible. Events with the final state lepton and  $\tau$ -jet of the same-sign are not expected to come from  $Z \rightarrow \tau\tau$  events which have opposite-sign. The backgrounds (apart from the  $t\bar{t}$  background, which is anyway low) contribute in the same way to the opposite-sign and the same-sign samples. Hence, the effect of backgrounds will be minimized using same-sign events, subtracted from the opposite-sign events.

For each reconstructed event, the leading and isolated lepton (electron or muon) with  $p_T^\ell > 15$  GeV and  $|\eta^\ell| < 2.5$  is chosen and a set of basic cuts is applied:  $\cancel{E}_T > 20$  GeV (rejects QCD events), the transverse mass calculated from  $\cancel{E}_T$  and the lepton  $< 50$  GeV (suppresses events from semileptonic  $W$  decays), and  $\Sigma\cancel{E}_T < 400$  GeV (suppresses QCD). In addition it is required to have no tagged  $b$  jets (suppresses  $t\bar{t}$  and  $b\bar{b}$  events). Then at least one identified  $\tau$ -jet with  $p_T^{\tau\text{-jet}} > 15$  GeV,  $|\eta^{\tau\text{-jet}}| < 2.5$ , and a track multiplicity of one or three is required. The  $\Delta\phi$  between the isolated lepton and the  $\tau$ -jet is required to be in the range between 1 – 2.8, which reduces badly reconstructed events and further rejects backgrounds.

With  $100 \text{ pb}^{-1}$  of data, 210 signal events (opposite-sign) are expected in the invariant mass range  $66 \text{ GeV} < m_{\tau\tau} < 116 \text{ GeV}$ . A total background of 16 events is expected. Figure 20 (left) shows the reconstructed mass peak for  $Z \rightarrow \tau\tau$  events as well as the small total backgrounds after analysis cuts for opposite-sign and same-sign events.

Figure 20 (right) shows a very good sensitivity of the measured  $Z$  mass reconstructed from  $\tau$ -pairs to the absolute  $\cancel{E}_T$  scale. With an integrated luminosity of  $100 \text{ pb}^{-1}$ , the  $Z$  mass can be reconstructed with an uncertainty of  $\pm 0.8$  GeV. Taking into account the statistical uncertainty only, the  $\cancel{E}_T$  scale could be determined with a precision of  $\sim 3\%$ . But systematic effects, such as the subtraction of same-sign events and the stability of the fit will affect the measurement of the reconstructed mass peak. Therefore, assuming a resolution of  $\pm 3\sigma$  on the reconstructed  $Z$  mass, the  $\cancel{E}_T$  scale can be determined to about  $\pm 8\%$ .

## 6.3 $Z \rightarrow \ell\ell$ events

This analysis uses inclusive  $Z \rightarrow ee$  and  $Z \rightarrow \mu\mu$  samples to investigate the scale and resolution of the  $\cancel{E}_T$  reconstruction in the first data. In these samples the transverse momentum of the two leptons from the  $Z$  boson decay are balanced by the hadronic recoil and  $\Sigma\cancel{E}_T$  reaches values up to a few hundred GeV.

Events are selected by requiring two well reconstructed, identified and isolated leptons with  $p_T > 25$  GeV. They have to have equal or opposite charge and a reconstructed mass,  $m_{\ell\ell}$ , in the interval 70 – 100 GeV. In a sample of  $250 \text{ pb}^{-1}$  of data, about 400k events are expected.

Figure 20: (left) Reconstructed invariant mass of the pair of  $\tau$  leptons for  $Z \rightarrow \tau\tau$  decays and all backgrounds: opposite-sign background (dashed) and same-sign background (dotted). (right) Reconstructed invariant mass of the pair of  $\tau$  leptons for  $Z \rightarrow \tau\tau$  decays as a function of the  $\cancel{E}_T$  scale. The horizontal lines correspond to  $\pm 1\sigma$  and to  $\pm 3\sigma$  w.r.t. the  $Z$  peak position. The analysis is based on an integrated luminosity of  $100 \text{ pb}^{-1}$  of data.

Backgrounds from  $Z \rightarrow \tau\tau$  and  $W \rightarrow \ell\nu$  events are negligible. The background from QCD events in which two leptons are falsely identified is expected to be small but has to be carefully evaluated when data are available. In the present study, these backgrounds are not considered as they are expected to have negligible impact.

In Section 3, projections of  $\cancel{E}_T$ , called  $\cancel{E}_L$  and  $\cancel{E}_P$ , were introduced. This analysis aims at optimizing the principle of using projections by resolving the missing transverse momentum along the so called 'longitudinal axis' which is defined by the combined direction of flight of the two leptons. The perpendicular axis is also defined in the transverse plane which is orthogonal to the longitudinal axis. The axes as reconstructed from the measured angles of the leptons and their measured energies are thus not used at this point, which would fully exploit the good angular resolution of the ATLAS detector. In general, the longitudinal axis points in the direction of flight of the  $Z$  boson and away from the hadronic recoil.

Figure 21 (left) shows, for  $Z \rightarrow ee$  events, the average  $\cancel{E}_T$  resolved along both axes as a function of the transverse momentum of the lepton system resolved along the longitudinal axis.

The results for the longitudinal axis exhibit a negative offset of up to  $\sim 4 \text{ GeV}$  at high values of  $p_T$  of the lepton system, while the results for the perpendicular axis are consistent with zero. For  $Z \rightarrow \mu\mu$  events similar results are obtained. It has been verified that this offset is not caused by real neutrinos in the event. If the event topology is considered, it is clear that this is suggesting that the magnitude of the hadronic recoil  $p_T$  is underestimated. The resolution of the  $\cancel{E}_T$  projection on both axes as a function of the total scalar sum of the activity in the hadronic calorimeter,  $\sum E_{T,\text{cluster}}$ , is shown in Figure 21(right) for  $Z \rightarrow ee$  events. The fitted curve is of the form  $\sigma(\cancel{E}_T) = P_0 \sqrt{\sum E_{T,\text{cluster}}} + P_1$  and illustrates the stochastic behavior of the calorimetric energy measurement.

These results on  $Z \rightarrow ee$  and  $Z \rightarrow \mu\mu$  events demonstrate that potential problems of the  $\cancel{E}_T$  reconstruction can be located with high accuracy using the first data.

#### 6.4 $W \rightarrow \ell\nu$ events

Events with  $W \rightarrow e\nu$  and  $W \rightarrow \mu\nu$  will be copiously produced at the LHC. Tens of thousands of events with an excellent signal-to-background ratio can be collected per  $\text{pb}^{-1}$ . With these events, a good understanding of the  $\cancel{E}_T$  reconstruction can be achieved up to  $\cancel{E}_T$  values of few hundred GeV. The average  $\sum \cancel{E}_T$  is of the order of 150 GeV.

In order to isolate  $W \rightarrow \ell\nu$  events, two basic selection cuts are required: existence of one high  $p_T$

Figure 21: For  $Z \rightarrow ee$  events: (left)  $\cancel{E}_T$  projected onto the longitudinal and perpendicular axes as explained in the text as function of the  $p_T$  of the lepton system resolved along the longitudinal axis. (right) The width  $\sigma(\cancel{E}_T)$  as a function of  $\Sigma E_{T,\text{cluster}}$ . Both plots use a sample corresponding to  $250 \text{ pb}^{-1}$  of data.

charged lepton with  $|\eta| < 2.5$  and  $\cancel{E}_T > 20 \text{ GeV}$ . Possible backgrounds are from  $t\bar{t}$  production,  $W \rightarrow \tau\nu$ ,  $Z \rightarrow \ell\ell$ , and QCD events.

Two methods have been investigated to check the  $\cancel{E}_T$  reconstruction using these events. The first is based on the fact that the average  $p_T$  of the charged lepton and the neutrino are the same, so the ratio  $R = p_{T,\nu}/p_{T,\ell}$  has been studied. This variable should be  $\sim 1$ , but its distribution is distorted by the kinematic and acceptance requirements on the charged leptons. The method and related systematics have been checked with the fast ATLAS simulation. It is expected to be sensitive to values of  $\cancel{E}_T$  up to 60 GeV even with  $1 \text{ pb}^{-1}$  of data. Full simulation studies are in progress.

The second method, based on the shape of the reconstructed transverse mass of the  $W$  boson, is sensitive to both the  $\cancel{E}_T$  resolution and the scale. The transverse mass,  $m_T^W$ , is reconstructed under the hypothesis that  $\cancel{E}_T$  is completely due to  $p_{T,\nu}^y$ . An example of an  $m_T^W$  distribution is shown in the next section for  $t\bar{t}$  events, which have high values of  $\Sigma \cancel{E}_T$  of typically 500 GeV. The focus in this section however is on a dedicated analysis of the corresponding distribution for Drell-Yan events at lower  $\Sigma \cancel{E}_T$  as statistically required.

The  $m_T^W$  distribution (for Drell-Yan events) is fitted in a binned log-likelihood fit that uses template histograms. To minimize the dependence on the kinematics of the  $W$  boson, e.g. on its transverse momentum, the fit is restricted to values of  $m_T^W$  in the range of 65 to 90 GeV. The template histograms of the  $m_T^W$  distributions are generated by convolving the true transverse mass distribution with the  $\cancel{E}_T$  response:  $\cancel{E}_{x,y} = \alpha p_T^y(x,y) \oplus \text{Gauss}(0, \sigma)$  where parameters  $\alpha$  and  $\sigma$  are the  $\cancel{E}_T$  scale and resolution (in GeV), respectively. Since the  $\cancel{E}_T$  resolution strongly depends on the activity in the calorimeter, the analysis is performed in several  $\Sigma \cancel{E}_T$  intervals.

Figure 22 (left) shows the resolution for  $W \rightarrow \mu\nu$  events. The results of the fit agree well with the expectations using truth information labeled as ‘pseudo-data’. In Fig. 22 (right) the result for the  $\cancel{E}_T$  scale is shown. The scale is measured at the 1% level over a large range of  $\Sigma \cancel{E}_T$ , confirming the excellent performance of this technique. The template fitting performs well in the low  $\Sigma \cancel{E}_T$  region, while a small discrepancy is observed in the high  $\Sigma \cancel{E}_T$  region.

This method described so far is applicable to  $W \rightarrow \mu\nu$  events, whereas in  $W \rightarrow e\nu$  events it has to be modified because the electron is included in the  $\Sigma \cancel{E}_T$  calculation, while the muon is not. This leads to a significant correlation between  $\Sigma \cancel{E}_T$  and the shape of the transverse  $W$  mass distribution when the template is made including the  $\Sigma \cancel{E}_T$  dependence. Similar results for the  $\cancel{E}_T$  scale and resolution are obtained, but systematic uncertainties have not yet been estimated.

Also if the backgrounds, including the QCD background, cannot be efficiently suppressed by the

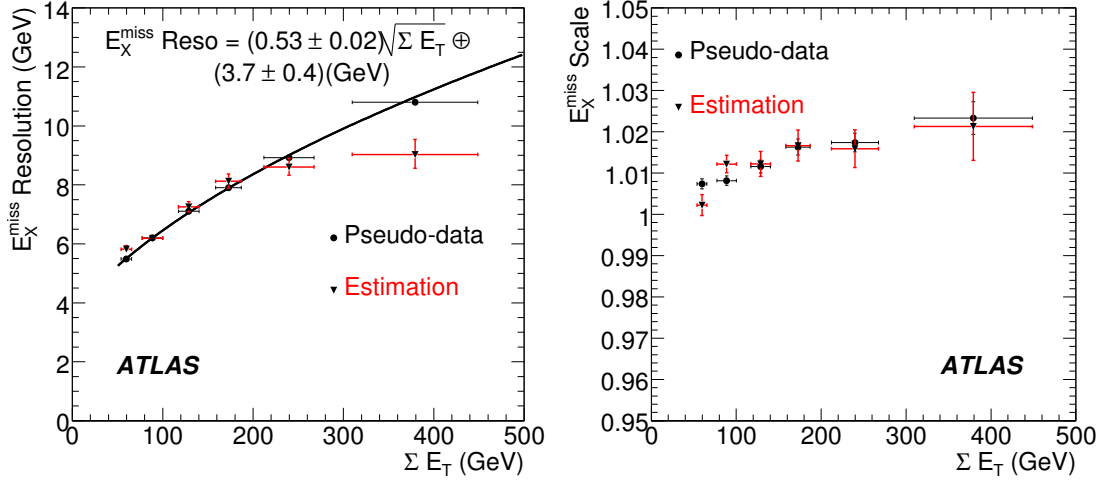

Figure 22: For  $W \rightarrow \mu \nu$  events:  $\cancel{E}_T$  resolution (left) and scale (right) as a function of  $\Sigma \cancel{E}_T$ , using the second method described in the text. The circular dots represent the value calculated from pseudo-data and the triangular markers represent the estimation.

selection cuts, their influence could be non-negligible. Work is in progress on that.

### 6.5 Semileptonic $t\bar{t}$ events

Semileptonic  $t\bar{t}$  events have an interesting multi-jet topology. With genuine  $\cancel{E}_T$  in the range from 20 GeV to 100 GeV and a total transverse energy of typically 500 GeV, they are representative of other physics channels such as SUSY. This section shows that the reconstructed transverse  $W$  mass as well as a kinematic fit that exploits all mass constraints in  $t\bar{t}$  events without requiring  $b$  jet tagging, will be useful to investigate possible problems of the  $\cancel{E}_T$  measurement in early data. Both methods are sensitive to the scale of  $\cancel{E}_T$  to the level of a few percent (statistically) when a sample with an integrated luminosity of  $200 \text{ pb}^{-1}$  is used. These methods are affected differently by jet energy scales and background and can provide complementary information.

About 7k events survive the selection requirements, which are: at least 3 jets with  $p_T \geq 40 \text{ GeV}$ , at least one more jet with  $p_T \geq 20 \text{ GeV}$ ,  $\cancel{E}_T \geq 20 \text{ GeV}$ , and one isolated lepton ( $e$  or  $\mu$ ), with  $p_T \geq 20 \text{ GeV}$ . The requirements strongly suppress the background from QCD events, which is expected to have no effect and is ignored. The QCD background is expected to be  $< 10\%$  in  $t\bar{t}$  events, so, after the requirements for the kinematic fit, this assumption should be safe. The background from  $W$ +jets events is at the level of 20% and is included in this study.

In  $t\bar{t}$  analyses the usual assumption is that the  $\cancel{E}_T$  in an event can be assigned to the neutrino from the leptonically decaying  $W$ . With this assumption, the transverse mass  $m_T^W$  can be reconstructed from the  $\cancel{E}_T$  vector and the transverse momentum of the charged lepton. Figure 23 (left) shows that the shape of the  $m_T^W$  distribution is distinctly different for various ranges of fake  $\cancel{E}_T$ <sup>4</sup>, illustrating the power of these events to locate problems. To demonstrate that the transverse  $W$  mass distribution can be used to check the  $\cancel{E}_T$  scale in early data, two additional event samples with the true  $\cancel{E}_T$  scaled by 0.8 and 1.2, respectively have been produced and reconstructed. The samples are analysed by fitting a Gaussian shape to the core of the peak in the transverse mass distributions. The peak position shifts by -7 and +7 GeV for the sample with scale of 0.8 and 1.2 respectively, both with an statistical uncertainty of 0.5 GeV, indicating a sensitivity

<sup>4</sup>Here fake  $\cancel{E}_T$  is defined as the scalar difference of reconstructed  $\cancel{E}_T$  and true  $\cancel{E}_T$ .

to the  $\cancel{E}_T$  scale at the level of 2%.

Note that backgrounds other than  $W$ +jets events are not considered in this study. Background from SUSY events can have a severe impact on the distribution by shifting the peak and thus mimicking a  $\cancel{E}_T$  scale calibration offset. The existing knowledge of  $t\bar{t}$  events can be combined in a kinematic fit to improve the measured quantities and to investigate the scale of the  $\cancel{E}_T$  measurement. The following mass constraints are available:  $m_W^{\text{had}} = m_W^{\text{lep}} = 80.4$  GeV, where  $m_W^{\text{had}}$  is the reconstructed mass of two light jets of the hadronically decaying  $W$  and  $m_W^{\text{lep}}$  is the reconstructed mass of the lepton and the neutrino of the leptonically decaying  $W$ . The reconstructed mass of the leptonically decaying top quark and that of the hadronically decaying top quark are assumed to be  $m_{\text{top}}^{\text{had}} = m_{\text{top}}^{\text{lep}} = 175$  GeV. The neutrino's transverse momentum is set equal to  $\cancel{E}_T$  and its longitudinal momentum is analytically calculated from the  $m_W^{\text{lep}}$  constraint.

The  $\chi^2$  function of the fit is built using the energy of the four leading jets, with fit parameters to scale the corrected jet energies, a constraint on the product of the fit parameters to the a-priori known or assumed overall jet energy scale and with the implementation of the four mass constraints. All twelve possible permutations of assigning jets to the two top quarks and  $W$  bosons respectively are considered. Finally, only the permutation with the lowest  $\chi^2$  is selected in each event.

It is found that the  $\cancel{E}_T$ , re-calculated after the fit, is not significantly improved. However, using a cut on  $\chi^2$  improves the resolution on  $\cancel{E}_T$ , so it is possible to use the  $\chi^2$  of a kinematic fit to classify  $t\bar{t}$  events with a relatively good  $\cancel{E}_T$  measurement without using  $b$  tagging. In the first data this classification helps to locate possible detector problems.

The kinematic fitting procedure can be utilized to check the  $\cancel{E}_T$  scale in early data. Background events are expected to be incompatible with the constraints used in the fit and thus be reduced by a cut on  $\chi^2$ . Therefore, in contrast to the study using the transverse  $W$  mass as described above, this method suffers significantly less from backgrounds.

After applying the fit to the events and requiring  $\chi^2 < 10$  and in additional  $\cancel{E}_T > 40$  the background from  $W$ +jets event is reduced to the 1% level. A robust estimator of the  $\cancel{E}_T$  scale is the measured transverse momentum difference of the (anti-) top quark mother of the leptonically and hadronically decaying  $W$  respectively:  $\Delta p_T = p_T^{\text{lep}} - p_T^{\text{had}}$  where  $p_T^{\text{lep}}$  is the combined transverse momentum of the measured charged lepton,  $\cancel{E}_T$  and one  $b$  jet, while  $p_T^{\text{had}}$  is the momentum of the jets of the hadronically decaying  $W$  and the other  $b$  jet. Of course, the assignment of the jets to the correct top quark is not guaranteed. Nevertheless, this quantity is remarkably sensitive to the  $\cancel{E}_T$  scale, as can be seen in Fig.

Figure 23: In semileptonic  $t\bar{t}$  events, (left) the reconstructed transverse  $W$  mass in various ranges of fake  $\cancel{E}_T$ , (right) the distribution of the measured momentum difference of the two top quarks,  $\Delta p_T$  for (true)  $\cancel{E}_T$  scales of 0.8, 1.0 and 1.2 as indicated. The analysis is based on an integrated luminosity of  $200 \text{ pb}^{-1}$  of data.

23(right). The mean values of the distributions are  $-16.4 \pm 0.9$  GeV,  $-4.5 \pm 0.8$  GeV, and  $4.5 \pm 0.9$  GeV for scales of 0.8, 1.0, and 1.2, respectively. This implies a sensitivity on the  $\cancel{E}_T$  scale at the level of 2%. The systematic variation due to a shift of the top quark mass of 2.5 GeV is about 2%.

## 7 Summary

The  $\cancel{E}_T$  in ATLAS is calculated from the energy in the calorimeter and from the reconstructed muons. The energy in the calorimeter is classified and calibrated according to the reconstructed objects to which it belongs. Two algorithms for reconstruction and calibration are presently implemented in the ATLAS software, one Cell-based, where the  $\cancel{E}_T$  reconstruction and calibration is done starting from the energy deposited in calorimeter cells, and the other one Object-based, where the  $\cancel{E}_T$  reconstruction is done from the reconstructed, classified and calibrated objects and from the energy outside of them. The performance of the two is similar.

The  $\cancel{E}_T$  performance has been checked on a large variety of events with physical  $\cancel{E}_T$  such as  $Z \rightarrow \tau\tau$ ,  $A/H \rightarrow \tau\tau$ , SUSY, and  $t\bar{t}$ , as well as events with no physical  $\cancel{E}_T$  like minimum bias events, events with QCD jets, and  $Z$ +jets processes. The resulting linearity of the response is within 5%, even for low true  $\cancel{E}_T$  values of the order of 40 GeV. The  $\cancel{E}_T$  resolution,  $\sigma$ , follows an approximate stochastic behaviour over a wide range of values of the total transverse energy deposited in the calorimeters. A simple fit to a function  $\sigma = a \cdot \sqrt{\Sigma E_T}$  yields values between 0.53 and 0.57 for the parameter  $a$ , for  $\Sigma E_T$  values between 20 and 2000 GeV. Deviations from this simple behaviour are expected and observed for low values of  $\Sigma E_T$  where noise is an important contribution, and for very high values of  $\Sigma E_T$  where the constant term in the jet energy resolution dominates. For values of the true  $\cancel{E}_T$  below 40 GeV, the accuracy of the measurement of the direction of the  $\cancel{E}_T$  vector for small values of  $\cancel{E}_T$  degrades rapidly. In contrast, for high values of the true  $\cancel{E}_T$ , azimuthal accuracies better than 100 mrad can be achieved. This accuracy of the measurement of the  $\cancel{E}_T$  direction allows an isolation cut on  $\cancel{E}_T$ , which can efficiently suppress events with a badly measured jet and the resulting  $\cancel{E}_T$  pointing in the jet direction.

A dedicated study of fake  $\cancel{E}_T$  shows that instrumental effects like hot/dead/noisy cells (regions) in calorimeters, as well as beam-gas scattering or other machine backgrounds, or displaced vertices, are very important, and that their understanding will be crucial in the first days of data taking. Different methods can be used to clean events and to correct/recover the  $\cancel{E}_T$  measurement. Mis-measurements in the detector itself, due to high- $p_T$  muons escaping from the fiducial acceptance or from large losses of deposited energy in cracks or inactive materials, might also effectively limit the performance of the  $\cancel{E}_T$  reconstruction and have therefore been studied in detail.

With the first  $100\text{pb}^{-1}$  the algorithms for  $\cancel{E}_T$  reconstruction and calibration can be checked studying the  $\cancel{E}_T$  linearity and resolution in minimum bias events and in Standard Model processes like  $Z$  and  $W$  decays and in  $t\bar{t}$  processes. Complementary methods for the determination of the  $\cancel{E}_T$  scale in-situ have been studied and it has been shown that it will be possible to determine the  $\cancel{E}_T$  scale with a precision of at least 8%.

## ***b*-Tagging**

# ***b*-Tagging Performance**

## **Abstract**

The ability to identify jets stemming from the fragmentation and hadronization of *b* quarks is important for the high- $p_T$  physics program of ATLAS: top physics, Higgs boson searches and studies, new phenomena. After an overview of the reconstruction of the key ingredients for *b*-tagging, the tagging techniques are described. The performance of *b*-tagging algorithms is then detailed, as well as the impact on performance of several factors and new promising directions. Finally, expected performance in the first data and the anticipated uncertainty with which it can be measured are briefly discussed.

## **1 Introduction**

This note discusses the identification of jets stemming from the hadronization of *b* quarks, or *b*-tagging. The ability to identify jets containing *b*-hadrons is important for the high- $p_T$  physics program of a general-purpose experiment at the LHC such as ATLAS. This is in particular useful to select very pure top samples, to search and/or study Standard Model or supersymmetric (SUSY) Higgs bosons which couple preferably to heavy objects or are produced in association with heavy quarks, to veto the large dominant  $t\bar{t}$  background for several physics channels and finally to search for new physics: SUSY decay chains, heavy gauge bosons, etc.

The large majority of these studies requires good *b*-tagging performance for jets with a transverse momentum ranging from 20 to 150 GeV. However, for super-symmetric processes, jets of  $p_T$  as high as 500 GeV may have to be tagged [1], and for exotic phenomena *b*-jets of up to a few TeV can be produced. For top studies, the signal rates are very high at the LHC and therefore a moderate *b*-tagging efficiency ( $> 50\%$ ) is acceptable, while a fraction of light jets mis-identified as *b*-jets below a few per mille suppresses most of the  $W$ +jets background (see for instance Ref. [2]). One of the most demanding channels for *b*-tagging is the production of a light Standard Model Higgs boson in association with a top-antitop pair [3]:  $t\bar{t}H(H \rightarrow b\bar{b})$ . Four *b*-jets have to be tagged with very high efficiency ( $\epsilon_b \approx 70\%$ ) since the signal cross-section is low, and the mis-tagging rate must be kept below 1% to fight the large  $t\bar{t}$ +jets background.

The identification of *b*-jets takes advantage of several of their properties which allow us to distinguish them from jets which contain only lighter quarks. First the fragmentation is hard and the *b*-hadron retains about 70% of the original *b* quark momentum. In addition, the mass of *b*-hadrons is relatively high ( $> 5$  GeV). Thus, their decay products may have a large transverse momentum with respect to the jet axis and the opening angle of the decay products is large enough to allow separation. The third and most important property is the relatively long lifetime of hadrons containing a *b* quark, of the order of 1.5 ps ( $c\tau \approx 450\mu\text{m}$ ). A *b*-hadron in a jet with  $p_T = 50$  GeV will therefore have a significant flight path length  $\langle l \rangle = \beta\gamma c\tau$ , traveling on average about 3 mm in the transverse plane before decaying. Such displaced vertices can first be identified inclusively by measuring the impact parameters of the tracks from the *b*-hadron decay products. The transverse impact parameter,  $d_0$ , is the distance of closest approach of the track to the primary vertex point, in the  $r - \phi$  projection. The longitudinal impact parameter,  $z_0$ , is the  $z$  coordinate of the track at the point of closest approach in  $r - \phi$ . The tracks from *b*-hadron decay products tend to have rather large impact parameters which can be distinguished from tracks stemming from the primary vertex. The other more demanding option is to reconstruct explicitly the displaced vertices. These two approaches of using the impact parameters of tracks or reconstructing the secondary vertex will be referred to later on as spatial *b*-tagging. Finally, the semi-leptonic decays of *b*-hadrons can be used by tagging the lepton in the jet. In addition, thanks to the hard fragmentation and high mass

of *b*-hadrons, the lepton will have a relatively large transverse momentum and also a large momentum relative to the jet axis. This is the so-called soft lepton tagging (the lepton being soft compared to high- $p_T$  leptons from *W* or *Z* decays).

The tagging methods relying on the impact parameter of tracks are detailed in this note. Only a summary and the main results of the other methods are given. The techniques employed to reconstruct either a single inclusive vertex or to attempt to resolve the complex topologies with a secondary *b*-hadron vertex and a tertiary *c*-hadron vertex are discussed in Ref. [4], as well as the reconstruction of the primary vertex. The tagging with soft muons or electrons from *b*-hadron decays is detailed respectively in Ref. [5] and Ref. [6]. The expected performance of the *b*-tagging algorithms in ATLAS, and the impact of several factors, are explained in detail in this note. However, the assessment of the impact of residual misalignments on the performance is just starting and first results are available in Ref. [7]. While a large effort is put into having a very accurate Monte Carlo simulation, the *b*-tagging performance must be measured in data. Several studies aiming at measuring the *b*-tagging efficiency in dijet events (Ref. [8]) or in *t $\bar{t}$*  events (Ref. [9]) have been performed. The studies to measure the mis-tagging rates are just starting and are not discussed. Finally, the high-level trigger of ATLAS has the capability to select *b*-jets. This is particularly interesting for channels with several *b*-jets where jet thresholds can be lowered at the first level thanks to the *b*-tagging applied at the second and event-filter levels. The high-level trigger *b*-tagging performance and strategies are discussed in Ref. [10].

The layout of this note is as follows: in Section 2, the reconstruction of the key objects for *b*-tagging is briefly explained and the performance summarized. Since the definition of the flavour of a jet is not unambiguous in Monte Carlo, the estimators used to assess the performance are defined in Section 3. Section 4 is intended to be a pedagogical approach to the various tagging algorithms available and to the likelihood ratio formalism used by ATLAS. The *b*-tagging performance for various physics processes is described in Section 5, relying on the current state-of-the-art *b*-tagging production software. In Section 6, a few additional studies aiming at better understanding some critical aspects of the *b*-tagging are detailed, while in Section 7 three studies showing new directions to improve the *b*-tagging performance are presented. In both cases the studies are described in a separate section because either they required specific datasets or they relied on software and/or cuts/optimizations which were different from the ones currently in use in the ATLAS software or they even required new software developments. In addition, the anticipated uncertainty with which the *b*-tagging performance may be measured in data is discussed in Section 8. Finally in Section 9, the main findings and the expected performance in the first data are summarized.

## 2 Reconstruction of the key objects

The reconstruction of the various objects needed for *b*-tagging and its performance are summarized in this section.

### 2.1 Charged tracks

The tracks reconstructed in the ATLAS Inner Detector [11] are the main ingredient for *b*-tagging. On average a track consists of 3 pixel hits, 4 space-points in the silicon micro-strip detector and about 36 hits in the Transition Radiation Tracker (TRT). The innermost pixel layer (the so-called *b*-layer) is located at a radius of 5 cm, while the TRT extends up to a radius of 1 m. The tracker is immersed in a 2 T magnetic field generated by the central solenoid. The intrinsic measurement accuracy of the pixels is around 10  $\mu\text{m}$  in  $r\phi$  and 115  $\mu\text{m}$  in  $z$ . All these allow the tracker to measure efficiently and with good accuracy the tracks within  $|\eta| < 2.5$  and down to  $p_T \sim 500$  MeV. For a central track with  $p_T = 5$  GeV, which is typical for *b*-tagging, the relative transverse momentum resolution is around 1.5% and the transverse

impact parameter resolution is about 35  $\mu\text{m}$ . Further details can be found in Refs. [11, 12].

Most of the results in this note are based on the default pattern-recognition and fitting algorithm, NewTracking. Its performance is described in Ref. [12]. When relevant, some comparisons are made with an alternate algorithm, iPatRec.

### 2.1.1 Baseline track selection

The track selection for *b*-tagging is designed to select well-measured tracks and reject fake tracks and tracks from long-lived particles ( $K_s$ ,  $\Lambda$  or other hyperon decays) and material interactions (photon conversions or hadronic interactions).

Two different quality levels are used. For the standard quality level, at least seven precision hits (pixel or micro-strip hits) are required. The transverse and longitudinal impact parameters at the perigee must fulfil  $|d_0| < 2$  mm and  $|z_0 - z_{pv}| \sin \theta < 10$  mm respectively, where  $z_{pv}$  is the longitudinal location of the primary vertex. Only tracks with  $p_T > 1$  GeV are considered. For the *b*-tagging quality, the extra requirements are: at least two hits in the pixel detector of which one must be in the *b*-layer, as well as  $|d_0| < 1$  mm and  $|z_0 - z_{pv}| \sin \theta < 1.5$  mm. This selection is used by all the tagging algorithms relying on the impact parameters of tracks, while slightly different selections are used by the secondary vertex algorithms as discussed in Ref. [4].

### 2.1.2 Tracking efficiency

The *b*-tagging performance strongly depends upon the tracking efficiency. The tracking performance inside jets, where the track density may be high, is discussed in the following. The tracking performance for single tracks is discussed in Ref. [12].

Figure 1 shows the tracking efficiency and fake rate for tracks in  $t\bar{t}$  events as a function of the track pseudo-rapidity. For the efficiency denominator, only charged primary pions<sup>1</sup> produced well before the *b*-layer ( $|x - x_{pv}| < 10$  mm,  $|y - y_{pv}| < 10$  mm) and with  $p_T > 1$  GeV and  $|\eta| < 2.5$  are considered. The first level of the efficiency corresponds to the basic reconstruction efficiency, where a track matched to a Monte Carlo particle is found. The fake rate is defined as the fraction of reconstructed tracks which do not pass the matching criteria used for the efficiency, i.e. less than 80% of their hits are coming from the same Monte Carlo particle. At high pseudo-rapidities, the tracking performance deteriorates mostly because of increased material and more ambiguous measurements.

Figure 2 shows the tracking efficiency and fake rate for tracks in  $t\bar{t}$  events as a function of their distance  $\Delta R = \sqrt{\Delta\phi^2 + \Delta\eta^2}$  to the axis of the closest jet, for tracks fulfilling the *b*-tagging quality cuts. The tracking performance degrades near the core of the jet where the track density is the highest and induces pattern-recognition problems. This is especially visible for high- $p_T$  ( $> 100$  GeV) jets.

Finally, in Figure 3 the tracking efficiency and fake rates obtained with the default algorithm and with iPatRec are compared. The first plot shows the comparison for several bins in the track  $p_T$  for all jets, while the second plot is as a function of the distance to the jet axis for jets with  $E_T > 100$  GeV. It is interesting to note that the two algorithms have a different working point: the default algorithm maintains a low level of fakes at the price of losing in efficiency, while the complementary choice was taken for iPatRec. This difference in treatment will lead to different *b*-tagging performance for jets with high momentum, as discussed in particular in Section 5.6. The features seen in these plots are specific to the pattern-recognition inside jets: for instance the decrease of the NewTracking efficiency at high track  $p_T$  is not visible for isolated tracks; it is here correlated with the local track density since high- $p_T$  tracks are more likely to originate from denser high- $p_T$  jets.

<sup>1</sup>For the tracking studies only pions were considered, but similar results are expected for charged kaons, protons, etc. which are all used for *b*-tagging.

Figure 1: Tracking efficiency (top plot) and fake rate (bottom plot) versus track pseudo-rapidity, for three levels of track selection: matching (blue triangles), standard quality cuts (red squares) and  $b$ -tagging quality cuts (black circles), in  $t\bar{t}$  events.

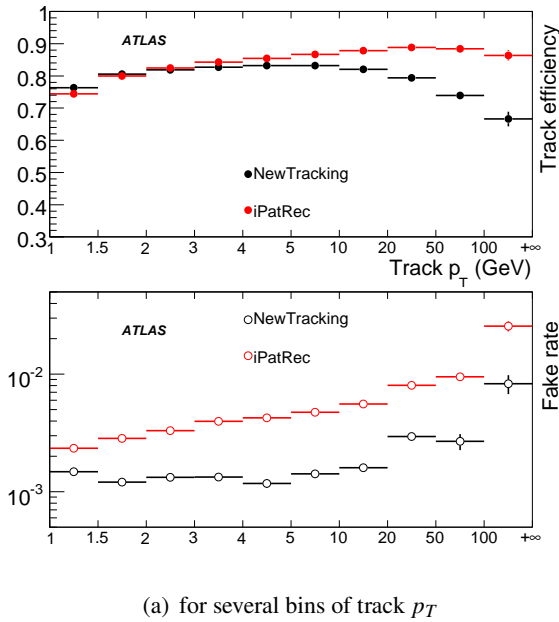

Figure 2: Tracking efficiency (top plot) and fake rate (bottom) versus distance to jet axis, for tracks fulfilling the  $b$ -tagging quality cuts and associated to low- $p_T$  jets (black symbols) or high- $p_T$  jets (green symbols), in  $t\bar{t}$  events.

(a) for several bins of track  $p_T$

(b) versus the distance to the jet axis

Figure 3: Tracking efficiency (top plots) and fake rate (bottom plots) in  $t\bar{t}$  events after the  $b$ -tagging quality cuts, for two tracking algorithms: default NewTracking (black symbols) and iPatRec (red symbols).

Figure 4: Fraction of tracks with shared hits versus distance to the jet axis. Tracks fulfilling the *b*-tagging quality cuts, and with at least one shared hit in the silicon systems are shown. The standard definition of shared hits (see text) is shown as well.

Figure 5: Transverse impact parameter significance  $d_0/\sigma_{d_0}$  for tracks in light jets. Two categories of tracks are used: regular ones (red plain curve) and tracks with shared hits (blue dashed). Both distributions are normalized to unity.

### 2.1.3 Tracks with shared hits

Tracks originating from the same point and passing the track selection cuts will not necessarily have the same impact parameter distributions. First of all, even using the track parameters normalized to their error will not compensate for all resolution effects, such as non-Gaussian tails. In addition, the pattern-recognition process itself can produce tracks of variable quality depending on their hit contents. Those tracks require a special treatment to be flagged appropriately. The most significant subset of such tracks is formed by the tracks which are sharing some of their hits with other tracks.

Figure 4 shows the fraction of tracks which are sharing at least one hit with another reconstructed track versus the distance of the track to the jet axis, for jets originating from  $t\bar{t}$  events. Currently for *b*-tagging purposes, a track is defined as a track with shared hits if it has at least one shared hit in the pixels or two shared hits in the strips. As expected, the fraction of tracks with shared hits increases with the local track density, and is therefore higher for high- $p_T$  jets and in the core of the jets. In  $t\bar{t}$  events the average  $p_T$  for taggable (*i.e.*  $p_T > 15$  GeV and  $|\eta| < 2.5$ ) *b*-jets and light jets are respectively 74 and 55 GeV. The fraction of tracks with shared hits is about 2%. For jets with a transverse momentum of about 140 GeV ( $WH$  events with  $m_H=400$  GeV, see below), this fraction is twice as high. In both cases the fraction is roughly similar for NewTracking and iPatRec. In an extreme case, for  $Z' \rightarrow b\bar{b}$  events with  $m_{Z'} = 2$  TeV, a majority of tracks have shared hits and the fraction depends significantly on the reconstruction algorithm (*cf.* Section 5.6). Even when the overall level of shared hits is relatively low, it has been demonstrated that those tracks should be treated appropriately since their impact on the *b*-tagging performance is significant. Indeed, the impact parameter significances, defined as the ratios  $d_0/\sigma_{d_0}$  and  $z_0/\sigma_{z_0}$  of the impact parameters to their measured error, for tracks in light jets exhibit a very different behavior depending on whether the track is a regular one or a track with shared hits, as shown in Figure 5. It is clear that tracks with shared hits can mimic lifetime more easily.

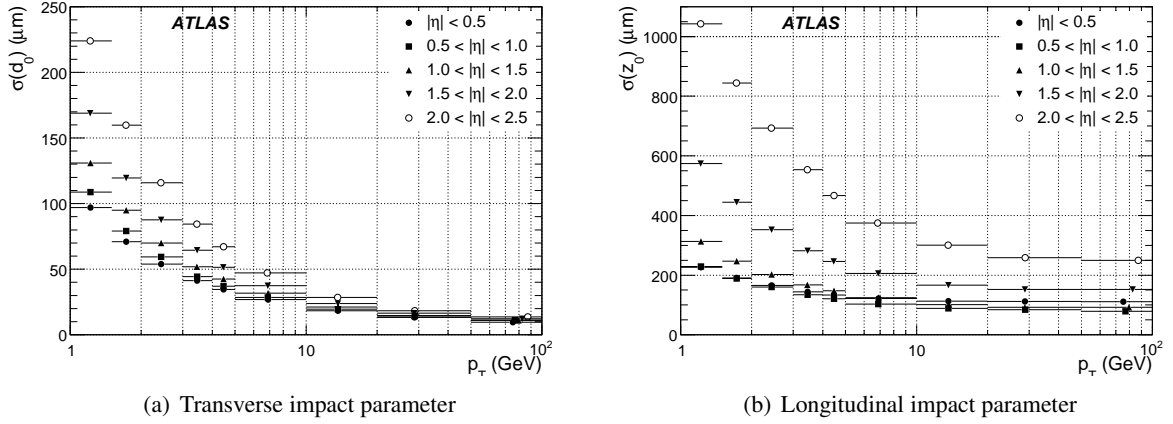

Figure 6: Track impact parameter resolution versus track  $p_T$ , for several bins in the track pseudo-rapidity.

### 2.1.4 Impact parameter resolution

The resolution of the track impact parameter is a crucial ingredient to be able to discriminate tracks coming from long-lived hadrons and prompt tracks. To estimate it, all the reconstructed tracks in  $t\bar{t}$  events fulfilling the  $b$ -tagging quality cuts and matched to a good Monte-Carlo track as defined in Section 2.1.2 were used. The difference between the reconstructed and the true impact parameter within a bin was fitted with a single gaussian, whose  $\sigma$  is reported on Figures 6(a) and 6(b), for respectively the transverse and longitudinal impact parameters. For a central track with  $p_T = 5$  GeV, which is typical for  $b$ -tagging, the transverse impact parameter resolution is about  $35 \mu\text{m}$ .

## 2.2 Primary vertex finding

Another key ingredient for  $b$ -tagging is the primary vertex of the event. The impact parameters of tracks are recomputed with respect to its position and tracks compatible with the primary vertex are excluded from the secondary vertex searches. At LHC the beam-spot size will be  $\sigma_{xy} = 15 \mu\text{m}$  and  $\sigma_z = 5.6 \text{ cm}$ : therefore the primary vertex is especially important for the  $z$  direction, while in the transverse plane only the beam-line could be used. The strategies to find the primary vertex and their performance are explained in Ref. [4]. The efficiency to find the primary vertex is very high in the high- $p_T$  events of interest, and the resolution on its position is around  $12 \mu\text{m}$  in each transverse direction and  $50 \mu\text{m}$  along  $z$ . With pile-up, the presence of additional minimum bias vertices makes the choice of the primary vertex less trivial: at a luminosity of  $2 \times 10^{33} \text{ cm}^{-2}\text{s}^{-1}$  (on average 4.6 minimum bias events per bunch-crossing) a wrong vertex can be picked up as the primary vertex in about 10% of the cases [4], thus causing a deterioration in the  $b$ -jet tagging efficiency.

## 2.3 Jet algorithms

The baseline jet algorithm for the studies in this note is a seeded cone algorithm using the calorimeter towers with a cone size of  $\Delta R = 0.4$ , and where the cells were calibrated using the H1 method (see Ref. [13] for details). The impact on  $b$ -tagging performance of using other jet algorithms is discussed in Section 6.4.

For  $b$ -tagging purposes, only the jet direction is relevant. In the first place, this direction is used to define which tracks should be associated with the jets. The actual tagging is done on this subset of tracks. Currently tracks within a distance  $\Delta R < 0.4$  of the jet axis are associated to the jet. A given track

is associated to only one jet (the closest in  $\Delta R$ ). This is the case for actually any jet collections, regardless of the cone size of the jet. The jet direction is also used to sign the impact parameters of the tracks in the jet as explained in Section 4.1.2.

Except when stated otherwise, there was no attempt to remove from the reconstructed jet collection the jets which are composed of only electrons. In the  $t\bar{t}$  sample (semi-leptonic and di-leptonic channels), about 5% of the taggable reconstructed jets are electrons. There is no dedicated treatment for muons. Isolated muons are very unlikely to fake jets, at least for the common processes under consideration in this note where  $p_T(\mu) < 100$  GeV. Muons in jets, stemming from  $b/c$ -hadron semi-leptonic decays and measured in the muon spectrometer, deposit on average about 3 GeV in the calorimeter but their momentum as measured in the inner detector and the muon system is not used to refine the kinematics of the jet, which remain purely calorimeter-based.

Only jets fulfilling  $p_T > 15$  GeV and  $|\eta| < 2.5$  are deemed taggable and considered in the performance studies.

## 2.4 Soft lepton reconstruction

Leptons arising from semi-leptonic decays of  $b$ -hadrons or subsequent  $c$ -hadrons can be used to tag  $b$ -jets.

Soft muons are reconstructed [5] using two complementary reconstruction algorithms. A *combined muon* corresponds to a track fully reconstructed in the muon spectrometer that matches a track in the inner detector. Low-momentum muons (below  $p \sim 5$  GeV) which cannot reach the muon middle and outer stations are identified by matching an inner detector track with a segment in the muon spectrometer inner stations. Muons satisfying some basic requirements ( $p_T > 3$  GeV,  $|d_0| < 4$  mm) are associated to the closest jet provided that  $\Delta R < 0.5$ . Finally, the kinematic properties of the jet-muon system are used in order to reject the background caused by punch-throughs and decays-in-flight in light jets.

Reconstructing soft electrons [6] in the calorimeter inside a jet is more difficult. This is achieved by matching an inner detector track to an electromagnetic cluster. For a given track, only the energy contained in a small window around the track extrapolation is used. The contribution of neighbouring hadronic showers is therefore reduced. The identification procedure takes full advantage of the tracking capabilities of the inner detector as well as of the granularity of the electromagnetic calorimeter: a likelihood ratio combines inner detector information such as transition radiation hits with shower shape variables from the calorimeter. The performance is, however, highly dependent on the track density in jets as well as the quantity of matter in front of the electromagnetic calorimeter.

## 3 Performance estimators

### 3.1 Labelling

To define  $b$ -tagging performance, the Monte Carlo event history is used to know the type of parton from which a jet originates. This *labelling* procedure is not unambiguous and is not strictly identical for different Monte Carlo generators. For the results presented here, a quark labelling has been used: a jet is labelled as a  $b$ -jet if a  $b$  quark with  $p_T > 5$  GeV is found in a cone of size  $\Delta R = 0.3$  around the jet direction. The various labelling hypotheses are tried in this order:  $b$  quark,  $c$  quark and  $\tau$  lepton. When no heavy flavour quark nor  $\tau$  lepton satisfies these requirements, the jet is labelled as a light-jet. No attempt is made to distinguish between  $u$ ,  $d$ ,  $s$  quarks and gluon since such a label is even more ambiguous.

### 3.2 Efficiency and rejection

For performance studies, only jets fulfilling  $p_T > 15$  GeV and  $|\eta| < 2.5$  are considered and referred to as taggable jets. In the following, jets for which no track passed the  $b$ -tagging quality cuts are still counted in the performance estimators. However, events where the primary vertex could not be reconstructed are ignored. In addition,  $b$ -jets were not categorized according to the nature of the  $b$ -hadron decay:  $b$ -jets with semi-leptonic decays behave quite differently from jets with hadronic decays, even when using purely spatial methods, but in the following no distinction was made.

The tagging efficiency is naturally defined as the fraction of taggable jets labelled as  $b$ -jets (see previous section) which are actually tagged as  $b$ -jets by the tagging algorithm under study. The mis-tagging rate is the fraction of taggable jets not labelled as  $b$  which are actually tagged as  $b$ -jets. For historical reasons the jet rejection is used instead: this is simply the inverse of the mis-tagging rate.

### 3.3 Purification

A difficulty arises as soon as the jet multiplicity is high and various jet flavours are present in a single event: a jet with  $\Delta R(\text{jet} - b) = 0.31$  is labelled as a light jet, although tracks from  $b$ -hadron decay with high lifetime content are likely to be associated to it.

This leads to a decrease of the estimated performance, not related to the  $b$ -tagging algorithm itself but to the labelling procedure which strongly depends on the activity of the event. In order to obtain a more reliable estimation of  $b$ -tagging performance, a purification procedure has been devised: light jets for which a  $b$  quark, a  $c$  quark or a  $\tau$  lepton is found within a cone of size  $\Delta R = 0.8$  around the jet direction are not used to compute the rejection.

The performance estimated after purification represents the intrinsic power of the  $b$ -tagging algorithms and should be similar for different kinds of hard event, whereas results obtained for the complete light jet sample are more dependent on the event type. On the other hand, the latter is more representative of the actual  $b$ -tagging power for a given physics analysis. This is illustrated in Figure 7: the light jet rejection in simple  $WH$  events is similar without or with purification (left plot), while for busier  $t\bar{t}$  events (right plot) the two curves differ in the region where lifetime content as opposed to resolution effects dominates (*i.e.* for  $\varepsilon_b < 80\%$ ). In the following, jets fulfilling the purification procedure will be referred to as purified or pure jets, the ones failing this procedure will be called non-pure jets, while all the jets will be called raw jets.

## 4 $b$ -tagging algorithms

In this section the various algorithms used in ATLAS to tag  $b$ -jets are explained. The spatial algorithms, built on tracks and subsequently vertices, are the most powerful ones. Most of them are based on a likelihood ratio approach, but simpler and more robust tagging algorithms are also available. Soft lepton tagging algorithms are also very important, in particular since the correlation with the previous ones is minimal. Their performance is summarized in section 4.3.

### 4.1 Spatial algorithms based on likelihood ratio

All tracks in the jet fulfilling the  $b$ -tagging quality cuts described in 2.1.1 are considered for the spatial  $b$ -tagging algorithms. In typical  $t\bar{t}$  events, the average number of those tracks per light ( $b$ -) jet is 3.7 (5.5) and their average  $p_T$  is 6.6 (6.3) GeV, respectively.

Figure 7: Rejection of light jets and *c*-jets with and without purification versus *b*-jet efficiency for *WH* ( $m_H = 120$  GeV) and  $t\bar{t}$  events, using the tagging algorithm based on 3D impact parameter and secondary vertex.

#### 4.1.1 $V^0$ and secondary interactions rejection

The preselection cuts on impact parameters reject a large fraction of long-lived particles and secondary interactions. Among the remaining tracks, the ones identified by the secondary vertex search (section 4.1.3) as likely to come from  $V^0$  decays are rejected (they amount to between 1% and 3% of the tracks in light and *b*-jets respectively). To do so, the search starts by building all two-track pairs that form a good vertex. The mass of the vertex is used to reject the tracks which are likely to come from  $K_S$ ,  $\Lambda$  decays and photon conversions. The radius of the vertex is compared to a crude description of the innermost pixel layers to reject secondary interactions in material. The cuts and performance of this selection are described in Ref. [4].

#### 4.1.2 Impact parameter tagging algorithms

For the tagging itself, the impact parameters of tracks are computed with respect to the primary vertex (cf. section 2.2). On the basis that the decay point of the *b*-hadron must lie along its flight path, the impact parameter is signed to further discriminate the tracks from *b*-hadron decay from tracks originating from the primary vertex. The sign is defined using the jet direction  $\vec{P}_j$  as measured by the calorimeters (cf. section 2.3), the direction  $\vec{P}_t$  and the position  $\vec{X}_t$  of the track at the point of closest approach to the primary vertex and the position  $\vec{X}_{pv}$  of the primary vertex:

$$\text{sign}(d_0) = (\vec{P}_j \times \vec{P}_t) \cdot \left( \vec{P}_t \times (\vec{X}_{pv} - \vec{X}_t) \right)$$

The experimental resolution generates a random sign for the tracks originating from the primary vertex, while tracks from the *b/c* hadron decay tend to have a positive sign. The sign of the longitudinal impact parameter  $z_0$  is given by the sign of  $(\eta_j - \eta_t) \times z_{0t}$  where again the *t* subscript refers to quantities defined at the point of closest approach to the primary vertex.

The distribution of the signed transverse impact parameter  $d_0$  is shown on Figure 8, left plot, for tracks coming from *b*-jets, *c*-jets and light jets. The right plot shows the significance distribution  $d_0/\sigma_{d_0}$

Figure 8: Signed transverse impact parameter  $d_0$  distribution (left) and signed transverse impact parameter significance  $d_0/\sigma_{d_0}$  distribution (right) for *b*-jets, *c*-jets and light jets.

which gives more weight to precisely measured tracks. Combining the impact parameter significances of all the tracks in the jet is the basis of the first method to tag *b*-jets. Three tagging algorithms are defined in this way: IP1D relies on the longitudinal impact parameter, IP2D on the transverse impact parameter and finally IP3D which uses two-dimensional histograms of the longitudinal versus transverse impact parameters, taking advantage of their correlations.

#### 4.1.3 Secondary vertex tagging algorithms

To further increase the discrimination between *b*-jets and light jets, the inclusive vertex formed by the decay products of the bottom hadron, including the products of the eventual subsequent charm hadron decay, can be sought. The reader is referred to Ref. [4] for all details. The search starts by building all two-track pairs that form a good vertex, using only tracks far enough from the primary vertex ( $L_{3D}/\sigma_{L_{3D}} > 2$  where  $L_{3D} \equiv \|\vec{X}_{pv} - \vec{X}_t\|$  is the three dimensional distance between the primary vertex and the point of closest approach of the track to this vertex). Vertices compatible with a  $V^0$  or material interaction are rejected. All tracks from the remaining two-track vertices are combined into a single inclusive vertex, using an iterative procedure to remove the worst track until the  $\chi^2$  of the vertex fit is good. Three of the vertex properties are exploited: the invariant mass of all tracks associated to the vertex, the ratio of the sum of the energies of the tracks participating to the vertex to the sum of the energies of all tracks in the jet and the number of two-track vertices. These properties are illustrated in Figure 9 for *b*-jets and light jets. The so-called SV tagging algorithms make different use of these properties: SV1 relies on a 2D-distribution of the two first variables and a 1D-distribution of the number of two-track vertices, while SV2 is based on a 3D-histogram of the three properties which requires quite some statistics. The secondary vertex finding efficiency depends in particular on the event topology, but the typical efficiency  $\epsilon_b^{SV}$  is higher than 60% in *b*-jets. The SV taggers require an a priori knowledge of  $\epsilon_b^{SV}$  and  $\epsilon_u^{SV}$ .

A completely new algorithm, JetFitter, is also available, which exploits the topological structure of weak *b*- and *c*-hadron decays inside the jet. A Kalman filter is used to find a common line on which the primary vertex and the beauty and charm vertices lie, as well as their position on this line approximating the *b*-hadron flight path. With this approach, the *b*- and *c*-hadron vertices are not merged, even when

Figure 9: Secondary vertex variables: invariant mass of all tracks in vertex (left), energy fraction vertex/jet (center) and number of two-track vertices (right) for *b*-jets and light jets.

only a single track is attached to each of them. The discrimination between *b*-, *c*- and light jets is based on a likelihood using similar variables to the SV tagging algorithm above, and additional variables such as the flight length significances of the vertices. This algorithm and its performance are also described in detail in Ref. [4].

#### 4.1.4 Formalism of likelihood ratio

For both the impact parameter tagging and the secondary vertex tagging, a likelihood ratio method is used: the measured value  $S_i$  of a discriminating variable is compared to pre-defined smoothed and normalized distributions for both the *b*- and light jet hypotheses,  $b(S_i)$  and  $u(S_i)$ . Two- and three-dimensional probability density functions are used as well for some tagging algorithms. The ratio of the probabilities  $b(S_i)/u(S_i)$  defines the track or vertex weight, which can be combined into a jet weight  $W_{Jet}$  as the sum of the logarithms of the  $N_T$  individual track weights  $W_i$ :

$$W_{Jet} = \sum_{i=1}^{N_T} \ln W_i = \sum_{i=1}^{N_T} \ln \frac{b(S_i)}{u(S_i)} \quad (1)$$

The distribution of such a weight is shown in Figure 10 for *b*-, *c*- and light jets for two different tagging algorithms: IP2D and the sum of the weights from IP3D and SV1. When no vertex is found, the SV taggers return a weight of  $\ln \frac{1-\epsilon_p^{SV}}{1-\epsilon_u^{SV}}$ . To select *b*-jets, a cut value on  $W_{Jet}$  must be chosen, corresponding to a given efficiency. The relation between the cut value and the efficiency depends on the jet transverse momentum and rapidity, and therefore is different for different samples.

#### 4.1.5 Likelihood ratio and track categories

As seen already, tracks may exhibit different behavior even after the track selection, such as the tracks with shared hits (Figure 4). One idea to take advantage of the different properties of tracks is to arrange all tracks into various categories and use dedicated probability density functions for each category. The likelihood ratio formalism permits to incorporate such categories in a straightforward way. After the division of the tracks into disjoint categories  $j$ , where every category has its own set of reference histograms  $b_j$  and  $u_j$ , the jet weight can simply be written as the sum over all tracks in each category  $N_T^j$  and all categories  $N_C$ :

$$W_{Jet} = \sum_{j=1}^{N_C} \left( \sum_{i=1}^{N_T^j} \ln \frac{b_j(S_i)}{u_j(S_i)} \right) \quad (2)$$

Figure 10: Jet *b*-tagging weight distribution for *b*-jets, *c*-jets and purified light jets. The left plot is for the IP2D tagging algorithm. The right plot corresponds to the IP3D+SV1 tagging algorithm.

Currently in the *b*-tagging software, two track categories are used: the *Shared* tracks (tracks with shared hits), and the complementary subset of tracks called *Good* tracks. These track categories are only used for the time being for the IP1D, IP2D and IP3D tagging algorithms.

## 4.2 Other spatial algorithms

The spatial algorithms based on likelihood ratios require an a-priori knowledge of the properties of both *b*-jets and light jets. Methods to measure them in data are being devised for the *b*-jets [8, 9] but will require at least about  $100 \text{ pb}^{-1}$ . In addition, there is no clear way to extract a pure enough sample of light jets, and Monte Carlo simulation will probably have to be used once a thorough validation against data has been performed. A few other spatial tagging algorithms, less powerful, are therefore developed, which have less reliance on Monte Carlo and are expected to be easier and faster to commission with the first real data.

The simplest approach that could be used, at least at the beginning, is the counting of tracks with large impact parameter or large impact parameter significance. Requiring a few of these tracks provides a sample enriched in *b*-jets. The performance of such a tagging algorithm is not discussed in this note because it is not yet fully implemented in ATLAS. Such a simple tagger may also be very useful at the trigger level.

Another approach is to combine the impact parameter of all the tracks in the jet. JetProb is an implementation of the ALEPH tagging algorithm [14], used extensively at LEP and later at the Tevatron. The signed impact parameter significance  $d_0/\sigma_{d_0}$  of each selected track in the jet is compared to a resolution function  $\mathcal{R}$  for prompt tracks, in order to measure the probability that the track *i* originates from the primary vertex (Figure 11(a)):

$$\mathcal{P}_i = \int_{-\infty}^{-|d_0^i/\sigma_{d_0}^i|} \mathcal{R}(x) dx \quad (3)$$

The resolution function can be measured in data using the negative side of the signed impact parameter distribution (cf. section 6.5.1), assuming there is no contribution from heavy-flavour particles which

is not strictly true.

The individual probability of each of the  $N$  tracks associated to the jet are then combined to obtain a jet probability  $\mathcal{P}_{jet}$  which discriminates *b*-jets against light jets (Figure 11(b)):

$$\mathcal{P}_{jet} = \mathcal{P}_0 \sum_{j=0}^{N-1} \frac{(-\ln \mathcal{P}_0)^j}{j!} \quad (4)$$

where

$$\mathcal{P}_0 = \prod_{i=1}^N \mathcal{P}'_i \quad \text{and} \quad \begin{cases} \mathcal{P}'_i = \frac{\mathcal{P}_i}{2} & \text{if } d_0^i > 0 \\ \mathcal{P}'_i = \left(1 - \frac{\mathcal{P}_i}{2}\right) & \text{if } d_0^i < 0 \end{cases} \quad (5)$$

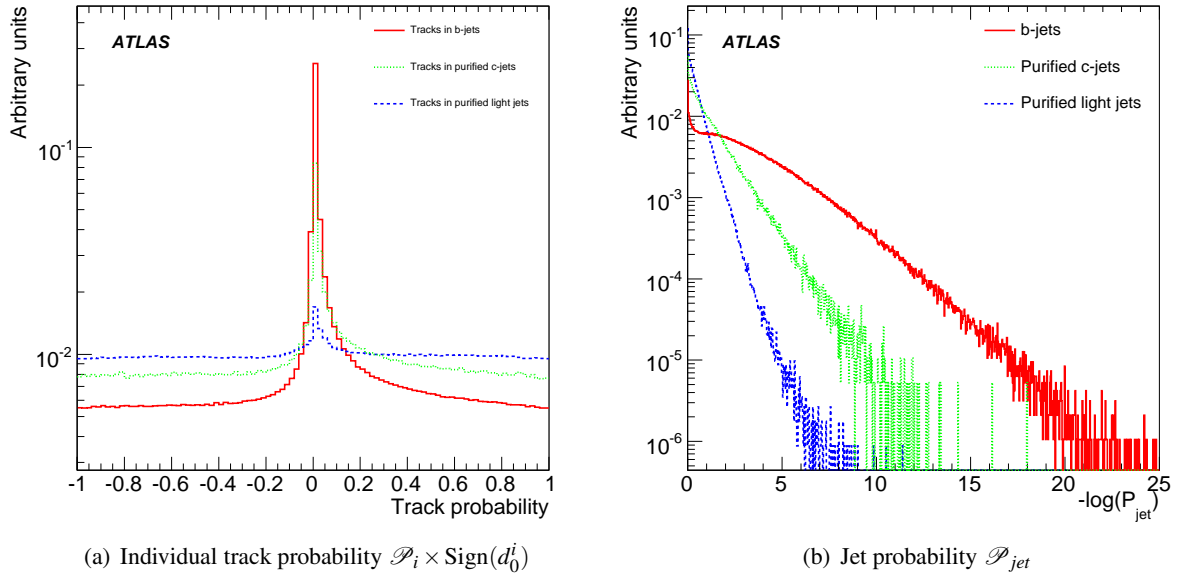

Figure 11: Distributions of the probability of compatibility with the primary vertex for individual tracks (left plot) and for all tracks in the jet (right plot) as defined for JetProb. The cases of *b*-jets (red plain), *c*-jets (green dashed) and light jets (blue dotted line) are shown.

### 4.3 Soft lepton algorithms

Soft lepton tagging relies on the semi-leptonic decays of bottom and charm hadrons. Therefore it is intrinsically limited by the branching ratios to leptons: at most 21% [15] of *b*-jets will contain a soft lepton of a given flavour, including cascade decays of bottom to charm hadrons. However, tagging algorithms based on soft leptons exhibit very high purity and low correlations with the track-based tagging algorithms, which is very important for checking and cross-calibrating performance in data (see for instance Ref. [8]).

#### 4.3.1 Soft muons

Once a reconstructed muon is associated to a jet as explained briefly in Section 2.4, a likelihood permits to discriminate light jets from *b*-jets. The algorithm and its performance are detailed in Ref. [5] and will not be discussed further in this note. To summarize, a light jet rejection of about 300 can be achieved for

a *b*-tagging efficiency of 10%. Those numbers include the semi-leptonic branching ratio, the detector acceptance, the reconstruction efficiency as well as the jet-muon association efficiency. This was estimated in  $t\bar{t}$  events, including a simulation of the cavern background (low-energy neutrons and photons stemming from the interaction of forward particles with the shielding) which reduces the rejection level by about 30%. The performance is relatively steady in the jet  $p_T$  range 15-100 GeV and in pseudo-rapidity.

#### 4.3.2 Soft electrons

A likelihood ratio is also used for soft electrons. The algorithm and its performance are detailed in Ref. [6] and will not be discussed further in this note. A light jet rejection of about 100 can be achieved for a *b*-tagging efficiency of 7%. The efficiency of the soft electron identification is high, since two-thirds of the true *b*-jets containing a real soft electron are tagged by the soft electron algorithm. However, about 25% of light jets are mis-tagged by real electrons from photon conversions and Dalitz decays. This was estimated in  $WH$  ( $m_H = 120$  GeV) events without pile-up. Based on previous study [16], a further degradation by 10% (30%) is expected when on average 4.6 (23) minimum-bias events are added. While the performance is constant in jet  $p_T$  in the range 15-100 GeV, it degrades quickly with the jet pseudo-rapidity because of the higher amount of dead material, the poor performance in the transition region between the barrel and end-cap cryostats of the electromagnetic calorimeter ( $1.37 < |\eta| < 1.52$ ) and the absence of the TRT beyond  $|\eta| > 2$ .

### 4.4 Combining tagging algorithms

Currently only the likelihood-based tagging algorithms have been combined, since the formalism is easy in this case: the weights of the individual tagging algorithms are simply summed up. The most commonly used tagging algorithm, IP3D+SV1, is actually such a combination. It should be noted that the SV tagging algorithms have been optimized to work in conjunction with the IP ones. Another one combines IP3D and JetFitter. Multivariate approaches to combine all tagging algorithms, including the soft lepton ones, have not received much attention so far. There are, however, some new studies and the use for instance of boosted decision trees is discussed in Section 7.3.

### 4.5 Calibration of tagging algorithms

The likelihood-based tagging algorithms require knowledge of the probability density functions of the discriminating variables for both the *b*- and light jet hypotheses: this is called the calibration of the tagging algorithms, or their reference histograms. In the following, those functions have been derived from a large sample of jets coming from  $t\bar{t}$  and  $t\bar{t}jj$  events. Several issues about the calibration and its impact on *b*-tagging performance are discussed in Section 6.5.

## 5 Performance for various physics processes

In this section, the *b*-tagging performance is reviewed for several physics channels of interest. Several spatial tagging algorithms are considered: JetProb and IP2D which are best suited for the initial period, IP3D and then IP3D+SV1 for regular operations once the secondary vertexing is understood and finally IP3D+JetFitter for the ultimate performance.

### 5.1 Dependence on jet transverse momentum and pseudo-rapidity

The spatial *b*-tagging performance depends strongly on the jet momentum and rapidity: the  $p_T$  and  $\eta$  dependencies of the *b*-tagging efficiency and light jet rejection for a given cut on the *b*-tagging weight

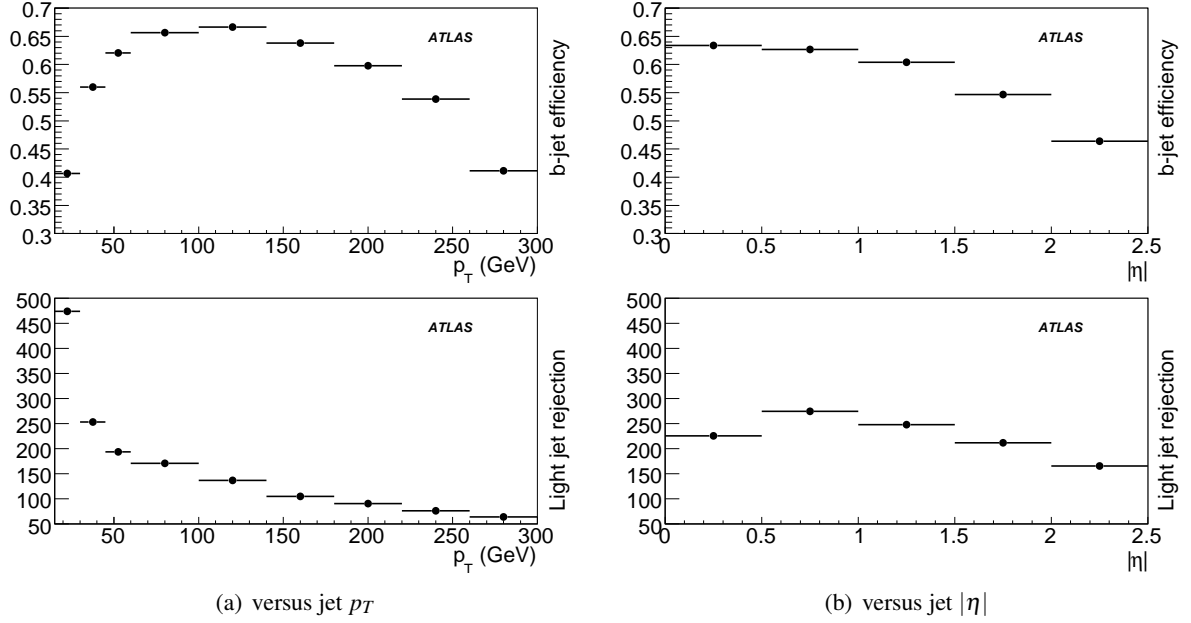

Figure 12: *b*-tagging efficiency and purified light jet rejection obtained with the IP3D+SV1 tagging algorithm operating at a fixed cut of 4 on the *b*-tagging weight, for  $t\bar{t}$  events.

Figure 13: Rejection of light jets with purification versus jet  $\eta$  for the IP3D+SV1 tagging algorithm and for two different physics channels: jets from  $t\bar{t}$  events and from  $WH$  ( $m_H = 120$  GeV) events, for a fixed 60% tagging efficiency in each bin.

are shown in Figure 12. At high  $p_T$  or at high  $|\eta|$ , the *b*-jet tagging performance is poor, regardless of which tagging algorithm is used. At low  $p_T$ , maintaining a reasonable *b*-jet efficiency is possible only by loosening the cut on the weight, at the price of a very low rejection of light jets. The strong dependence, especially in  $p_T$ , makes the extraction of the *b*-jet efficiency from data complicated and means that more integrated luminosity will be required, since several bins are needed.

Because of these strong  $p_T$  and  $\eta$  dependencies, and since various samples have very different spectra, it is not straightforward to compare between channels the integrated rejection numbers shown in the following. It is worth noting that this dependence is really a two-dimensional one, thus Figure 12 is useful for illustrative purposes but the  $(p_T, |\eta|)$  spectrum of the jets in the sample considered is not properly factorized out. This is important for instance to parametrize the *b*-tagging performance. This is

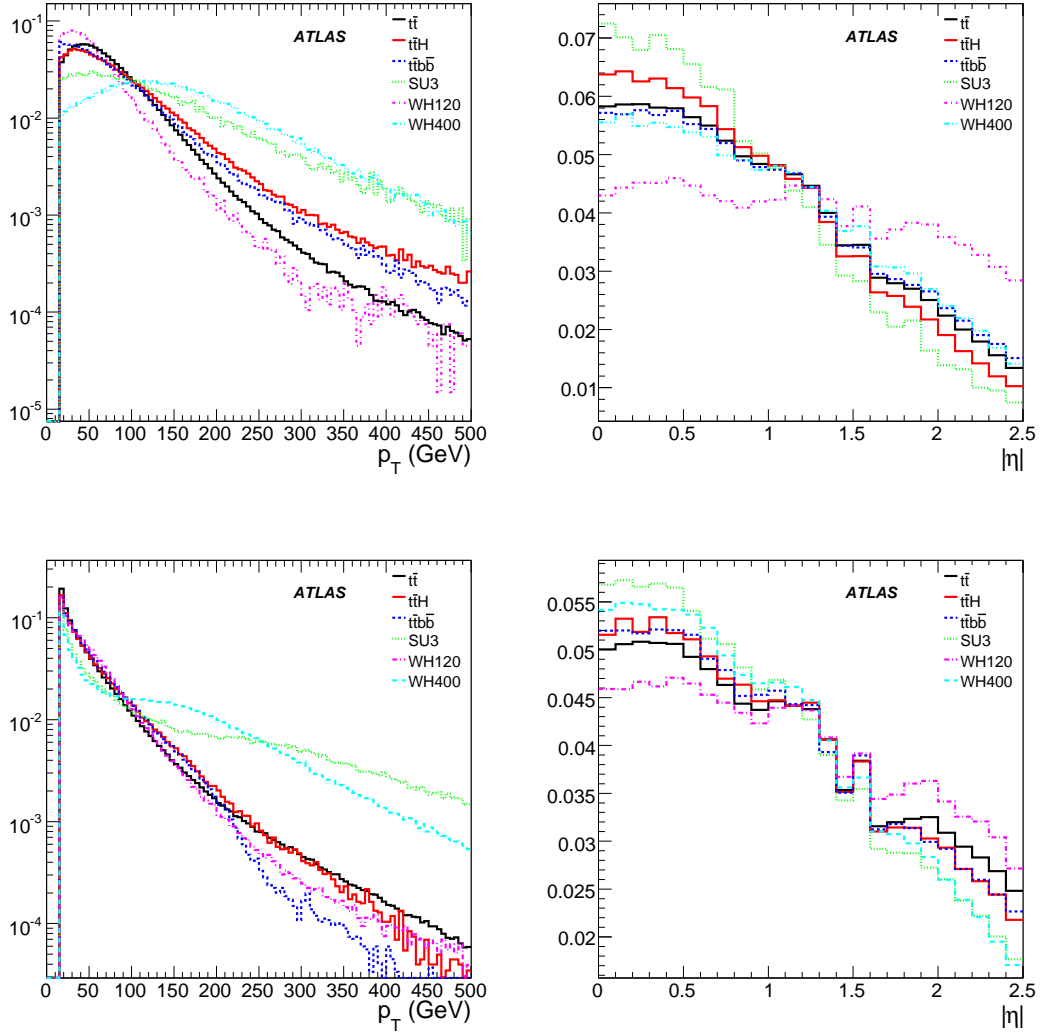

Figure 14:  $p_T$  and  $|\eta|$  spectra of  $b$  (upper plots) and light (lower plots) jets for the various channels considered in this section.

further illustrated in Figure 13: the rejections achieved in two different samples become more similar as a function of  $\eta$  when looking in bins of  $p_T$ . The remaining differences are mostly because the binning in  $p_T$  is still too large, but also because of other minor differences between the samples: for example they have been generated with different Monte Carlo generators (cf. section 6.6).

For reference, the  $p_T$  and  $|\eta|$  spectra of  $b$  and light jets in the various samples used in the following are shown on Figure 14. They affect the integrated rejections for the various channels.

## 5.2 Simple topologies: WH channels

This first class of events illustrates the performance obtained on simple event topologies where the jet multiplicity is very low. As discussed in Section 3.3, purification is not an issue in this case.

Events from Higgs boson production in association with a  $W$  boson are interesting in this respect and are a benchmark for  $b$ -tagging performance, even though the channel itself is no longer thought to be very promising at the LHC (see however Ref. [17] for a recent re-investigation). The  $W$  decays

leptonically, and there are only two jets coming from the hard process, originating from the  $H$  decay. To study the  $b$ -tagging efficiency the decay  $H \rightarrow b\bar{b}$  is simulated while here for the rejection of charmed and light jets the Higgs boson is forced to decay to  $c\bar{c}$  or to the unlikely  $u\bar{u}$  channel respectively.

The  $b$ -tagging performance obtained on this kind of events and for  $m_H = 120$  GeV is shown in Table 1 for the tagging algorithms considered. Two typical  $b$ -tagging efficiencies were considered: 50% and 60%. For each tagging algorithm, the cuts on the weight required to achieve these efficiencies were determined over the whole sample, and then applied to estimate the rejections.

To study more energetic jets, similar physics processes have been considered for a different Higgs boson mass,  $m_H=400$  GeV (again such a choice is unphysical since a 400 GeV Higgs boson would not decay to  $b\bar{b}$  but is useful for these studies). The results are shown in Table 1 for the light jet rejection and in Table 2 for the  $c$ -jet rejection. The differences in performance between the two mass cases are the result of the different  $p_T$  and  $\eta$  spectra: the jets for  $m_H = 400$  GeV are more energetic and explain most of the discrepancy, this effect being only slightly balanced by the fact that jets for  $m_H = 120$  GeV are more forward. For this channel, the gain obtained with JetFitter is more visible.

### 5.3 Multi-jets channels: the top case

The jet multiplicity in pair-produced top quark events is much higher. In the following, the channels where at least one of the  $W$  bosons decays to leptons are considered. For the dominant lepton+jets channel, there are usually at least four jets from the hard process and extra jets from radiation. Several flavours of jets are present at the same time in the event: two  $b$ -jets from the top quarks, light jet(s) and often a  $c$ -jet from the  $W$  decaying hadronically. This increases the likelihood of having light jets contaminated with heavy flavour and also makes the labelling of jets even more ambiguous as discussed previously. The benchmark curves of jet rejection versus  $b$ -tagging efficiency are shown on Figures 15(a) and 15(b), for light jets and for several tagging algorithms. The jets of the various flavours were taken from the same sample in this case, unlike for events of the  $WH$  channels. Table 1 shows the light jet rejection achieved in  $t\bar{t}$  events and in  $t\bar{t}jj$  events, both samples being generated with MC@NLO+HERWIG. The latter events are  $t\bar{t}$  events which were filtered in order to have at least six jets, of which four are taggable. Since the performance in those two samples is similar, they have been merged. For light jets, both the raw (without purification) and purified rejections are shown. For  $c$ -jets and  $\tau$ -jets the purification does not make any significant difference. The rejection power of  $c$ -jets (Table 2 and Figure 15(c)) is naturally very limited because of the lifetime of  $c$ -hadrons and is almost independent of the physics process. Without any optimization, the  $b$ -tagging algorithms also prove to be useful for the identification of  $\tau$ -jets, as shown on Figure 15(d). The small discontinuities in the curves on Figure 15, visible notably for the IP3D tagger, are due to the conjunction of a coarser binning of the underlying probability density functions for this tagger and the presence of single-track jets (notably electrons faking jets). This effect is more pronounced for the  $\tau$ -jets (Figure 15(d)) where single-prong decays are abundant.

The impact on the light jet rejection of electrons faking jets can be seen in the fourth block of Table 1. Electron jets are seldom mis-tagged as  $b$ -jets, since they have usually a single prompt high- $p_T$  track which is well-measured. In this sample, the high- $p_T$  electrons are coming from  $W \rightarrow e\nu$  or indirectly from  $W \rightarrow \tau\nu$ . In the fourth part of Table 1, a jet  $j$  is considered as an electron faking a jet, and therefore discarded, if it matches with a reconstructed electron candidate  $e$ :  $\Delta R(e, j) < 0.1$  and  $E_T(e)/E_T(j) > 0.75$ .

It is interesting to notice that, despite the more complex topology of these  $t\bar{t}$  events, the integrated light-jet rejection achieved is higher than for the  $WH$  ( $m_H=120$  GeV) case. This is mostly because jets in  $t\bar{t}$  events are more central than the ones in  $WH$  ( $m_H=120$  GeV) production (cf. Figure 14), and the  $b$ -tagging performance degrades quickly at large pseudo-rapidities as seen already.

Table 1 shows the light jet rejection achieved in even more complex topologies with at least six jets. Those channels are relevant for the Higgs discovery channel  $t\bar{t}H(b\bar{b})$  which requires a high  $b$ -tagging

Table 1: Integrated rejection of light jets (with and without purification when it applies), for various event types and for several tagging algorithms. For each case, the cut on the  $b$ -tagging weight is chosen to lead to the quoted average  $b$ -tagging efficiency  $\varepsilon_b$  over the sample considered. The quoted errors are statistical only.

efficiency since four jets are *b*-tagged and the cross section is low: therefore the more typical working points of  $\epsilon_b$  around 60-70% are shown. As shown in Figure 14, the  $p_T$  spectrum for the *b*-jets in these samples is harder than for *b*-jets in  $t\bar{t}$  events, explaining partly the differences in performance. In addition the high *b*-jet multiplicity in  $t\bar{t}H$  events leads to some lifetime contamination in the few light jets available in this sample. All these samples are based on PYTHIA Monte Carlo, unlike the  $t\bar{t}jj$  sample which is a background for this channel as well but is based on MC@NLO+HERWIG Monte Carlo and was kept separate for this reason.

#### 5.4 High- $p_T$ jets: SUSY

Events from the SUSY bulk region (SU3 point, see Ref. [1]) were considered. In these events, the average taggable jet multiplicity is about 5.3 and a large number of  $\tau$ -leptons are produced in the decay chain of charginos and neutralinos. There are on average 0.6 *b*-jets per event, with a relatively hard  $p_T$  spectrum as shown on Fig. 14: the average  $p_T$  is 144 GeV. On average about 0.6 taggable jets per event are labelled as  $\tau$ , compared to 0.2 in the semi-leptonic  $t\bar{t}$  channel. They are not considered as light jets. The results are shown in Tables 1 and 2: because the  $p_T$  of the jets is quite high, the light jet rejection is similar to that achieved for  $WH$  ( $m_H = 400$  GeV) events but significantly worse than for the other channels.

#### 5.5 Degradation of performance at low and high $p_T$

At low  $p_T$ , performance is degraded mostly because multiple scattering is increased. This also holds for the high  $|\eta|$  region, where the amount of material in the tracking region increases very significantly, inducing more secondary interactions. There is currently no rejection of secondary interactions found in the pixel disks, unlike in the barrel (cf. Section 4.1.3). More importantly, the increase of the extrapolation distance from the *b*-layer to the primary vertex at large pseudo-rapidities significantly degrades the  $z_0$  resolution as seen in Figure 6(b).

Several effects conspire to reduce the *b*-tagging performance as the jet  $p_T$  increases above 120 GeV. First of all, the fraction of fragmentation tracks increases with the parton transverse momentum, as shown in Figure 16, while the jet is collimated into a narrower cone: since a fixed-size cone is currently used to associate tracks to the jet this leads to a dilution of the discriminating power in *b*-jets. The density of tracks in the core of energetic jets challenges the pattern-recognition ability of the software and of the inner detector itself, leading to either a reduced tracking efficiency or a high level of fakes as shown in Figure 3 for jets with  $E_T > 100$  GeV. Finally, for very energetic *b*-hadrons the Lorentz boost leads

(a) Non-purified light jets

(b) Purified light jets

(c)  $c$ -jets

(d)  $\tau$ -jets

Figure 15: Rejection of light jets,  $c$ - and  $\tau$ -jets versus  $b$ -jet efficiency for  $t\bar{t}$  and  $t\bar{t}jj$  events and for all tagging algorithms: JetProb, IP2D, IP3D, IP3D+SV1, IP3D+JetFitter.

to a much enhanced decay length. The typical  $c\tau$  ( $\sim 450\mu\text{m}$ ) of  $b$ -hadrons is thus scaled by a factor  $\gamma \sim |p_B|/m_B$  which can be large. For high  $p_T$  jets, the  $b$ -hadron can decay at a rather large radius  $R_B$ , as illustrated in Table 3: close to the inner radius of the pixel detector, leading to more tracking ambiguities in the first detection layers, or even after the first pixel layer. In the latter case, the current requirement (for the IPnD and JetProb tagging algorithms) of a hit on the  $b$ -layer actually kills the signal. At very high  $p_T$  (above 500 GeV), these effects become so critical that a dedicated strategy has to be devised, as discussed in the next section. In the current simulation, the  $b$ -hadrons decaying at a radius larger than the beam-pipe or the  $b$ -layer radii do not interact with these objects, while in real events this will even more reduce the performance.

Figure 16: Fraction of selected tracks which are not from B/D decays versus jet  $p_T$ , in  $b$ -jets from  $WH$  ( $m_H = 400$  GeV) events.

Table 3: Fraction of  $b$ -jets in  $WH$  ( $m_H = 400$  GeV) events for which the  $b$ -hadron decays beyond the beam-pipe vacuum (first column) or beyond the  $b$ -layer (second column).

	$R_B > 2.9$ cm	$R_B > 5.1$ cm
all $E_T$	9.0%	2.8%
$E_T > 100$ GeV	12.2%	3.9%
$E_T > 200$ GeV	21.1%	7.9%

## 5.6 The case of very high- $p_T$ jets: exotic physics

The very high  $p_T$  range is defined as jets exceeding a transverse energy of 500 GeV. Identification of such very high  $p_T$   $b$ -jets is required for the search for heavy resonances with (predominantly) hadronic decays. A large number of exotic physics models presents signatures with very high  $p_T$   $b$ -jets, up to a few TeV. An example is the decay  $Z_H \rightarrow Zh$  in the little Higgs model [18], where  $Z \rightarrow e^+e^-$  and  $h \rightarrow b\bar{b}$ .

In the following, three samples corresponding to the process  $Z' \rightarrow q\bar{q}$ , where  $q$  denotes  $u$ ,  $b$  and  $c$  quarks respectively were used. The  $Z'$  mass is chosen to be 2 TeV, so that the primary partons have transverse momenta in the range from 300 GeV to 1 TeV.

The  $b$ -tagging algorithms rely particularly on the determination of the jet axis as an approximation of the  $b$ - and  $c$ -hadron flight direction. The difference between the jet pseudo-rapidity and the true  $b$ -hadron direction exhibits a narrow Gaussian core. The widths of the core range are  $\sigma_\eta \approx 0.025$  and  $\sigma_\phi \approx 0.010$  mrad, with a moderate dependence on jet  $E_T$  and pseudo-rapidity. Non-gaussian tails give rise to large RMS:  $\text{RMS}_{\eta,\phi} \approx 0.050$ . The particles from the decay of the highly boosted  $b$ -hadron are emitted at very small angles. Up to half of the tracks from the  $b$ -hadron decay lie within the azimuthal angle between the  $b$ -hadron and the jet. In these cases the sign of the impact parameter cannot be determined accurately.

The reconstruction of tracks in high  $p_T$  jets presents a series of specific challenges, as already explained in Section 5.5. Particles are associated to reconstructed jets using a  $\Delta R < 0.4$  criterion. To highlight reconstruction effects only true pions reaching the outer radius of the tracker are taken into account. Particles are moreover required to originate from a well-defined vertex: either the primary vertex of the event or the  $b/c$ -hadron decay vertex. Only the first level of the efficiency, i.e. the matching to hits (Section 2.1.2), is considered. With this definition the efficiency on a reference sample of low  $p_T$  jets is close to 100% and essentially independent of the jet energy and of the distance to the jet axis. In Figure 17 the track efficiency in the  $Z'$  sample is plotted versus the jet transverse energy, for the default track reconstruction - NewTracking - and for iPatRec.

The algorithmic reconstruction efficiency for prompt tracks is only slightly degraded. Even in the

Figure 17: Algorithmic tracking efficiency for long-lived pions as a function of the jet transverse energy, for prompt tracks or tracks from  $b/c$ -hadron decays, and for two reconstruction algorithms: NewTracking and iPatRec.

Figure 18: Raw light jet rejection for jets from  $Z' \rightarrow q\bar{q}$  with  $m_{Z'} = 2$  TeV, versus jet transverse energy, for the IP3D+SV1 tagging algorithm (with tracks from iPatRec). and for three  $b$ -tagging efficiencies.

very harsh environment of a 1 TeV jet, the efficiency is approximately 90%. The degradation is most pronounced in the core of the jet ( $\Delta R < 0.1$ ). For pions originating in  $b/c$ -hadron decays a much more significant degradation of the efficiency towards high jet  $E_T$  is observed. For 1 TeV jets the efficiency is approximately 50%. The efficiency shows a strong dependence on the decay vertex radius. It is worth mentioning that NewTracking and iPatRec assign very different errors to the positions defined by large pixel or SCT clusters arising in the inner layers with such dense jets: the former assigns a very small error assuming only one particle was involved in the cluster, while the latter is assuming the opposite and assigns the maximal error (cluster width/ $\sqrt{12}$ ).

In very high  $p_T$  jets the probability that two or more tracks share a hit is very high ( $> 10\%$ ), unlike what was seen for low and moderate  $p_T$  jets (cf. Figure 4). The number of shared hits per track - evaluated for individual sub-detectors, or for the complete silicon tracker - is a factor 2-3 larger in iPatRec. For particles from very displaced  $b/c$ -hadron decay vertices reconstructed with iPatRec, tracks with a shared hit in the  $b$ -layer actually outnumber the tracks with an unambiguous assignment. Again the two tracking algorithms have made opposite choices for their working point: NewTracking considers shared hits are stemming from pattern-recognition errors and tries to assign them to the best track, which is not necessarily meaningful when the cluster is really originating from several near-by particles, while iPatRec does not try to resolve the ambiguity.

The high multiplicity of fragmentation tracks, the degraded tracking efficiency, the ambiguities in hit assignment particularly in the innermost layer and the uncertainty in the impact parameter sign, all render high  $p_T$  jets a harsh environment. This may be improved though by the use of dedicated reconstruction algorithms. A priori, the current simulation should also be updated to transport properly the  $b$ -hadrons through the material. While studies have started, they are beyond the scope of this note. For the time being, a re-optimization of the default tagging algorithm parameters has been performed with the aim of improving the  $b$ -tagging performance over a large jet  $E_T$  range (from 200 GeV to 1 TeV). The cone size for the jet-to-track association was reduced to 0.2 (see Section 7.2 for a possible improvement of the

current treatment), the  $p_T$  cut on tracks raised to 5 GeV and the use of tracks without a hit in the  $b$ -layer was allowed (see also Section 7.1).

The tagging performance on iPatRec tracks is found to be on average 60% better than for the default algorithm. The choice of iPatRec to maintain high tracking efficiency inside dense jets (cf. Figure 3), even at a price of higher fake rates, seems to be instrumental in achieving better performance here. The resulting  $b$ -tagging performance is presented in Figure 18. Given the modest level of rejection achieved, a tagging efficiency of 40% is considered here. Without any tuning, the rejection level of the IP3D+SV1 tagging algorithm would be about three times worse for the same  $b$ -tagging efficiency.

In this study, the standard (low  $p_T$ ) reference histograms were used for the tagging algorithms. So far, none of the methods developed to extract the calibration histograms from data has been shown to work for these very high  $p_T$  jets. Reference histograms for very high  $p_T$  jets may be extracted from Monte Carlo simulation, provided it reliably describes the data. Doing so, a modest improvement of the performance (up to 50% higher light jet rejection for the same  $b$ -tagging efficiency compared to the results shown here) can be achieved.

To conclude,  $b$ -tagging for very high  $p_T$  jets faces a series of specific difficulties. This study demonstrated that a rejection between 10 and 70 for jets with  $p_T > 500$  GeV can be achieved by tuning the current algorithms. Further improvements require dedicated treatments at the clustering level (with probably a second-pass approach to break down large clusters coming from near-by particles) and at the pattern-recognition stage of the track reconstruction. On small preselected datasets, retracking with a specially optimized pattern-recognition algorithm should be possible.

## 6 Specific studies to characterize $b$ -tagging performance

In this section, a few additional studies aimed at better understanding some critical aspects of the  $b$ -tagging performance are detailed. Those studies are described in a separate section because either they required specific datasets or they rely on software and/or cuts/optimizations which are different from the ones currently in use in the ATLAS software.

### 6.1 Impact of residual misalignments

All the studies in this note do not take into account the effect of residual misalignments. While all the samples studied were simulated with misalignments, they were reconstructed assuming a perfect knowledge of those misalignments. However, detailed studies, discussed in Ref. [7], are in progress on this subject. Two different approaches were used: residual misalignment sets and actual realignment. In the former, the events simulated with misalignments are reconstructed using the knowledge of the misalignments, but the true detector elements positions are shifted and/or rotated slightly from their actual position to mimic residual misalignments. The individual pixel modules were shifted by about 10  $\mu\text{m}$  in  $x$  and 30  $\mu\text{m}$  in  $y$  and  $z$ , and rotated by about 0.3 mrad. The pixel layers, disks and the whole detector were displaced by slightly smaller amounts. In this case, the light jet rejection drops by a factor 2 for the same  $b$ -tagging efficiency. For residual misalignments about half as big, the drop in light jet rejection is degraded by 40% compared to the ideal case. The reduction of residual misalignments relies on the actual alignment procedure, which is performed to obtain the new positions of the detector elements. This is the most realistic case considered so far, and includes many (but not all) systematic deformations caused by the alignment procedure itself. In this case, the light jet rejection is at most 25% lower for the same  $b$ -tagging efficiency.

## 6.2 Impact of the tracker material on performance

A major effort has been invested in describing accurately the material in the tracking volume of ATLAS. However, some underestimation is possible. To assess the impact of extra material on the *b*-tagging performance, results with different geometries were compared. Extra material was added, mostly beyond the *b*-layer, increasing the thickness in radiation lengths by about 8% (15%) at  $|\eta| \approx 0(1)$ . The first noticeable effect is the degradation of the impact parameter resolution. The other effect is an increased fraction of particles undergoing interactions in the matter of the detector and producing secondary particles which can, directly or through pattern-recognition problems, fake non-prompt tracks. At a 60% *b*-tagging efficiency, the extra material decreases by 10% the light jet rejection power. About 60% of the loss of rejection is explained by the worsening of the impact parameter resolution, and about 40% by extra secondaries.

## 6.3 Impact of the pixel detector conditions

The pixel detector and notably the innermost *b*-layer are critical for achieving good *b*-tagging performance. The detector efficiency clearly affects the tracking performance but is also explicitly a key ingredient for *b*-tagging since the *b*-tagging quality cuts require that each track have at least two pixel hits of which one is in the *b*-layer. These pixel hit requirements are made in order to maintain the highest resolution on the impact parameter of tracks.

A single pixel inefficiency of 5% has been used to simulate the events. Measurements on the pixel staves before the detector integration gave a single pixel inefficiency below  $\sim 0.3\%$  (and below  $\sim 0.1\%$  for the *b*-layer for which the highest quality components were used). The effect of this inefficiency is especially relevant at small  $|\eta|$  where half of the pixel clusters contain only one pixel. The impact of varying the fraction of randomly distributed dead pixels was studied for three tagging algorithms on a large statistics (600k events)  $t\bar{t}$  sample and the results are shown in Table 4. When decreasing the fraction of dead pixels from 5% to 1%, the tracking efficiency for tracks fulfilling the *b*-tagging quality cuts improves by up to 2.5% absolute (around  $\eta \sim 0$ ), leading to a relative gain in rejection of about 10%.

Table 4: Reference light jet rejection for several tagging algorithms and the relative change with various configurations of the pixel system (see text) for a 60% *b*-tagging efficiency in  $t\bar{t}$  events. The used reference histograms were produced with the respective samples.

	IP2D	IP3D	IP3D+SV1
Reference rejection (5% of dead pixels)	$54 \pm 1$	$77 \pm 2$	$229 \pm 10$
Relative change with 1% of dead pixels	+9%	+10%	+17%
Relative change with a dead half-stave on <i>b</i> -layer	-8%	-8%	-10%
Relative change with a dead bi-stave on <i>b</i> -layer	-34%	-34%	-28%
Relative change with a dead half-stave on external pixel layer	< 1%	< 1%	-1%
Relative change with a dead bi-stave on external pixel layer	-1%	-1%	-4%

More global problems, such as chip and module inefficiencies were not considered in the studies. Their effect has been studied in detail in Ref. [19] and can be very important. However, the latest measurements made right before the detector integration indicate that only one module (in the middle layer) out of 1744 is dead and that fewer than 5 chips are dead out of 27904. Besides single module failures, more dramatic failures might happen. During the pixel operation, it is thought that the two most likely sources of potential failures could be an opto-board failure, leading to half a stave (at most 7 modules) not functioning and a cooling problem implying that a whole bi-stave (26 modules) could

not be used. To study those scenarios, the pixel digitization was modified to disable the corresponding modules, in either the *b*-layer or the external pixel layer. The impact on *b*-tagging performance of these two scenarios is shown in Table 4. In the case of well-identified module failures, it is clear that some recovery strategies can be used, either directly in the tracking code or at least in the *b*-tagging algorithm, for instance by not requiring a hit on a dead module.

## 6.4 Jet algorithms

For *b*-tagging purposes, an accurate knowledge of the jet direction is relevant. In the first place, this direction is used to define which tracks should be associated to the jets. Then it is used to sign the impact parameter of tracks.

As mentioned earlier, all *b*-tagging results are given for jets reconstructed with a cone algorithm of size  $\Delta R = 0.4$ . Since a given physics analysis may opt for a different jet algorithm, the impact of this choice on the *b*-tagging performance is tested in this section. In all cases, as it is the default in the *b*-tagging software, only the tracks within a distance  $\Delta R < 0.4$  of the jet axis were used for the tagging, even for jet algorithms which could benefit from a less geometric track-jet association such as the  $k_T$  algorithm.

Several cone sizes  $\Delta R$  and size parameters  $R$  were studied for the cone algorithm and the  $k_T$  algorithm: from 0.2 to 0.8 in steps of 0.1. Finally, the *b*-tagging performance of the mid-point algorithm [20], an alternate jet algorithm addressing the infrared sensitivity of cone algorithms, was also checked, for two different cone size of  $\Delta R = 0.4$  and 0.7. In this study, electrons faking jets were removed.

Figure 19 shows the rejection of light jets versus the *b*-tagging efficiency obtained with the IP3D+SV1 tagging algorithm, for several jet algorithms run on  $t\bar{t}$  events. Results with and without purification are very different. With purification (Figure 19(b)) there is no significant difference in performance in the relevant range of *b*-tagging efficiency ( $40\% < \epsilon_b < 75\%$ ).

Figure 19: Rejection of light jets versus *b*-tagging efficiency for the IP3D+SV1 tagging algorithm applied on jets reconstructed with different algorithms: cone algorithm with size  $\Delta R = 0.4, 0.7$  or  $k_T$  algorithm with parameter  $R = 0.4, 0.6$ . See text for the last plot.

This stability is the anticipated behavior, since only the jet direction is meaningful for *b*-tagging purposes and it does vary with the jet algorithm but not drastically for moderate jet  $p_T$ : the mean of the distance  $\Delta R(b, jet)$  for a 50 GeV jet is 0.081 for a jet of size  $\Delta R = 0.4$  and 0.095 for a jet of size  $\Delta R = 0.7$  (see Ref. [9] for more details). For completeness, it should be mentioned that no differences were found between tower-based and topological cluster-based jets.

Without the purification procedure (Figure 19(a)), the results are different for different jet definitions. However, the interpretation is not straightforward. In principle broader jets could be more easily contaminated by neighbouring tracks originating from distinct partons whose showers could not be resolved: light jets for instance could be contaminated by heavy-flavour decay products. However, this effect should be marginal since the maximum track-jet distance for association is kept to  $\Delta R = 0.4$  in all

cases.

A better explanation is linked to the ambiguity and arbitrariness of the labelling procedure: with fewer, broader jets the assignment of partons to the jets is more ambiguous and more likely to have  $\Delta R(b, jet) > 0.3$ , and thus more jets wrongly labelled as light jets. Therefore, for example, the rejection at  $\varepsilon_b = 50\%$  with a cone radius  $\Delta R = 0.7$  appears to be three times less than with a cone of radius 0.4, by relabelling the jets with a  $\Delta R$  cut of 0.4 instead of 0.3 this difference can be virtually eliminated as seen in Figure 19(c). Thus although it appears to be more difficult to define the true flavour of a broader jet this does not necessarily exclude the choice of a cone size of 0.7 for a given analysis.

## 6.5 Sensitivity to the calibration of tagging algorithms

Most of the ATLAS tagging algorithms make use of an a priori knowledge to discriminate *b*-jets from light jets, which comes in various forms. The simplest of these ingredients is the transverse impact parameter resolution function used by the JetProb tagging algorithm to measure the compatibility of tracks with the primary vertex. The likelihood ratio tagging algorithms rely on several such distributions, with the further complication that they must be known for both the light and the *b*- hypothesis. In this section, the way this knowledge may affect the performance is studied. It is not currently possible to know if these settings are a good representation, both in nature and amplitude, of the differences data/Monte Carlo that will be observed, but at least they give information about the robustness of the tagging algorithms. All the results are given for the  $t\bar{t}$  sample.

### 6.5.1 JetProb tagging algorithm

JetProb is expected to be one of the first tagging algorithms to be commissioned in ATLAS. To perform well, the resolution function (cf. Section 4.2) must be measured in data to avoid possible short-comings of the Monte Carlo simulation (resolutions and non-gaussian tails mostly). One of the major advantages of this tagging algorithm is that a priori any track from any physics process, e.g. the tracks from the first minimum-bias events, could be used to calibrate the resolution function, provided the contamination of non-prompt tracks can be kept at a very low level.

The sensitivity to this last point was studied by checking two different scenarios to select tracks in order to build the resolution functions. In all cases, only reconstructed tracks with negative impact parameter significance and fulfilling the *b*-tag quality cuts are used. This was done on  $t\bar{t}$  events but similar or better (because of less heavy flavour contamination) results are expected for minimum-bias events. In the ideal case, the tracks are required to match to a true particle whose true origin is at the primary vertex of the event. In the realistic case, this requirement was not enforced. The distributions of the negative impact parameter significance  $d_0/\sigma_{d_0}$  of tracks obtained in the two cases exhibit significant differences in the tails: in the ideal case, 0.6% of the tracks have  $|d_0| > 5\sigma_{d_0}$  (the RMS of the distribution is 1.3) while this fraction is 3.2% for the realistic case (RMS is 2.1). These distributions are then used as resolution functions to measure the *b*-tagging performance on the same events: at a 50% *b*-tagging efficiency, the light jet rejection with the realistic scenario is 15% lower than for the ideal case.

### 6.5.2 Likelihood-based tagging algorithms

For the likelihood-based tagging algorithms, the probability density functions for all the variables (cf. Section 4.1) are built for the *b*-jet and light jet hypotheses using Monte Carlo. The  $t\bar{t}$  channel can be used in data to isolate a sample of pure *b*-jets from which the various distributions can be derived, using the methods described in [9]. However, more than a few hundreds of  $\text{pb}^{-1}$  of data are needed. For the light jets, it seems very difficult to isolate a pure enough sample in data. In this section, the sensitivity

to the calibration is estimated using reference histograms obtained from Monte Carlo with very different settings.

First the impact of using a different tracking algorithm for the calibration (iPatRec) and for the performance measurement (NewTracking) was assessed and led to a very small variation of the rejection power, below 10%. Another study consisted of using different detector descriptions for calibrating and testing: the two geometries compared were relatively similar, with a relative difference in the amount of material in the tracking volume of 8% (15%) at  $\eta \sim 0$  (1). At most a 5% change in rejection power is seen in this case. Another issue is the sample composition of the reference histograms: using only  $t\bar{t}$  events or a mix of  $t\bar{t}$ ,  $WH$  ( $m_H = 120, 400$  GeV) and SUSY events does not change significantly ( $< 5\%$  relative change on rejection power) the  $b$ -tagging performance on a  $t\bar{t}$  sample. However, larger effects are expected when  $b$ -tagging is run on a very different sample from the one used for the calibration.

A possible bias when building the calibration distributions and looking at performance on the same event sample was studied by dividing the sample into two. The bias on the resulting rejection factors was found to be usually negligible, and in all cases below 10%.

Finally, it was checked what statistics are needed to define the underlying histograms for the various tagging algorithms in order for results to be stable. This was checked on semi-leptonic  $t\bar{t}$  events by halving a 600k event sample, building calibrations on 10k, 50k, 100k and 300k events from the first half-sample and checking the performance on the other half. To obtain a rejection level stable within 3%, 50k events are needed for all the IP and SV tagging algorithms when used in a regime where  $\varepsilon_b \geq 50\%$ .

## 6.6 Sensitivity to the Monte Carlo modelling

In the Monte Carlo modelling, several parameters can affect the ability to tag  $b$ -jets. Any effect that can change the lifetimes of the produced particles, the multiplicity of the charged tracks or the momenta of these tracks can potentially change the tagging efficiency. This modelling is not necessarily a good description of data, and in addition it is also performed differently across generators.

### 6.6.1 Fragmentation

First of all, various fragmentation models, describing the non-perturbative process in which quarks hadronize into colorless hadronic states, are implemented in the Monte Carlo generators. For heavy-flavour quarks, two options are available in the PYTHIA generator: the Lund-Bowler model and the Peterson fragmentation model. While the former has been found to give reasonable agreement with experimental data at LEP, SLC and HERA, the latter is currently the default in ATLAS PYTHIA productions. The impact of these various fragmentation models was investigated with six different  $t\bar{t}$  samples. For the Peterson fragmentation, three samples were produced with different values for the  $\varepsilon_b$  parameter: 0.003, 0.006 (default), 0.012. For the Lund-Bowler model, the  $r_Q$  parameter was varied: 0.50, 0.75, 1.0 (default). The maximum relative discrepancy in the  $b$ -tagging efficiency was found to be around 6%, comparing the Peterson model with  $\varepsilon_b = 0.012$  to the Lund-Bowler model for  $r_Q = 0.5$ . However, this choice of parameters is a bit extreme: the difference between the default Peterson model and the Lund-Bowler model with  $r_Q = 0.75$  (which was found to fit best the OPAL and SLD data) leads to an uncertainty on the  $b$ -tagging efficiency of 1.1% for a fixed  $b$ -tagging cut leading to a  $b$ -tagging efficiency of 72%.

### 6.6.2 Heavy flavour production

The production fraction of various  $b/c$ -hadron species can also lead to different  $b$ -tagging efficiencies since they have different lifetimes and decay modes. The measured  $b$ -hadron fractions [15] and their values in the generators are shown in Table 5. For HERWIG, the defaults have been changed following

the CDF tuning [21] by setting the CLPOW parameter to 1.2, in order to obtain a *b*-baryon fraction in agreement with the PDG and with PYTHIA. Another ingredient is the production of excited bottom and charm states which can give rise to soft charged pions or kaons, affecting the topology of the events: this has not been studied yet.

Table 5: Fraction (in %) of *b*-hadron species from the PDG (assuming  $f(B_d) = f(B^\pm)$ ) and in PYTHIA, the default HERWIG and HERWIG tuned for ATLAS (CLPOW=1.2).

	$B_d$	$B^\pm$	$B_s$	Baryons
PDG	$39.8 \pm 1.0$	$39.8 \pm 1.0$	$10.4 \pm 1.4$	$9.9 \pm 1.7$
PYTHIA (ATLAS)	39.7	39.2	12.1	9.1
HERWIG	44.3	44.8	10.8	0.0
HERWIG (tuned)	39.4	39.9	10.4	10.3

The various production fractions of each type of the *b*-mesons were varied according to the measured errors from PDG 2006 [15], and the impact on a simulated PYTHIA  $t\bar{t}$  sample was studied by a re-weighting technique. This source of systematics can be safely neglected since the net effect is an uncertainty below the per mil level on the tagging efficiency.

### 6.6.3 *b*-hadron lifetimes and decays

The uncertainty on the lifetime of the various *b* hadrons was also studied and found to give rise to an uncertainty of 0.3% for a *b*-tagging efficiency of 72%.

The uncertainty in the charged track multiplicity of *b* hadron decays was estimated by comparing PYTHIA with measurements from LEP [22]. The resulting uncertainty on the *b*-tagging efficiency was found to be 0.9%.

### 6.6.4 Heavy flavour decays with EvtGen

The two event generators used in ATLAS to fragment and decay particles, PYTHIA and HERWIG, implement different algorithms to simulate the decays of generated particles, using their own decay tables to specify decay modes and branching fractions. The sophistication of the decay simulation and the scope of decay tables vary considerably between generators. For *B* meson decays, arguably the most detailed simulation is currently provided by EvtGen [23].

Since the *b*-tagging performance on Monte-Carlo samples may depend on details of simulated particle decays, such as the charged particle multiplicity or the spatial distribution of secondary decay vertices in *B* decays, the impact of using EvtGen as a decayer instead of PYTHIA was studied on  $t\bar{t}$  events. For this study, a decay file for inclusive decays was assembled based on the latest (as of summer 2005) version of the decay files used by the BaBar and CDF experiments. For decay channels where experimental data is available, branching fractions were taken from PDG [15], while the remaining decays are simulated generically with JETSET.

For this study, two specific samples were generated: the first  $t\bar{t}$  sample was generated by PYTHIA and the decays were handled by PYTHIA. The second one was generated in the same way except that particle decays were simulated by EvtGen. As expected, changing the particle decay simulation leads to small differences in some distributions of generator-level quantities. For example, the mean multiplicity of charged pions in decays of  $B^\pm$  and  $B^0$  mesons, not including decays of long-lived weakly decaying strange particles such as  $K_s^0$  and  $\Lambda$ , is 3.89 (RMS 2.19) with PYTHIA and 3.62 (RMS 2.13) with EvtGen. The average multiplicity obtained by EvtGen agrees well with the experimental value of  $3.58 \pm 0.07$  [15].

The *b*-tagging weight distributions obtained with the two generators are thus slightly different. For a fixed *b*-tagging weight cut, the *b*-jet efficiency varies by about 1%. Tuning the cut to keep the same *b*-tagging efficiency in both samples leads to non-negligible changes in the light jet rejection: it decreases by about 5% to 15% when EvtGen is used, depending on the tagging algorithm and chosen *b*-jet efficiency.

## 7 Specific studies for improving *b*-tagging performance

In this section, three studies aiming at improving the *b*-tagging performance are presented. Most of them rely on specific software developments.

In the first part, new track categories are defined to make a better use of the slight differences in e.g. impact parameter resolution that such tracks may exhibit. A second study evaluates the potential gain by varying the way tracks are associated to jets. The last study shows the improvement obtained when combining several tagging algorithms in a multivariate approach. Those studies were done independently and no attempt was made yet to combine them. It is worth noting that some approaches advocated in the first two studies are expected to be highly correlated.

### 7.1 Improving performance with track categories

Grouping the tracks used for *b*-tagging in several categories has been discussed in Section 4.1.5. Dedicated treatment for *Shared* tracks (cf. 2.1.3) is already implemented and used in the current *b*-tagging software. Using dedicated probability density functions for the *Shared* tracks improves the light jet rejection by 23% (7%) for a *b*-jet tagging efficiency of 50% (60% respectively) in  $t\bar{t}$  events. This is the default treatment in the software. This effect is sample-dependent and is more important for samples with high jet multiplicities and energetic jets, which tend to be more collimated.

Using additional track categories to improve the *b*-tagging performance is being further investigated. A possible interest of the track categories is to try to loosen the track quality cuts and therefore gain in efficiency without diluting the discrimination power of the good tracks. As discussed in Section 2.1.2, requiring each track to have a hit on the *b*-layer leads to an absolute loss in efficiency of about 2.5%, which is not negligible for *b*-tagging purposes where few tracks are available. Thus one attempt consisted of trying to keep tracks with no *b*-layer hit in a special category. About 4% of the tracks in jets from  $t\bar{t}$  events which pass the rest of the *b*-tagging selection fall in this category.

The categories could also be used to deal with the non-Gaussian resolution tails and the imperfect treatment of the matter in the tracking error estimation process. A priori some fraction of these effects would be better treated from first principles directly in the tracking, but the experience with previous experiments shows that this is difficult in practice and therefore ad-hoc treatments may be justified. The natural variables to partition tracks are  $p_T$  (actually  $p$  for multiple-scattering) and pseudo-rapidity (since the material is very non-uniform in  $\eta$ ).

Finally, another potential use of track categories was studied: in *b*-jets, the fragmentation tracks accompanying the *b*-hadron decay products are prompt and should therefore have different distributions of the discriminating variables. Tracks with  $p_T(\text{track})/p_T(\text{jet}) < 0.04$  were defined as fragmentation tracks since those are in principle softer and were put in a special category. In typical *b*-jets from the  $t\bar{t}$  sample, this cut selects 13% of the tracks. Some correlation with the treatment in  $p_T$  bins (previous case above) is expected.

The use of these categories brings some improvement to the light jet rejection, as high as 60% for the binning in track  $p_T$  which is the most powerful way of partitioning tracks. The improvement for some categories depends on the sample: the dedicated category for fragmentation tracks for example is more helpful for the  $WH$  ( $m_H = 400$  GeV) sample where the actual decay products of the *b*-hadron are very

collimated and the fixed-size cone for associating tracks to the jets brings in a larger fraction of prompt tracks.

Various ways to combine all the new categories were investigated. The gain in rejection brought by the best combinations, using 11 partitions formed with the aforementioned categories, ranges from 20% to 70% depending on the sample and the tagging algorithm, for a 60% *b*-tagging efficiency.

## 7.2 Optimizing the track-to-jet association

As the jet transverse momentum increases, its particles are collimated into a narrower cone. But currently all tracks within  $\Delta R < 0.4$  of the jet axis are associated with the jet, regardless of its momentum. For a 300 GeV *b*-jet, only 30% of the tracks associated to the jet comes from the *b*-hadron decay products, as shown in Figure 16. Therefore at high  $p_T$  the *b*-tagging discriminating power is diluted since a larger fraction of the tracks in the jet may be picked up from environmental contamination: underlying event, pile-up or neighbouring jets in busy events. An alternative track-to-jet association has been studied, with a  $\Delta R$  cut varying with the jet  $p_T$ :  $\Delta R < f(p_T)$ . Based on the distribution of  $\Delta R(\text{jet}, \text{track})$  for tracks originating from *b*-hadron decays in *b*-jets, a functional form  $f(p_T)$  has been chosen which ensures that 95% of the tracks from *b*-hadron decays in these events are associated to the jet for any jet  $p_T$  in the range [15, 500] GeV.

The impact on *b*-tagging performance of using this association instead of the standard one is checked on  $t\bar{t}$  events. The relative improvement on the overall raw light jet rejection is 46% (7%) for respectively a *b*-tagging efficiency of 50% (60%). This improved treatment actually affects only the non-pure jets (22% of the light jets in this sample), for which the rejection triples for  $\epsilon_b = 50\%$  and doubles for  $\epsilon_b = 60\%$ . Obviously the fraction of non-isolated jets and therefore the possible gain with this method are sample-dependent.

## 7.3 Combining tagging algorithms with boosted decision trees

Several multi-variant techniques exist that can combine different *b*-tagging algorithms into a single classifier for discriminating *b*-jets from light jets. We investigated boosted decision trees (BDT).

BDT can be applied to any classification problem and their use for combining several *b*-tagging algorithms into a single classifier for discriminating *b*-jets from light jets was investigated [24]. In this study, a BDT classifier was optimized on a training sample containing *b*-jet and light jet patterns extracted from  $WH$  ( $m_H = 120$  GeV,  $H \rightarrow b\bar{b}$  or  $H \rightarrow u\bar{u}$ ) and  $t\bar{t}$  samples. The following input variables were used: the weight from the IP3D tagging algorithm, the three variables on which the SV tagging algorithms are based (cf. Figure 9), the number of tracks associated with the secondary vertex, the weights of the soft muon and soft electron tagging algorithms, the largest transverse and longitudinal impact parameter significances and transverse momentum of the tracks in the jet, the jet transverse momentum and the number of tracks in the jet. For a fair comparison with IP3D+SV1, a BDT classifier with only the first four variables was also studied. The predictive power of the classifier was estimated using a distinct sample of *b*-jet and *u*-jet patterns (test sample).

Table 6: Rejection of light jets given by IP3D+SV1 and the boosted decision tree for  $WH$  (with  $m_H=120$  GeV) and  $t\bar{t}$  events, for fixed *b*-tagging efficiencies of 50% and 60% in each sample.

	IP3D+SV1		BDT 4 variables		BDT 12 variables	
	$\epsilon_b = 50\%$	$\epsilon_b = 60\%$	$\epsilon_b = 50\%$	$\epsilon_b = 60\%$	$\epsilon_b = 50\%$	$\epsilon_b = 60\%$
$WH$ ( $m_H=120$ GeV)	529±40	155±6	682±79	189±12	762±93	201±13
$t\bar{t}$	393±16	143±3	484±34	161±6	563±42	187±8
$t\bar{t}$ after purification	720±42	205±6	808±73	226±11	1021±103	278±15

Table 6 compares the rejection of light jets given by the two BDT configurations and the likelihood ratio weight IP3D+SV1 for  $WH$  events and  $t\bar{t}$  events. It shows that with the same variables the BDT outperforms IP3D+SV1 by 10 to 30%. When using additional information, including the soft lepton tagging, the light jet rejection on both event topologies increases by about 50% with respect to IP3D+SV1. For these results, the training and test samples were based on similar events ( $WH$  or  $t\bar{t}$ ). When training the BDT on  $WH$  events and using  $t\bar{t}$  events for the test sample, the gain in rejection compared to IP3D+SV1 is lower but still interesting ( $> 20\%$ ).

## 8 Measuring *b*-tagging performance in data

For analyses using *b*-tagging, the estimation of the backgrounds from well-known Standard Model processes requires knowledge of the tagging and mis-tagging efficiency for the various flavours of jets with high accuracy. The quality of Monte Carlo simulation of these properties is unknown and therefore strategies must be developed to measure the tagging and mis-tagging efficiencies directly in data.

### 8.1 *b*-tagging efficiency

Several strategies for measuring the *b*-tagging efficiency directly in data are investigated in detail. The relative precision they permit has been estimated for a typical *b*-tagging efficiency of 60%.

The first approach, described in Ref. [8], relies on a sample of the abundantly produced dijet events, in which one of the jets contains a muon. A muon+jet trigger has been conceived and proposed for this purpose. Two methods, also employed at the Tevatron, are used to estimate the *b*-content of the dijet sample. The  $p_{T_{rel}}$  method is based on templates of the muon  $p_T$  relative to the jet axis. The templates are derived from Monte Carlo events for the three types of jets: bottom, charm and light (the latter will eventually be derived from data). The so-called System 8 method uses two samples of differing bottom quark content and two uncorrelated tagging algorithms, typically the soft muon one and the tagging algorithm to be calibrated, to form a system of equations from which the *b*-tagging efficiency can be extracted. Using  $50 \text{ pb}^{-1}$  of data, a detailed  $p_T$ - or  $\eta$ -dependent calibration curve could be derived with the  $p_{T_{rel}}$  method and with System 8. Since it is expected that the systematic uncertainties will dominate rapidly the total error for these methods, a careful study of systematics errors has to be done which was not fully completed for this note: the systematic errors studied so far indicate that it should be possible to control the absolute error on  $\epsilon_b$  to 6%. Currently the two methods are proven to work well for jets below a  $p_T$  of 80 GeV.

The second approach, discussed in Ref. [9], makes use of  $t\bar{t}$  events and is complementary: a little more data is needed but the tagging efficiency of higher  $p_T$  jets can be measured. Two distinct ways are described: by counting the number of selected  $t\bar{t}$  events with one, two or more *b*-tagged jets, or by studying directly the output distributions of *b*-tagging algorithms on samples of *b*-jets pre-selected by several methods (topological, kinematic or likelihood selection). The counting method allows measurement of the integrated *b*-tagging efficiency with a relative precision of  $\pm 2.2(\text{stat.}) \pm 3.5(\text{syst.})\%$  in the lepton+jets channel and  $\pm 3.7(\text{stat.}) \pm 2.7(\text{syst.})\%$  in the di-lepton channel for  $100 \text{ pb}^{-1}$  of data. For the topological selection,  $200 \text{ pb}^{-1}$  of data are needed and allow a relative precision of  $\pm 7.7(\text{stat.}) \pm 3.2(\text{syst.})\%$ .

### 8.2 Mis-tagging rates

Measuring the mis-tagging rate in data is more difficult and under study. The main approach is to use the negative tags (either in impact parameter or decay length) which describe the effects of a limited resolution on a priori prompt tracks and then to correct for long-lived particles ( $K_s$ ,  $\Lambda$ , etc), material interactions and heavy flavour jets which are negatively tagged. So far no study in ATLAS has estimated

the accuracy with which fake rates can be measured. However, based on the Tevatron experience, it seems that a 10% relative error could be achievable with  $100 \text{ pb}^{-1}$ .

### 8.3 Extracting reference distributions from data

For the likelihood tagging algorithms, reference distributions for light and *b*-jets are needed. In the case of *b*-jets, they could in principle [25] be measured in data from a pure sample of *b*-jets using the techniques developed for the *b*-tagging efficiency estimation in  $t\bar{t}$  events. As shown in Ref. [9], the various distributions can be checked in data with a few hundred  $\text{pb}^{-1}$ . However, much more data is needed to extract multi-dimensional likelihoods. For light jets, it seems difficult to extract from data a sample with sufficient purity. In any case, a Monte Carlo accurately describing the data is also needed to extrapolate those reference distributions to ranges where they certainly can not be measured, the very high- $p_T$  regime for instance.

## 9 Conclusions and outlook: realistic performance in first data

The first tagging algorithm to be commissioned with real data is expected to be (besides the track counting method) JetProb, using the tracks from any kind of events to define its resolution function. For a *b*-tagging efficiency of 60%, a light jet rejection of around 30 could be achieved with this tagging algorithm but further improvements are expected. The soft lepton tagging algorithms will be commissioned at the same time, leading to higher rejection levels when considering semi-leptonic *b*-jets. Once the quality of the Monte Carlo simulation is checked and better understood with data, a tagging algorithm relying on Monte Carlo templates for *b* and light jet hypotheses such as IP3D can be used, perhaps doubling the rejection power. The commissioning of the tagging algorithms relying on secondary vertexing may take more time, but tagging algorithms like SV1 should quadruple the initial rejection level, bringing it above 100. Finally the combination of the ultimate JetFitter tagging algorithm and the various improvements described in this note should permit a rejection of 200, or more interestingly to maintain a rejection of 100 at a higher *b*-tagging efficiency, around 70%.

Those estimates do not take into account the impact of residual misalignments in the tracker. However, a first study has been performed in which the actual alignment procedure was run. This is the most realistic study so far, and includes many systematic deformations caused by the alignment procedure itself. It concludes that the mis-tagging rate is at most 30% lower for the same *b*-tagging efficiency with a realistic early detector alignment.

The impact of several other effects on the *b*-tagging performance has been studied in this note. In the simulation used, the fraction of dead pixels is overestimated. Using 1% instead of 5% dead pixels improves the light jet rejection by about 10%. Relative improvement in the light jet rejection, from 10% in typical  $t\bar{t}$  events to 50% for high- $p_T$  samples, could be achieved with a tuning of the tracking in jets. The sensitivity to the accuracy of the passive material description in the simulation could be quite dramatic. However, a large effort has been made in describing accurately the material in the tracking volume. If an 8% to 15% discrepancy between Monte Carlo and data would remain, the impact on the *b*-tagging performance is a 10% relative change in light jet rejection power.

New ideas to improve the performance have been studied: the generalization of the track categories could bring a 10% to 60% improvement, optimizing the track-to-jet association could help significantly in busy events and finally the use of multivariate techniques such as BDT could lead to gains in the range 10-50%. However, all these potential gains only apply to some tagging algorithms, some  $p_T$  region, etc. Furthermore some correlations are expected among them. Therefore it will be interesting to assess the net impact of these improvements when they are all available, used simultaneously and optimized.

Finally, detailed studies have shown that the  $b$ -tagging efficiency can be measured directly in data using dijet or  $t\bar{t}$  events. With  $100 \text{ pb}^{-1}$ , a relative precision of about 5% can be achieved for  $b$ -jet efficiency. The accuracy with which the mis-tagging rates can be measured deserves more study, however, a 10% precision seems feasible based on the Tevatron experience.

# Vertex Reconstruction for $b$ -Tagging

## Abstract

Tagging of  $b$ -quark jets, “ $b$ -tagging”, is an important ingredient for Standard Model analyses as well as for searches for new physics. A property of  $b$ -quark jets exploited by  $b$ -tagging algorithms is the presence of secondary  $b$ - and  $c$ -hadron decay vertices. In this note, methods for the explicit reconstruction of secondary and/or tertiary decay vertices of  $b$ - and  $c$ -hadron decays are presented. The performance of the secondary vertex based  $b$ -tagging algorithms and the dependences on the event topology and jet kinematics are studied. The efficient reconstruction of the primary interaction vertex is also crucial for  $b$ -tagging, especially in the presence of pile-up interaction vertices at LHC luminosity. The ATLAS primary vertex reconstruction strategies and performances are presented in this note as well.

## 1 Introduction

Identification of  $b$ -quark jets relies on the properties of the production and weak decay of  $b$ -hadrons. The most important one is their relatively large lifetime of about 1.5 ps ( $c\tau \approx 450\mu\text{m}$ ). The resulting  $b$ -hadron flight path  $\langle l \rangle = \beta\gamma c\tau$  leads to a signature of one or more displaced secondary vertices (e.g. inside a jet originating from a  $b$ -quark with transverse momentum of 50 GeV  $b$ -hadrons travel on average about 3 mm in the transverse plane before their decay).

Numerous methods can be used for the identification of  $b$ -quark jets (usually called  $b$ -jet tagging or just  $b$ -tagging), based e.g. on the presence of leptons inside jets due to semileptonic  $b$ -hadron decays, kinematical properties of jets or explicit  $b$ - or  $c$ -hadron reconstruction. The most efficient tagging methods are based on the presence of displaced vertices inside jets. Such vertices can be detected either by the presence of tracks incompatible with the primary event vertex or by explicit reconstruction of those secondary vertices. Many track based and vertex based  $b$ -tagging methods are known together with combined methods using both track impact parameters and vertex reconstruction simultaneously.

The reconstruction of secondary  $b$ -hadron decay vertices inside jets is challenging for several reasons. The multiplicity of charged particle tracks belonging to the vertex is, contrary to the reconstruction of exclusive decay modes, a-priori not known. In cases of less than two reconstructed charged particles, a well defined secondary vertex cannot be reconstructed. This can happen either because of the charged particle multiplicity produced in the decay or limitations in the track reconstruction efficiency, as imposed by the geometrical acceptance of the inner tracking detectors or interactions in the detector material. Secondary vertex reconstruction efficiencies thus show an upper limit. In addition, weak  $b$ -hadron decays almost always lead to one or more charm hadrons which subsequently decay through weak interaction. Since  $c$ -hadrons also have significant lifetimes, the resulting topology is a set of charged particle tracks either stemming from the primary event vertex, the secondary  $b$ -hadron or tertiary  $c$ -hadron decay vertices. The resolution of the ATLAS tracking system does not resolve this decay topology in all cases. Vertex reconstruction inside jets for  $b$ -jet tagging thus has to be done in an inclusive way. It should be targeted towards highest efficiency to detect secondary vertices and identify its topology as well as possible. Kinematical features of reconstructed vertices like e.g. the invariant mass may be used in combination with spatial features (track-vertex and vertex-vertex distances, etc.) to increase the  $b$ -jet identification power of the algorithms.

Another important ingredient for tagging  $b$ -quark jets is the reconstruction of the primary event vertex. The size of the beamspot in the transverse plane (about 15  $\mu\text{m}$ ) is sufficiently small to allow the application of  $b$ -tagging algorithms if only information as defined in the transverse plane is used,

once the position of the beam is known with high precision. Explicit reconstruction on event by event basis does not improve significantly the resolution of the primary event vertex in the transverse plane. In the longitudinal direction along the beam, however, the a-priori knowledge of the interaction point is only poor (several cm). Explicit reconstruction is thus mandatory if *b*-tagging algorithms are not only based on track and vertex information in the transverse plane. Furthermore, at nominal running of the LHC, additional minimum bias events produce additional so-called pile-up vertices which have to be distinguished from the hard primary interaction. The main task of the primary vertex reconstruction for *b*-tagging is thus to reconstruct and identify the signal event vertex out of all interaction vertices along the beam.

At the LHC, *b*-tagging has to be applied to jets covering a wide kinematic range both in transverse momentum and pseudorapidity. *b*-tagging has to be applied over the full acceptance of the tracking detectors of about  $|\eta| < 2.5$ . The track reconstruction performance, and thus also the vertex reconstruction and *b*-tagging performance, varies strongly with transverse momenta and pseudorapidities of charged particle tracks.

This note focuses on aspects of primary and secondary vertex reconstruction relevant for *b*-tagging. Other aspects, also more technical ones, and performance issues are addressed in notes dedicated to primary [1] and secondary vertex reconstruction [2, 3]. The note is structured as follows. In Section 2 some information on definitions, physics input objects and data sets used in this note is given. Section 3 describes the reconstruction of the primary event vertex, its performance and impact on *b*-tagging. Algorithms designed for the inclusive reconstruction of secondary decay vertices inside jets based on two different methods are described in Section 4. The performance of these algorithms in terms of secondary vertex related quantities is discussed in Section 5. Their combination with the pure track impact parameter based *b*-tagging algorithms is described in Section 6. The *b*-tagging performance of the algorithms is presented in Section 7. Section 8 gives a summary of the note together with an outlook towards possible future improvements.

## 2 Definitions, Reconstruction Details and Datasets

This section gives definitions and technical details of data reconstruction and analysis procedures used in this note. More detailed information can be found in [4].

The efficiency to tag a jet of flavour *q* as *b*-jet,  $\epsilon_q$ , is defined as:

$$\epsilon_q = \frac{\text{Number of jets of real flavour } q \text{ tagged as } b}{\text{Number of jets of real flavour } q}. \quad (1)$$

Usually  $\epsilon_b$  is called *tagging efficiency* and  $\epsilon_{udsc}$  *mistagging rate*. The inverse of the mistagging rate  $r_{udsc} = 1/\epsilon_{udsc}$  is called *b-tagging rejection power* or simply *rejection*. The assignment of a certain flavour to a jet in the Monte Carlo simulation is not unambiguously defined. The following definition has been introduced: the jet flavour is the flavour of the heaviest quark after gluon radiation and splitting within a cone of some size around the jet direction. The default cone size used in ATLAS and in the current note is  $\Delta R < 0.3$ . To test the pure algorithmic performance of the algorithms, a procedure called “purification” may be applied. Here, a light quark jet is only considered if there is no heavy parton (*b*- or *c*-quark) or  $\tau$  lepton within a cone of 0.8 around the jet direction.

Several jet reconstruction algorithms are available in ATLAS [5]. The *b*-tagging performance may depend on the jet algorithm, but the studies of this dependence are outside the scope of this note (see [4] for such studies). For the studies in this note, an iterative cone algorithm with a cone size of  $\Delta R = 0.4$  using combined calorimeter towers as input, has been used. Charged particle tracks have been reconstructed with a Kalman filter based algorithm [6].

Offline ATLAS jet reconstruction and track reconstruction are independent. An assignment of tracks to jets is thus necessary. The current ATLAS method used also in this note is also based on a geometrical cone around the jet direction. All charged tracks within a certain cone (the default value is  $\Delta R < 0.4$ ) around the jet axis are assigned to a jet.

The following fully simulated Monte Carlo samples have been used for the performance studies described in this note:

- Higgs boson production in association with a  $W$  boson. The  $W$  boson was forced to decay into a muon and its anti-neutrino,  $W \rightarrow \mu \bar{\nu}_\mu$ , the Higgs boson was forced to decay into pairs of  $b$ -,  $c$ - or  $u$ -quarks:  $H \rightarrow b\bar{b}$ ,  $H \rightarrow c\bar{c}$ ,  $H \rightarrow u\bar{u}$ . This ensures that the jets of different quark flavour have very similar kinematics. To cover a wide range of jet transverse momenta, samples with Higgs boson masses of  $m_H = 120$  GeV and  $m_H = 400$  GeV have been produced.
- Events with pairs of top quarks,  $t\bar{t}$ , where one or both  $W$  bosons decayed leptonically.
- Events with pairs of top quarks and at least two additional jets:  $t\bar{t}jj$ . These events show a large hadronic activity with a high probability of overlapping jets.

During the first few years the LHC will operate at a luminosity of  $2 \cdot 10^{33} \text{ cm}^{-2}\text{s}^{-1}$  (low luminosity mode), reaching  $10^{34} \text{ cm}^{-2}\text{s}^{-1}$  (high luminosity mode) at later stages. Each signal event triggered and reconstructed in the ATLAS detector will be overlayed by several low- $p_T$  proton-proton interactions, commonly denoted as minimum bias interactions. The average number of minimum bias interactions per bunch crossing is 4.6 and 23 for the low and high luminosity modes, respectively. To study the influence of these additional so-called *Pile-Up* interactions, fully simulated Monte-Carlo samples for the low luminosity mode have also been generated for the WH ( $m_H = 120$  GeV) data set.

To parametrize the trajectory of a charged particle in a magnetic field, so-called “perigee” parameters are used [6]. The ATLAS track based *b*-tagging algorithms use  $d_0$  and  $z_0$ , the transverse and longitudinal impact parameters at the point of closest approach of the trajectory to the primary vertex in the transverse plane. To reduce the dependence on the track parameter resolutions, the corresponding variables are divided by their errors. Each impact parameter *significance* also gets a sign based on the track and jet directions. The sign is positive if the track crosses the jet axis in front of the primary vertex and negative if behind. Most of the tracks produced in *b*-hadron decays have a positive sign whereas tracks originating from the primary vertex have both signs with equal probabilities [4]. The distance between the primary and secondary vertices may also have a sign based on the jet direction.

### 3 Primary Vertex Reconstruction

In this section different strategies for the reconstruction of primary vertices currently implemented in the ATLAS reconstruction software are described. The evaluation of the algorithms is performed in the *single collision* and low luminosity pile-up modes.

The reconstruction of primary vertices can generally be subdivided into two problems: vertex finding and vertex fitting. The primary vertex finding deals with the association of reconstructed tracks to a particular vertex candidate. The task of the vertex fitting is to reconstruct the position of the primary vertex and its covariance matrix, recalculate the parameters of the incident tracks using the vertex constraint and provide a measure of goodness of the fit, such as for example the  $\chi^2$  of the fit [7]. In addition, the  $\chi^2$  of the refit of track parameters with the knowledge of the reconstructed vertex is a criterion of track to vertex compatibility.

A brief description of the mathematical properties of the algorithms for primary vertex reconstruction and evaluation of their performance with respect to *b*-tagging are presented below. For a more detailed description of the algorithms the reader is referred to [1].

### 3.1 Algorithms for Vertex Fitting

Several strategies for vertex fitting are currently implemented in the ATLAS reconstruction software. All implemented vertex fitters are based on the minimization of a  $\chi^2$  function with respect to a position of the vertex and parameters of incident tracks at this position. In addition, all fitters are currently using the exact analytical solution for the dependence of the track parameters on the vertex position and track parameters at the vertex. Indeed, the full solution with respect to the ATLAS version of perigee parametrization has a simple form, which is also computationally economical [1]. The approach to the minimization of the  $\chi^2$ , treatment of components of track momenta in the vicinity of the vertex candidate and reweighting of tracks during the iterative process, however, differs from algorithm to algorithm.

#### 3.1.1 The Billoir Full and Fast Vertex Fitting Algorithms

Two algorithms, the *Billoir Full* and the *Billoir Fast Vertex Fitter* were implemented, following the schema presented in [8]. Here, the inversion of the full  $(3n + 3) \times (3n + 3)$  matrix<sup>1</sup> of parameters of the fit, where  $n$  is the number of tracks, is replaced with  $n$  inversions of  $(3 \times 3)$  matrices. Compared to the global  $\chi^2$  minimization, this approach leads to a significant gain in CPU time due to the inversion of smaller matrices. In addition to the reconstruction of the vertex position and its covariance matrix, the *Billoir Full Vertex Fitter* also refits the parameters of the incident tracks with the knowledge of the vertex.

The *Billoir Fast Vertex Fitter* is a simplified version of the vertex fit, where the trajectories of charged particles are approximated with straight lines in the vicinity of the vertex and their momentum components  $p = (\theta, \phi, q/p)$  are considered to be constant. While the precision of this approach is only a little smaller than the one of the *Full Billoir Vertex Fitter*, the fit itself is significantly faster due to the reduction of the size of covariance matrices to be inverted. It should also be noted, that the *Fast Vertex Fit* does not refit the momenta of the incident tracks. Due to its reasonable resolution and high CPU performance, this is the default vertex fitter to be used with *InDetPriVxFinder*, as explained in Section 3.2.1.

#### 3.1.2 The Sequential and Adaptive Vertex Fitting Algorithms

The *Sequential Vertex Fitter* implements the conventional Kalman Filter for vertex fitting as described in [7]. The vertex estimate is updated iteratively using the information from a single track at a time. The *SequentialVertexSmoother* allows the refit of parameters of incident trajectories with the knowledge of the reconstructed vertex position. In addition, the smoother allows for a calculation of the smoothed  $\chi^2$  of a track, which is a good criterion of compatibility of a track to a vertex.

A robust version of the above algorithm is the *AdaptiveVertexFitter*. It is an iterative reweighted Kalman Vertex Fitter, where each track is down-weighted according to its compatibility to the actual vertex position [9]. The dependence of the weighting factor on the iteration number of the fit is determined by a thermodynamic annealing procedure. The assignment of tracks to a vertex candidate thus becomes stronger with iterations and the outliers are efficiently discarded.

#### 3.1.3 The TrkVKalVrtFitter Algorithm

The *TrkVKalVrtFitter* is a universal vertex fitter with constraints. It uses the Billoir method [8] to estimate the local vertex position and calculate refit track parameters with the requirement of passing through the vertex position. The possibility of applying a beam spot constraint when reconstructing the primary vertex is also provided. Neutral and charged particles can be used simultaneously in the fit.

<sup>1</sup>In the vicinity of the vertex, the polar angle  $\theta$  and the momentum  $p$  of the trajectories are considered to be constant. The number of parameters of the fit therefore reduces to  $3n + 3$ : 3 remaining parameters for each of  $n$  tracks and 3 vertex coordinates.

In the presence of badly measured tracks the precision and stability of the fit may be improved by the optional use of robust functionals. In each iteration step the error matrix for each track is recalculated based on an eigenvector decomposition and downweighting of badly measured directions in the track parameter space. Several functionals for downweighting known as *M-type estimators* are implemented [2].

### 3.2 Vertex Finding Strategies

Three different strategies for primary vertex finding are currently implemented. These are the *InDetPriVxFinder*, the *InDetAdaptiveMultiPriVxFinder* and the *VKalVrtPrim*. In the *InDetPriVxFinder* the process of primary vertex finding is decoupled from the vertex fitting and the maximal number of reconstructed vertices is therefore defined at the seeding step. The latter two algorithms exhibit a *finding through fitting* approach, where the number of vertex candidates changes according to the results of the previous iteration of the fit.

#### 3.2.1 The InDetPriVxFinder Algorithm

The reconstruction strategy of the Inner Detector Primary Vertex Finder consists of three steps. It starts with the selection of good quality tracks originating from the beam crossing area (the detailed selection cuts can be found in [1]).

After this initial track preselection, clusters in  $z$  are searched for in the resulting set of tracks. A simple sliding window algorithm is used for this purpose. First, the tracks are ordered in ascending order of their  $z_0$  impact parameter. The full range of  $z_0$  impact parameters is then scanned and clusters of fixed length are formed. In the low luminosity scenario, the default maximal cluster length was chosen to be 3 mm. The resulting clusters of tracks are considered as independent primary vertex candidates and corresponding vertices are reconstructed with the provided vertex fitting algorithm.

After the reconstruction of the initial vertex candidates, the tracks least compatible with a given vertex candidate are rejected and the vertex candidate is refitted (the *Billoir Fast Vertex Fitter* described in 3.1.1 is used by default) using one of the following procedures:

- All tracks, with a  $\chi^2$  contribution greater than a predefined value (by default, the threshold of  $\chi^2 = 5$  per track is chosen) are discarded and the vertex candidate is reconstructed again using remaining tracks.
- The least compatible tracks are removed from the vertex candidate iteratively one by one until no track with a  $\chi^2$  contribution greater than a predefined value is left or the number of remaining tracks is too little to continue. The vertex candidate is refitted at each iteration.

At present, the first algorithm is used as the default one. At the last stage of the primary vertex reconstruction, the obtained vertex candidates are sorted in descending order according to the sum of transverse momenta of their tracks. The vertex with the highest  $\sum p_T$  of the tracks is tagged as the signal one. It should be noted that the maximum number of reconstructed primary vertices is fully defined by the output of the cluster finding in the beginning of the algorithm. The iterative refit of the vertex candidates followed by the rejection of incompatible tracks serves for the refinement of the knowledge of the vertex positions only. The minimum number of tracks to form a vertex candidate is one in the case when the beam position is used as constraint, and two otherwise.

#### 3.2.2 The InDetAdaptiveMultiPriVxFinder Algorithm

The *InDetAdaptiveMultiPriVxFinder* is an example of a *finding-through-fitting* approach to the primary vertex reconstruction. The reconstruction starts with the preselection of tracks originating from the

beam crossing region (the detailed selection cuts can be found in [1]). A single vertex seed is created out of the preselected set of tracks. A vertex candidate is then reconstructed using the Adaptive Multi Vertex Fitter [10], as described in 3.1.2. The tracks which were considered to be outliers during the first fit are used to create a new vertex seed. At the next iteration a simultaneous fit of two vertices is performed. Each track is down-weighted with respect to the two vertices. The number of vertex candidates is growing with iterations and the vertices are competing with each other in order to attain more tracks. An annealing procedure is applied to this process: the assignment of tracks to vertices is becoming harder with iterations. The result of the fit is a set of reconstructed vertices with an almost solid track assignment. It has to be noted that for the adaptive fitters the starting point of the fit is of great importance.

### 3.2.3 The VKalVrtPrim Algorithm

In this algorithm, primary vertex reconstruction starts with the selection of a subset of tracks close to the beamspot position. A sliding window type algorithm (with window size  $\approx 4.5$  mm) selects a position along the beam which maximizes the vertex candidate quality value. This position becomes a seed for the vertex fitter. It accepts all tracks close to the found vertex candidate position and tries to fit a single vertex. If the quality of the vertex is not satisfactory, one or several tracks with the biggest  $\chi^2$  contribution are rejected and the fit is repeated. The algorithm works until a vertex with good quality is obtained. Best results may be achieved with the combination of a robust fitting functional and the rejection of tracks during the fit. After a successful fit, the participating tracks are removed from the set of selected tracks and the sliding window algorithm starts a search of the next vertex candidate for the remaining tracks. *VKalVrtPrim* runs until no more vertex candidates can be obtained in the remaining track sample.

The vertex candidate quality value used in the search is a sum of the track transverse momenta, the transverse mass and  $p_T$  nonuniformity in the transverse plane. The vertex fitter uses the beam spot position as constraint in the fit.

## 3.3 Performance of Primary Vertex Reconstruction

In this section, the performance of different primary vertex reconstruction algorithms is evaluated. The studies are performed in single collision and low luminosity pile-up modes.

As mentioned above, the main tasks of primary vertex finding algorithms are:

- To find all primary vertices in a bunch crossing and reconstruct their positions with highest possible accuracy.
- To identify the hard scatter signal primary vertex among the set of reconstructed vertices with highest possible efficiency.

These two aspects will be investigated in the following. In this section the performance of five strategies for primary vertex reconstruction are compared: *VKalVrtPrim*, *InDetAdaptiveMultiPriVxFinder* and *InDetPriVxFinder* used with *SequentialVertexFitter*, *Billoir Fast* and *Billoir Full Vertex Fitters*. Monte Carlo samples of  $WH(120) \rightarrow \mu\nu b\bar{b}$  and  $WH(120) \rightarrow \mu\nu u\bar{u}$  events with and without low luminosity pile-up are used for this study.

### 3.3.1 Efficiency of Hard Scatter Signal Primary Vertex Identification

As mentioned above, an average of 4.6 minimum bias events are expected to overlay the signal event during low luminosity running of the LHC. The number of simulated primary vertices per bunch crossing, corresponding to the low luminosity mode of the LHC is shown in Figure 1 (left), together with the

Figure 1: Left: Number of simulated (black line) and reconstructed vertices per event for different reconstruction algorithms (dotted lines); right: distribution for the *InDetAdaptiveMultiPriVxFinder* of the primary vertex purity as defined in Eq. (2). The  $WH(m_H = 120\text{GeV}) \rightarrow \mu\nu b\bar{b}$  event sample has been used for these studies.

number of primary vertices reconstructed with different algorithms. All primary vertex finders return containers of reconstructed vertices ordered according to the probability of a given vertex to be produced in a signal collision. The identification of a signal vertex (first in the list) is performed in different ways depending on the algorithm. The *InDetPriVxFinder* orders the vertices according to the sum of transverse momenta of incident tracks, while the output of the *InDetAdaptiveMultiPriVxFinder* is sorted according to the sum of squares of transverse momenta. In all cases, the first vertex in the list is considered to be the primary signal vertex and is used by the *b*-tagging algorithms. In order to estimate the efficiency to find the correct signal vertex from the list of primary vertices two methods are used. In the first method the signal vertex is considered as reconstructed correctly if it is closer than  $500\text{ }\mu\text{m}$  in the  $z$  direction from the truth:  $|z_{\text{rec}} - z_{\text{truth}}| < 500\text{ }\mu\text{m}$ . The second method is based on the purity of reconstructed vertices. The definition of the primary vertex purity is based on the association of tracks fitted to a primary vertex to truth particles:

$$P = \frac{\sum w_{\text{signal}}}{\sum w_{\text{signal}} + \sum w_{\text{pileup}} + \sum w_{\text{noCorres}}} \quad (2)$$

where  $\sum w_{\text{signal}}$  is the sum of weights of all tracks associated with the signal primary vertex,  $\sum w_{\text{pile-up}}$  is the sum of weights of all tracks associated with pile-up events and  $\sum w_{\text{noCorres}}$  is the sum of weights of all tracks which were not matched to truth particles. It can be noted that for vertex algorithms which do not assign lower weights to tracks with respect to the vertex candidate during the fit, the sum of the weights of all tracks fitted to the vertex is equal to the track multiplicity. If the value of the purity for a reconstructed primary vertex candidate is above 0.5, it is assumed that the main contribution to the reconstructed vertex stems from signal tracks and therefore the signal primary vertex is correctly identified.

In Figure 1 (right) the distribution of the purity of the first vertex in the output list of the *InDetAdaptiveMultiPriVxFinder* for  $WH(120) \rightarrow \mu\nu b\bar{b}$  events is shown. It can be noted that in the majority of cases the purity of a tagged signal primary vertex is close to unity.

In Table 1 the fraction of events with correctly identified vertices for both distance based and purity based definitions are shown for different reconstruction algorithms. The  $WH(120) \rightarrow \mu\nu b\bar{b}$  and  $WH(120) \rightarrow \mu\nu u\bar{u}$  Monte Carlo samples with low luminosity pile-up were used for this study. It can be noted that the best performance is shown by the *InDetAdaptiveMultiPriVxFinder* and by *VKalVrtPrim*.

Table 1: Fractions of correctly identified primary vertices for different primary vertex reconstruction algorithms. The fractions are calculated according to the purity based (1) and distance based (2) definitions of the efficiency. The fraction of events where the signal vertex is in the list of reconstructed vertices (column denoted *in list*) is calculated according to the distance based definition.

<i>InDetPriVxFinder (Billoir Full)</i>	$89.8 \pm 0.2$	$89.3 \pm 0.2$	$97.6 \pm 0.1$	$94.0 \pm 0.2$	$93.8 \pm 0.2$	$98.2 \pm 0.1$
<i>InDetPriVxFinder (Billoir Fast)</i>	$89.8 \pm 0.2$	$89.3 \pm 0.2$	$97.6 \pm 0.1$	$94.0 \pm 0.2$	$93.8 \pm 0.1$	$98.2 \pm 0.1$

Also no significant difference is observed between purity based and distance based definitions of the efficiency. In addition, the observation is made that in the single-collision mode, the rate of wrongly identified vertices is essentially zero for all algorithms.

The misidentification of the signal vertex leads to a wrong estimate of the longitudinal impact parameters of tracks. This wrong estimate may lead to an incorrect identification of *b*- and light quark jets and a decrease of the *b*-tagging performance. A dependence of the *b*-tagging performance on the type of the primary vertex reconstruction algorithm is therefore expected.

### 3.3.2 Pointing Lepton

In the events containing isolated leptons (electrons or muons), or even a lepton inside a jet coming possibly from semileptonic decays of heavy hadrons, the properties of these leptons can be used to further increase the efficiency to identify correctly the primary vertex. The trajectory of a reconstructed lepton can be extrapolated to the interaction region. Each reconstructed vertex, for which the lepton has a longitudinal impact parameter  $z_0 < 3$  mm, gets an additional weight and can then be tagged as the signal vertex after reordering the list of reconstructed vertices. In Table 2 the fractions of events with correctly identified primary vertices after reordering according to the pointing lepton information are shown for different primary vertex finding algorithms. To estimate these fractions, the distance based definition of efficiency is used. Comparing to Table 1, it can be noted that the use of information from a reconstructed lepton increases the efficiency of correctly identifying the signal primary vertex in case of the *Billoir fitters*, which use the sum of squares of transverse momenta of tracks as sorting criteria. In most cases of misidentified vertices, the direction of the isolated lepton from the *W* boson decay is not in the kinematical acceptance of the inner detector, e.g. for the *InDetAdaptiveMultiPriVxFinder* ( $73 \pm 1$ )% of the outliers have the isolated muon with  $|\eta_\mu| > 2.5$ . Events with a well reconstructed isolated lepton, as it is the case in many analyses, thus show a much lower fraction of misidentified primary vertices.

Table 2: Fraction of correctly identified primary vertices for different algorithms using the distance based definition with reordering due to a lepton matched to the primary vertex.

	$WH \rightarrow \mu\nu b\bar{b}$	$WH \rightarrow \mu\nu u\bar{u}$

<i>InDetPriVxFinder (Billoir Full)</i>	$93.7 \pm 0.1$	$95.0 \pm 0.1$
<i>InDetPriVxFinder (Billoir Fast)</i>	$93.7 \pm 0.1$	$95.0 \pm 0.1$

### 3.4 Primary Vertex Resolution

In presence of the pile-up vertices spatial resolutions of the reconstructed primary vertex may degrade due to the partial acceptance of tracks from the superposed events. Tables 3 and 4 show the resolutions for the  $x$  and  $z$  coordinates of reconstructed primary vertices for different reconstruction algorithms.

Table 3: Resolutions on the  $x$  coordinate of primary vertices reconstructed with different strategies in  $WH \rightarrow \mu v b \bar{b}$  and  $WH \rightarrow \mu v u \bar{u}$  signal only and pile-up scenarios. The numbers shown are the widths of a fit with a single Gaussian to the corresponding distributions of residuals.

Algorithm	$\sigma_x$ [ $\mu\text{m}$ ] in $WH \rightarrow \mu v b \bar{b}$		$\sigma_x$ [ $\mu\text{m}$ ] in $WH \rightarrow \mu v u \bar{u}$	
	signal only	pile-up	signal only	pile-up
<i>InDetAdaptiveMultiPriVxFinder</i>	$11.46 \pm 0.05$	$11.66 \pm 0.05$	$10.13 \pm 0.05$	$10.34 \pm 0.05$
<i>VKalVrtPrim</i>	$11.44 \pm 0.05$	$11.59 \pm 0.05$	$10.04 \pm 0.05$	$10.25 \pm 0.06$
<i>InDetPriVxFinder (Billoir Full)</i>	$12.22 \pm 0.05$	$12.51 \pm 0.05$	$11.01 \pm 0.06$	$11.17 \pm 0.05$
<i>InDetPriVxFinder (Billoir Fast)</i>	$12.23 \pm 0.05$	$12.50 \pm 0.05$	$11.01 \pm 0.06$	$11.17 \pm 0.06$

Table 4: Resolutions on the  $z$  coordinate of primary vertices reconstructed with different strategies in  $WH \rightarrow \mu v b \bar{b}$  and  $WH \rightarrow \mu v u \bar{u}$  signal only and pile-up scenarios. The numbers shown are the widths of a fit with two Gaussians to the corresponding distribution of residuals ( $\sigma_{z,N}$  for the narrow and  $\sigma_{z,T}$  for the broad component, respectively). *Core Fraction* is the fraction of events contained in the narrow Gaussian.

Algorithm		$WH \rightarrow \mu v b \bar{b}$			$WH \rightarrow \mu v u \bar{u}$		
		$\sigma_{z,N}$ , [ $\mu\text{m}$ ]	$\sigma_{z,T}$ , [ $\mu\text{m}$ ]	Core Fraction [%]	$\sigma_{z,N}$ , [ $\mu\text{m}$ ]	$\sigma_{z,T}$ , [ $\mu\text{m}$ ]	Core Fraction [%]
<i>InDetAdaptiveMultiPriVxFinder</i>	signal only	$41.3 \pm 0.5$	$98 \pm 2$	76.3	$35.3 \pm 0.5$	$79 \pm 2$	75.8
	pile-up	$40.9 \pm 0.5$	$95 \pm 2$	75.1	$34.9 \pm 0.5$	$77 \pm 2$	75.5
<i>VKalVrtPrim</i>	signal only	$40.2 \pm 0.5$	$92 \pm 2$	71.1	$36.0 \pm 0.5$	$82 \pm 2$	78.1
	pile-up	$41.2 \pm 0.5$	$98 \pm 2$	74.1	$34.3 \pm 0.5$	$76 \pm 2$	73.2
<i>InDetPriVxFinder (Billoir Full)</i>	signal only	$49.3 \pm 0.5$	$132 \pm 3$	76.3	$40.4 \pm 0.6$	$99 \pm 3$	76.4
	pile-up	$48.6 \pm 0.5$	$127 \pm 3$	76.7	$41.0 \pm 0.5$	$103 \pm 3$	79.1
<i>InDetPriVxFinder (Billoir Fast)</i>	signal only	$49.3 \pm 0.5$	$132 \pm 3$	76.2	$40.3 \pm 0.6$	$98 \pm 3$	76.0
	pile-up	$48.6 \pm 0.5$	$127 \pm 3$	76.5	$40.9 \pm 0.5$	$103 \pm 3$	79.0

The numbers shown are the widths of a fit with a single Gaussian for the  $x$  coordinate and two Gaussians for the  $z$  coordinate, respectively, to the corresponding distribution of the residuals. In addition the ratio of the narrow Gaussian and the sum of the two Gaussians is given for the  $z$  coordinate. It can be noted that the best results are obtained with the *VKalVrtPrim* and *InDetAdaptiveMultiPriVxFinder* and that the values of coordinate resolutions for all algorithms are very close to those obtained for the non-pile-up case. It can therefore be concluded, that in the low-luminosity conditions the degradation of spatial resolution appears to be very small.

### 3.5 Impact on $b$ -Tagging Performance

The beam interaction region in ATLAS has an approximately gaussian transverse profile with  $\sigma = 15\mu\text{m}$ . This size is smaller than the typical transverse impact parameter ( $d_0$ ) [6] resolution of charged particle tracks.  $b$ -tagging algorithms based on transverse impact parameter significances only (IP2D method [4]) are thus only slightly sensitive to the details of the primary vertex reconstruction and the presence of

Table 5: Light jet rejection for  $WH(m_H = 120 \text{ GeV})$  events (signal only and pile-up scenarios) using different primary vertex reconstruction algorithms. Only jets with at least one track associated are considered in these performance studies. *IP2D*, *IP3D* and *IP3D + SV1* *b*-tagging methods are described in details in [4]

pile-up vertices. This is demonstrated in the first column of Table 5. Since the vertex reconstruction accuracy in the longitudinal direction is also better than the typical longitudinal impact parameter resolution ( $z_0$  [6]), the *b*-tagging performance is not influenced significantly by the choice of the primary vertex algorithm in the case where only the signal vertex is present. This can be seen by comparing the rows labelled *signal only* in Table 5 for the different primary vertex reconstruction algorithms.

The presence of pile-up vertices, however, changes the situation for the longitudinal coordinate considerably. The  $z$  position resolution is not affected significantly by the presence of additional vertices as is shown in Table 4, but the longitudinal size of the beam interaction region is much bigger ( $\sigma_z \approx 5.6 \text{ cm}$ ) than the transverse one. Any misidentification of the primary interaction vertex thus produces artificially large  $z_0$  track impact parameters. Consequently, most of the tracks are rejected by the *b*-tagging track selection procedure in these cases and the jets to be tagged do not have any tracks associated. Such jets can not be tagged as *b*-quark jets anymore. Since the vertex misidentification probability is not negligible in some event topologies, as can be seen from Table 1, the performance of *b*-tagging algorithms using information from the longitudinal coordinate is appreciably affected. The degradation of the *b*-tagging performance in the presence of pile-up vertices for these algorithms is shown in the second and third columns of Table 5 for the *IP3D* and *IP3D+SV1* algorithms which use this information.

An additional complication for *b*-tagging with pile-up originates from the rather large amount of soft jets produced in pile-up interactions. These jets do not have reconstructed tracks inside at all in many cases and are thus considered as light quark jets by the *b*-tagging algorithms. This, however, causes an unphysical change of the *b*-tagging performance not related to the performance of the algorithms themselves, because a different set of jets is used to estimate the performance. To minimize this effect, the results in Table 5 are obtained for jets with at least one associated track. This approach is different from the one normally used for *b*-tagging performance studies. The numbers in Table 5 thus have to be taken with care when comparing with other *b*-tagging results. The observed degradation of the *b*-tagging performance confirms the results obtained in a previous study [11], where a more dramatic decrease of the *b*-tagging performance was demonstrated for the case of the nominal LHC luminosity ( $10^{34} \text{ cm}^{-2} \text{ s}^{-1}$ ) when each beam crossing produces 24 pile-up events on average.

There are several possibilities to improve the *b*-tagging performance in pile-up scenarios. The pres-

ence of jets without any tracks associated to them (especially if the requirement of a small longitudinal impact parameter is not fulfilled for most of the tracks) is an indication that the correct primary vertex has not been reconstructed in this particular event. In such cases, one could either try to use the second vertex from the list of primary vertex candidates (according to the ordering of vertices as applied by the primary vertex reconstruction algorithm) or drop the information in the longitudinal direction, thus falling back to a *b*-tagging algorithm working in the transverse plane only. The reconstruction of the primary event vertex, as currently implemented, is a universal procedure not depending on the topology of the event. Adding information specific to a particular analysis could help in some cases to increase the fraction of correctly identified primary vertices, e.g. reconstructing the primary vertex only from prompt isolated high  $p_T$  leptons for channels where these are present. These options have to be studied in the future.

## 4 Inclusive Secondary Vertex Reconstruction in Jets

A *b*-jet originates from a *b*-quark, which produces a *b*-hadron in the fragmentation. The *b*-hadron then decays due to electroweak interactions, which cause the transition of the *b*-quark preferably into a *c*-quark ( $|V_{cb}|^2 \gg |V_{ub}|^2$ ), which then subsequently also undergoes a weak decay. As a result, the typical topology of the particles in a *b*-jet seen in the detector is a decay chain with two vertices, one stemming from the *b*-hadron decay and at least one from *c*-hadron decays. The eventual intermediate presence of excited *b*- or *c*-hadron states does not change this picture because their strong or electromagnetic decays do not cause measurable lifetimes. A unique feature of jets originating from the fragmentation of *b*-quarks is thus the presence of *b*- and *c*-hadron decay vertices.

An exclusive reconstruction of these decays cannot be done with high efficiency. The large *b*-hadron masses lead to a huge number of possible decay modes with very small branching ratios, many of them involving neutral particles (which cannot be used for vertex reconstruction). The reconstruction of secondary *b*- and *c*-hadron decay vertices in jets thus has to be done in an inclusive way, where the number of charged particle tracks originating from *b*- and *c*-hadron decays is not known a-priori.

Trying to resolve the *b*- and *c*-hadron vertices of the decay cascade separately is very difficult for the following reasons:

- The probability to have at least two reconstructed charged particle tracks both from the *b*- and *c*-hadron decays is much less than 100%. This is both because of the charged particle multiplicities involved in these decays as well as the limited track reconstruction efficiency, mainly because of material interactions in the detector (as discussed in Section 5).
- The resolutions of the relevant track parameters, especially at low transverse momenta, are not sufficient to separate the two vertices efficiently.

Two different approaches for the inclusive reconstruction of secondary vertices are presented in Sections 4.1 and 4.2. The first one is based on a classical approach of fitting a single geometrical vertex. As explained, this is strictly speaking not the correct hypothesis, however, for the reasons given above, this is an approximation that works well for a large fraction of cases. The second algorithm is based on a kinematical approach, assuming that the primary event vertex and the *b*- and *c*-hadron decay vertices lie approximately on the same line, the flight path of the *b*-hadron. These underlying assumptions are discussed in more detail in the corresponding sections.

The most important issues in inclusive vertex reconstruction are to reconstruct the decay vertices with high efficiency and to associate efficiently to the vertices the charged particle tracks coming from the corresponding decays of *b*- and *c*-hadrons.

Another important issue is the detection and removal of sources of tracks with large impact parameters which do not have any relation to the *b*-quark content of a jet.  $K^0$  and  $\Lambda^0$  decays,  $\gamma$ -conversions and

hadronic interactions in the detector material must be removed as efficiently as possible before applying *b*-tagging.

Combining the information from secondary vertices and track impact parameters allows the optimization of the *b*-tagging performance and is described in Section 6.

## 4.1 The BTagVrtSec Algorithm

The main purpose of the *BTagVrtSec* algorithm is efficient *b*-jet tagging based on the detection of a secondary vertex inside a jet. It reconstructs secondary vertices due to *b*- and/or *c*-hadron decays inside a jet with high efficiency and calculates a jet weight, a discriminating variable which may be combined with similar variables from other tagging algorithms (see Section 6). This algorithm is based on the VKalVrt [2] vertex reconstruction package.

### 4.1.1 BTagVrtSec Vertex Reconstruction

As stated above, to separate *b*-quark jets from jets produced by light quarks and gluons, it is sufficient to detect unambiguously *b*- and *c*-hadron decay vertices inside the jet. The idea of the *BTagVrtSec* algorithm is to maximize the *b/c*-hadron vertex detection efficiency, keeping at the same time the probability to find a fake vertex inside light jets low. The default version of the algorithm constructs a single secondary vertex from the *b*- and *c*-hadron decay products. As justification of such an approach it should be noted, that the ability to reconstruct *b*- and *c*-hadron decay vertices separately is quite limited as already explained previously. Moreover, the precise reconstruction of the decay chain is less important for *b*-tagging than the detection of the secondary decay itself. The single vertex approximation allows a high secondary vertex detection efficiency, necessary for powerful *b*-tagging at the price of an imprecise kinematical reconstruction in cases when the distance between the *b*- and *c*-hadron vertices is big. Another advantage of the single vertex approximation is a more simple algorithm that might be easier to tune and calibrate on data.

The *BTagVrtSec* algorithm starts with a selection of tracks inside a jet. Tracks are selected with the same quality cuts as for the primary vertex reconstruction algorithm *VKalVrtPrim*, except for a relaxed cut on the transverse track impact parameter ( $d_0 \leq 3.5$  mm) and no requirement of the presence of a hit in the first layer (b-layer) of the pixel detector. This is done in order to maximize the efficiency to reconstruct  $V^0$  decays and material interactions with subsequent removal of the corresponding tracks from the *b*-tagging procedure. Tracks are selected in a cone around the jet axis. The size of the cone is a tunable parameter (the default value is  $\Delta R = 0.4$ ) which currently does not depend on the jet reconstruction algorithm.

The vertex search itself starts with a determination of all track pairs which form good ( $\chi^2 < 4.5$ ) two-track vertices inside the jet. In addition, each track of the pair must have a three dimensional distance from the primary vertex<sup>2</sup> divided by its error higher than 2.0 and the sum of these two significances must be higher than 6.0. In order to decrease the fake rate an additional requirement  $(\vec{V}_{2tr} - \vec{V}_{primary}, \vec{P}_{jet}) > 0$  is used.

Some of the reconstructed two-track vertices stem from  $K_s^0$  and  $\Lambda^0$  decays,  $\gamma \rightarrow e^+e^-$  conversions and hadronic interactions in the detector material. The corresponding distributions are shown in Figure 2. Figures 2 a) and b) show the invariant  $\pi^+\pi^-$  and  $p\pi^-$  mass spectra for accepted two particle vertices with peaks due to  $K_s^0$  and  $\Lambda^0$  decays. Figure 2 c) shows the distance between the primary and secondary vertices in the transverse plane with peaks due to interactions in the material of the beam pipe and pixel detector layers. Charged particle tracks coming from such vertices are marked as *bad* and do not participate further in the following *b*-tagging procedure for the given jet.

<sup>2</sup>The distance between the primary vertex and the point of closest approach of the track to this vertex.

Figure 2: Some distributions for reconstructed two track vertices:

a) the  $\pi^+\pi^-$  invariant mass spectrum with a peak of  $K^0$  decays; b) the  $p\pi$  invariant mass spectrum with a peak of  $\Lambda^0$  decays; c) the distance in the transverse plane between the primary and secondary vertices with the peaks due to interactions in the beam pipe (two walls at  $R \approx 30$  mm) walls and pixel layers ( $R = 50.5$  mm and  $R = 88.5$  mm).

In the next step of the algorithm all tracks inside the jet from accepted two-track vertices except for marked  $V^0$  decays and material interactions are combined into one *secondary track* list and the vertex fitting procedure from the *VKalVrt* package tries to fit a single secondary vertex out of all these tracks. If the resulting vertex has an unacceptable  $\chi^2$ , the track with the highest contribution to the vertex  $\chi^2$  is deleted from the *secondary track* list and the vertex fit is redone. This procedure iterates until a good  $\chi^2$  of the vertex fit is obtained or all tracks from the *secondary track* list have been removed.

Secondary vertices in light quark jets mainly stem from tracks coming from the primary vertex, typically with a bad measurement of their track parameters and errors.

Some *b*-tagging efficiency and rejection calibration algorithms require *negative tail* vertices. For the use in those algorithms the requirement for two-track vertices  $(\vec{V}_{2tr} - \vec{V}_{prim}, \vec{P}_{jet}) > 0$  may be dropped. In this condition in some cases *BTagVrtSec* reconstructs a final single secondary vertex *behind* the primary vertex:  $(\vec{V}_{sec} - \vec{V}_{prim}, \vec{P}_{jet}) < 0$ . Such secondary vertices are mostly fake vertices but give the necessary reference for calibration.

#### 4.1.2 *b*-Tagging with BTagVrtSec

Each *b*-tagging algorithm is based on variables which show significantly different behaviour for *b*-jets and light jets. For secondary vertex based algorithms the first variable is the presence of a reconstructed vertex in the jet itself, whose probability is big for *b*-quark jets and small for light quark jets. The vertex reconstruction procedure can, however, provide much more information which also may be used in a *b*-tagging algorithm to increase the efficiency. In order not to have a too complex procedure which is still easy to calibrate and to control, only the most sensitive variables should be taken into account.

Although *BTagVrtSec* can be used as a standalone *b*-tagging algorithm, it was developed primarily for working in combination with track impact parameter based algorithms [4]. The distance between primary and secondary vertices is thus not used because this kind of lifetime information is already contained in the track impact parameters. Three additional variables have been chosen for the *BTagVrtSec* tagging algorithm:

1. The mass of the reconstructed secondary vertex:  $M$ .

2. The ratio of the energy of charged particle tracks included in the secondary vertex and the total energy of all charged particle tracks in the jet:  $R$ ;
3. The number of good (excluding identified  $V^0$  decays or material interactions) two-track vertices in the jet:  $N$ .

The distributions of the first two variables are shown in Figure 9 in Section 5 for light, charm and *b*-jets. The distributions of the number of two-track vertices can be found in [4]. In standalone mode (without combination with track impact parameter based tagging algorithms) the three dimensional distance between the primary and secondary vertices may also be used.

To be reliable any *b*-tagging algorithm must be calibrated on data. To facilitate the calibration and to reduce the necessary amount of data the chosen variables have been transformed (for details see [12]):

- Invariant mass:  $M' = \frac{M}{M+1}$ ;
- Energy ratio:  $R' = R^{0.7}$ ;
- Number of good two-track secondary vertices:  $N' = \log N$ .

Due to the efficiency to reconstruct a secondary vertex inside a jet not reaching 100%, the probability density functions (PDF) of the vertex based variable have to contain a  $\delta$ -function [12].

$$PDF = (1 - \varepsilon) \cdot \delta(M', F', N') + \varepsilon \cdot ASH(M', F', N')$$

with  $\varepsilon$  being the efficiency to reconstruct a secondary vertex inside a jet. The continuous probability density function of the vertex variables is constructed from multidimensional calibration histograms using the ASH smoothing method [13].

Two slightly different taggers based on the *BTagVrtSec* algorithms are available in ATLAS, denoted SV1 and SV2. They use exactly the same variables but handle them in a different way. SV1 treats  $M'$  and  $R'$  jointly and adds  $N'$  as independent variable (2+1 decomposition), whereas SV2 uses joint three-dimensional probability density functions.

The only criterion for the selection of variables and tuning of the *BTagVrtSec* algorithm was *b*-tagging performance. Other quantities like the purity of the reconstructed secondary vertices were not considered. Although the achieved quality of the *b*-hadron decay vertex is quite good (see Section 5), for applications other than *b*-tagging *BTagVrtSec* may require a different tuning.

## 4.2 The JetFitter Algorithm

A new inclusive secondary vertexing algorithm which exploits the topological structure of weak *b*- and *c*-hadron decays inside a jet was recently developed.

### 4.2.1 Reconstruction of the Decay Chain Topology

As already stated, the fragmentation of a *b*-quark results in a decay chain with two vertices, one stemming from the *b*-hadron decay and at least one from *c*-hadron decays.

As described in Section 4.1, the *BTagVrtSec* algorithm relies on a vertexing algorithm in which displaced tracks are selected and an inclusive single vertex is obtained using a Kalman based  $\chi^2$  fit (as sketched in Figure 3).

The algorithm described here, called *JetFitter*, is based on a different hypothesis. It assumes that the *b*- and *c*-hadron decay vertices lie on the same line defined through the *b*-hadron flight path. All charged particle tracks stemming from either the *b*- or *c*-hadron decay thus intersect this *b*-hadron flight axis. There are several advantages to this method:

Figure 3: *BTagVrtSec* fits all displaced tracks to an inclusive vertex.

Figure 4: *JetFitter* performs a multi-vertex fit using the *b*-hadron flight direction as constraint.

- Incomplete topologies can also be reconstructed (in principle even the topology with a single track from the *b*-hadron decay and a single track from the *c*-hadron decay is accessible).
- The fit evaluates the compatibility of the given set of tracks with a *b*-*c*-hadron like cascade topology, increasing the discrimination power against light quark jets.
- Constraining the tracks to lie on the *b*-hadron flight axis reduces the degrees of freedom of the fit, increasing the chance to separate the *b*/*c*-hadron vertices.

From the physics point of view this hypothesis is justified through the kinematics of the particles involved as defined through the hard *b*-quark fragmentation function and the masses of *b*- and *c*-hadrons. The lateral displacement of the *c*-hadron decay vertex with respect to the *b*-hadron flight path is small enough not to violate significantly the basic assumption within the typical resolutions of the tracking detector (see Figure 4).

This hypothesis, extensively used in the *JetFitter* algorithm, was explored for the first time in the *ghost track algorithm* developed by the SLD Collaboration [14], where the already defined *b*-hadron flight axis is substituted by a *ghost track* and where a numerical global  $\chi^2$  minimisation procedure was used to perform the multi-vertex fit.

#### 4.2.2 The *JetFitter* Vertex Reconstruction Algorithm

In *JetFitter* the vertexing task is mathematically implemented as an extension of the Kalman Filter formalism for vertex reconstruction [7] and the decay chain is described through the determination of the following variables:

$$\vec{d} = (x_{PV}, y_{PV}, z_{PV}, \phi, \theta, d_1, d_2, \dots, d_N), \quad (3)$$

with:

- $(x_{PV}, y_{PV}, z_{PV})$ : the primary vertex position.
- $(\phi, \theta)$ : the azimuthal and polar directions of the *b*-hadron flight axis.
- $(d_1, d_2, \dots, d_N)$ : the distances of the fitted vertices, defined as the intersections of one or more tracks and the *b*-hadron flight axis, to the primary vertex position along the flight axis (N representing the number of vertices).

Before starting the fit, the variables are initialised with their prior knowledge:

- The primary vertex position (with covariance matrix), as provided by the primary vertex finding algorithm.
- The *b*-hadron flight direction, approximated by the direction of the jet axis, the error being provided by the convolution of the jet direction resolution with the average displacement of the jet axis relative to the *b*-hadron flight axis, as determined from Monte Carlo simulations.

The fit is then performed, resulting in the minimization of the  $\chi^2$  containing the weighted residuals of all tracks with respect to their vertices on the *b*-hadron flight axis. The charged particle tracks to be used in the determination of the decay chain are selected according to the  $\Delta R$  matching criterion explained in Section 2 and a further track selection is applied, in order to reduce the amount of fake tracks.

After the primary vertex and the *b*-hadron flight axis have been initialised, a first fit is performed under the hypothesis that each track represents a single vertex along the *b*-hadron flight axis, until  $\chi^2$  convergence is reached, obtaining a first set of fitted variables  $(\phi, \theta, d_1, d_2, \dots, d_N)$ .

A clustering procedure is then performed, where all combinations of two vertices (picked up among the vertices lying on the *b*-hadron flight axis plus the primary vertex) are taken into consideration, filling a *table of probabilities*. After the table of probabilities is filled, the vertices with the highest compatibility are merged, a new complete fit is performed and a new table of probabilities is filled. This procedure is iterated until no pairs of vertices with a probability above a certain threshold remain.

The result of this clustering procedure is a decay topology with a well defined association of tracks to vertices along the *b*-hadron flight axis, with at least one track for each vertex.

More details about the JetFitter vertex reconstruction algorithm can be found in [3].

#### 4.2.3 The JetFitter based *b*-Tagging Algorithm

The *b*-tagging algorithm implemented as a first application of *JetFitter* is based on separating *b*-jets from *c*- and light-quark (*u, d, s*) jets by means of the definition of a likelihood function.

The decay topology is described by the following discrete variables:

1. Number of vertices with at least two tracks.
2. Total number of tracks at these vertices.
3. Number of additional single track vertices on the *b*-hadron flight axis.

while the vertex information is condensed in the following variables:

1. Mass: the invariant mass of all charged particle tracks attached to the decay chain.
2. Energy Fraction: the energy of these charged particles divided by the sum of the energies of all charged particles associated to the jet.
3. Flight length significance  $\frac{d}{\sigma(d)}$ : the weighted average vertex position divided by its error.

The use of these variables allows the definition of a likelihood function of the form:

$$L^{b,l,c}(x) = \sum_{cat} coeff(cat) \cdot PDF_{cat}(mass) \cdot PDF_{cat}(energyFraction) \cdot PDF_{cat}\left(\frac{d}{\sigma(d)}\right), \quad (4)$$

which has to be parametrised separately for each of the three different flavours.

The information about the decay topology of the jet as reconstructed by *JetFitter* is represented by the category (the coefficient  $coeff(cat)$  representing how probable it is to find a certain topology for a given flavour), while the vertex information is contained in the probability distribution functions (*PDFs*).

Figure 5: 13 different topologies are defined, combining the three discrete variables in such way as to reduce their correlations. For the case of one single vertex with at least two tracks (1), the discrete  $PDFs$  for both the other two variables, total tracks at vertices (2) and single additional tracks (3), are used, but they are then considered as uncorrelated, so that their corresponding coefficients are just multiplied.

The discrete variables describing the decay topology are combined according to the scheme of Figure 5 into 13 category coefficients.

In order to reduce the correlations between the decay topology and vertex related variables and to increase the discrimination power, the  $PDFs$  are made category dependent. This splitting of  $PDFs$  is done only when strictly needed.

The templates for the vertex variables are shown in Table 6 for all three flavours. Each  $PDF$  was split independently into the categories it was found to be most correlated with, in order to maintain the number of split  $PDFs$  to be determined on Monte Carlo simulated events as low as possible. They were determined on the  $WH(m_H = 120 \text{ GeV})$  Monte Carlo events with  $H \rightarrow b\bar{b}$ ,  $H \rightarrow c\bar{c}$  and  $H \rightarrow u\bar{u}$  and on  $t\bar{t}$  Monte Carlo events.

The *JetFitter* based  $b$ -tagging algorithm can be either used as a stand-alone algorithm or in combination with pure impact parameter based algorithms (see Section 6).

## 5 Secondary Vertex Reconstruction Performance

In this section, the performance of the inclusive secondary vertex reconstruction algorithms as described in Sections 4.1 and 4.2 is discussed.

Table 6 shows the rate of reconstructed secondary vertices in  $b$ -quark and light quark jets in bins of jet transverse momentum and pseudorapidity for both secondary vertex reconstruction algorithms, as obtained on the  $t\bar{t}$  and  $t\bar{t}jj$  samples.

Above a certain transverse momentum, the efficiency to identify the secondary vertex in a  $b$ -jet for both algorithms approaches approximately a constant value around 75 – 80%, while the number of vertices reconstructed in light-jets consistently increases with higher jet transverse momentum.

Both effects have to do mainly with the ability to separate real or fake secondary tracks from the primary vertex: tracks from secondaries are selected according to the impact parameter significance of a track with respect to the primary vertex or to the three dimensional flight length significance of the secondary vertex. Therefore, these quantities are strictly related and, above a certain threshold, they are nearly invariant regardless of the boost and thus the flight length of the displaced  $b$ - or  $c$ -hadron produced. For low transverse momenta, the charged particle tracks from  $b$ -hadron decays suffer from

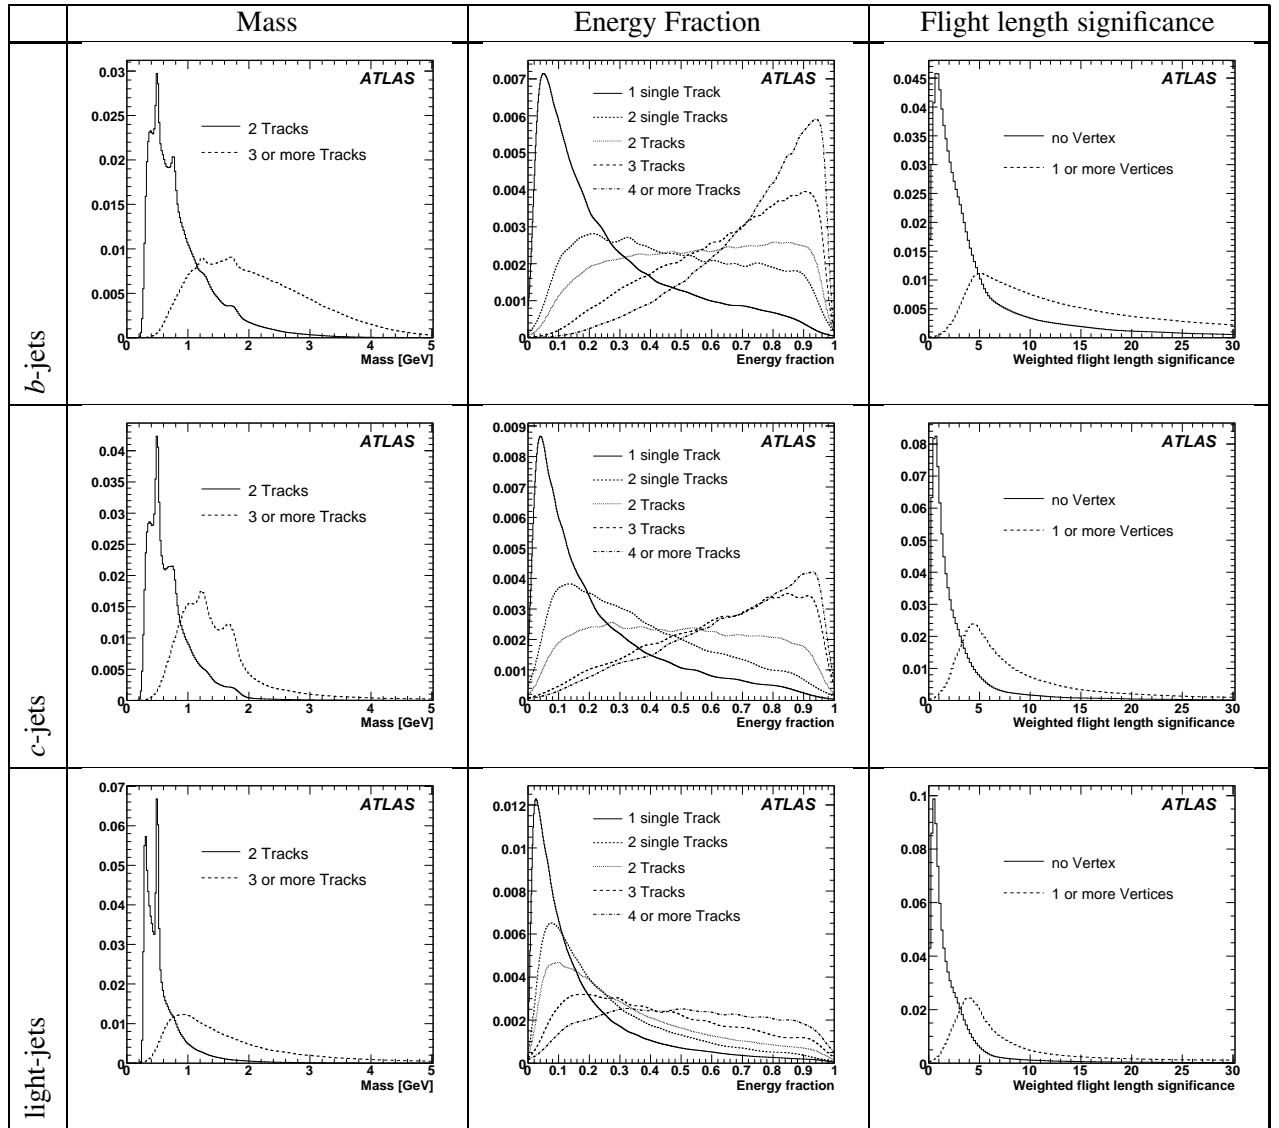

Figure 6: The *PDFs* for the mass, the energy fraction and the flight length significance are shown, separately for the three different jet-flavours and split according to the decay chain topology found by *JetFitter*.

larger multiple scattering, thus showing less significant displacements from the primary event vertex and reducing the secondary vertex reconstruction efficiency.

The rising amount of fake vertices in light quark jets with increasing jet transverse momenta is partly due to the nature of the fragmentation process in light quark jets, which produces a larger number of tracks coming from the primary interaction vertex the larger the transverse jet momentum is. Assuming the probability for a reconstructed track to represent an outlying measurement is approximately constant to first approximation, the probability of having tracks which fake secondaries increases roughly linearly with the number of primary tracks. The real secondary vertices produced in light quark jets, like photon conversions and  $V^0$  decays represent an additional source of vertices not related to heavy hadron decays. Furthermore, the pattern recognition during the track reconstruction phase is more difficult in dense jets as it is the case for higher jet transverse momenta (see [4]).

Table 6: The fraction of jets with at least one reconstructed secondary vertex passing the selection criteria to be used by the *b*-tagging algorithms in *b*-, *c*- and light quark jets for *BTagVrtSec* (top) and *JetFitter* (bottom). These numbers, given in percent, have been obtained on the  $t\bar{t}$  and  $t\bar{t}jj$  samples, applying the purification procedure.

The dependence of the vertex reconstruction efficiency on the jet pseudorapidity is mainly a consequence of the different resolutions which can be achieved in different regions of the Inner Detector: for increasing rapidities, the track resolutions close to the Interaction Point get worse, the track reconstruction efficiency starts to decrease and the number of fake tracks rises (a detailed quantitative explanation of these effects can be found in [6] and [4]).

It can also be concluded that the *BTagVrtSec* algorithm is slightly more efficient in reconstructing secondary vertices inside *b* quark jets, at the cost of a slightly higher rate of fake vertices produced in light quark jets compared to the *JetFitter* algorithm, at least in the barrel region of the Inner Detector.

Table 7 shows the population of some reconstructed topologies for *b*-quark, *c*-quark and light quark jets for *JetFitter*, as a function of the jet transverse momentum and pseudorapidity. As stated in Sec-

Table 7: Population of the different topologies of the vertices reconstructed by *JetFitter* in *b*-,*c*- and light quark jets, shown as a function of the jet transverse momentum  $p_T$  (top) and the jet pseudorapidity  $\eta$ . These numbers, given in percent, have been obtained on the  $t\bar{t}$  sample, applying the purification procedure.

Figure 7: Residuals of the reconstructed three dimensional (left) and transverse (right) flight length of the inclusive secondary vertex with respect to the true *b*–hadron position for both vertexing algorithms.

tion 4.2, the key feature of *JetFitter* is the ability to distinguish several decay chain topologies, in addition to recognizing the presence of a single inclusive decay vertex. The efficiencies and mistagging rates given above for the different categories show that most of the achievable gain is due to the 1 *Vertex* + 1 *Track* and 2 *Vertices* categories, where a gain in rejection against light quark jets of a factor  $\sim 4$  and  $\sim 16$  can be obtained on approximately  $\sim 10\%$  and  $\sim 5\%$  of the reconstructed *b*-jets, respectively. The dependence on  $p_T$  and  $\eta$  follows the same pattern as already described for the inclusive vertex reconstruction.

Figure 7 shows the resolution achieved on the inclusively reconstructed *b*-hadron decay vertex with respect to the true *b*-hadron position. A core can be seen, corresponding to the cases where most of the reconstructed tracks really stem from the *b*-hadron vertex, approaching the intrinsic resolution of the vertex reconstruction, while a very large tail to higher flight lengths can be observed, due to tracks coming from the decay of the charmed hadron of the  $b \rightarrow c$ -hadron cascade.

Another criterion to estimate the algorithmic performance of the secondary vertex finders is the fraction of charged particles arising from the decays of *b*- or *c*-hadrons and reconstructed as tracks in the Inner Detector that are correctly associated to a displaced vertex (*efficiency*) and –at the same time– which fraction of the tracks assigned by the secondary vertex finders to displaced vertices really stem from real *b*- or *c*-hadron decays (*purity*).

The average charged particle multiplicities at the secondary and tertiary decay vertices as obtained from the Monte Carlo generator PYTHIA was analyzed, where a minimum transverse momentum of 500 MeV was required for the charged particles. The decay products of a strong or electromagnetic *b*-hadron decay (e.g. pions from  $B^{**}$  decays) are not counted as coming from the secondary vertex, because of the lifetime of these states the decay particles emerge from the primary vertex. The decay products of a strongly or electromagnetically decaying *c*-hadron (e.g.  $D^*$  or  $D^{**}$ ) are considered as stemming from the *b*-hadron vertex, while only the decay products of weakly decaying *c*-hadrons are considered as originating from the *c*-hadron vertex.

The average charged particle multiplicity of the inclusive *b/c*-hadron vertex is  $\sim 4.7$ , as shown in Figure 8, distributed in  $\sim 2.3$  charged particles stemming from the *b*-hadron vertex and  $\sim 2.4$  charged particles originating from the *c*-hadron vertex. In the same figure the decay multiplicity at generator level (left) is compared with the number of tracks coming from the *b*- and *c*-hadron vertices which have been reconstructed as tracks in the Inner Detector (right). Around 80% of their charged decay products are correctly reconstructed as tracks and pass the standard track quality selection cuts. In order to strongly

Figure 8: Average charged particle decay multiplicity of the *b*- and/or *c*-hadrons at generator level (left), compared with the number of charged particles coming from the *b*- and/or *c*-hadron vertices reconstructed as tracks in the Inner Detector and passing some standard quality criteria (right). The  $WH(H \rightarrow b\bar{b})$  sample has been used.

Table 8: Efficiency (fraction of reconstructed tracks from the decays of *b*- or *c*-hadrons that are associated to the secondary vertices) and purity (fraction of tracks fitted to the secondary vertices that stem from real *b*- or *c*-hadron decays) for the two secondary vertex finders, separately for different topologies in the case of *JetFitter*. The  $WH(H \rightarrow b\bar{b})$  sample has been used.

Algorithm	Topology	Track efficiency	Track purity
BTagVrtSec	1 inclusive <i>B/D</i> vertex	69 %	92 %
JetFitter	1 vertex	74 %	91 %
	1 vertex + 1 track	80 %	85 %
	2 vertices	85 %	89 %

reduce the contamination of reconstructed secondary vertices by other charged particles originating from the primary interaction point, tracks originating from the *b*- or *c*-hadron vertices, but not distinguishable from primary tracks, are also suppressed to some extent by the track selection cuts. This and other selection criteria further reduce the *b*- and *c*-hadron decay products reconstruction efficiency, resulting in a compromise between the highest possible *efficiency* and a reasonable *purity*. In Table 8 the track association efficiencies and purities of the displaced tracks stemming from the *b*- or *c*-hadrons for the *BTagVrtSec* and *JetFitter* algorithms are shown, the efficiencies being normalized to the number of tracks from *b/c*-hadron decays which are reconstructed by the tracking detector. The fit of an inclusive *b/c*-hadron decay vertex, as performed by *BTagVrtSec*, allows to obtain a very high purity, but at the cost of starting to loose some tracks when the distance between the *b*- and *c*-hadron vertices starts to be relevant. *JetFitter* is able to recover a good part of this inefficiency, thanks to the ability of reconstructing more complex decay chain topologies, at the cost of a slightly lower purity.

Several topological and kinematical variables related to the reconstructed secondary vertices are used by the *b*-tagging algorithms, as described in sections 4.1 and 4.2. The invariant mass of charged particles associated to the vertex and the fraction of charged energy at the vertex relative to that of the jet, are used by both algorithms. The distributions of these variables are shown in Figure 9 for different regions of

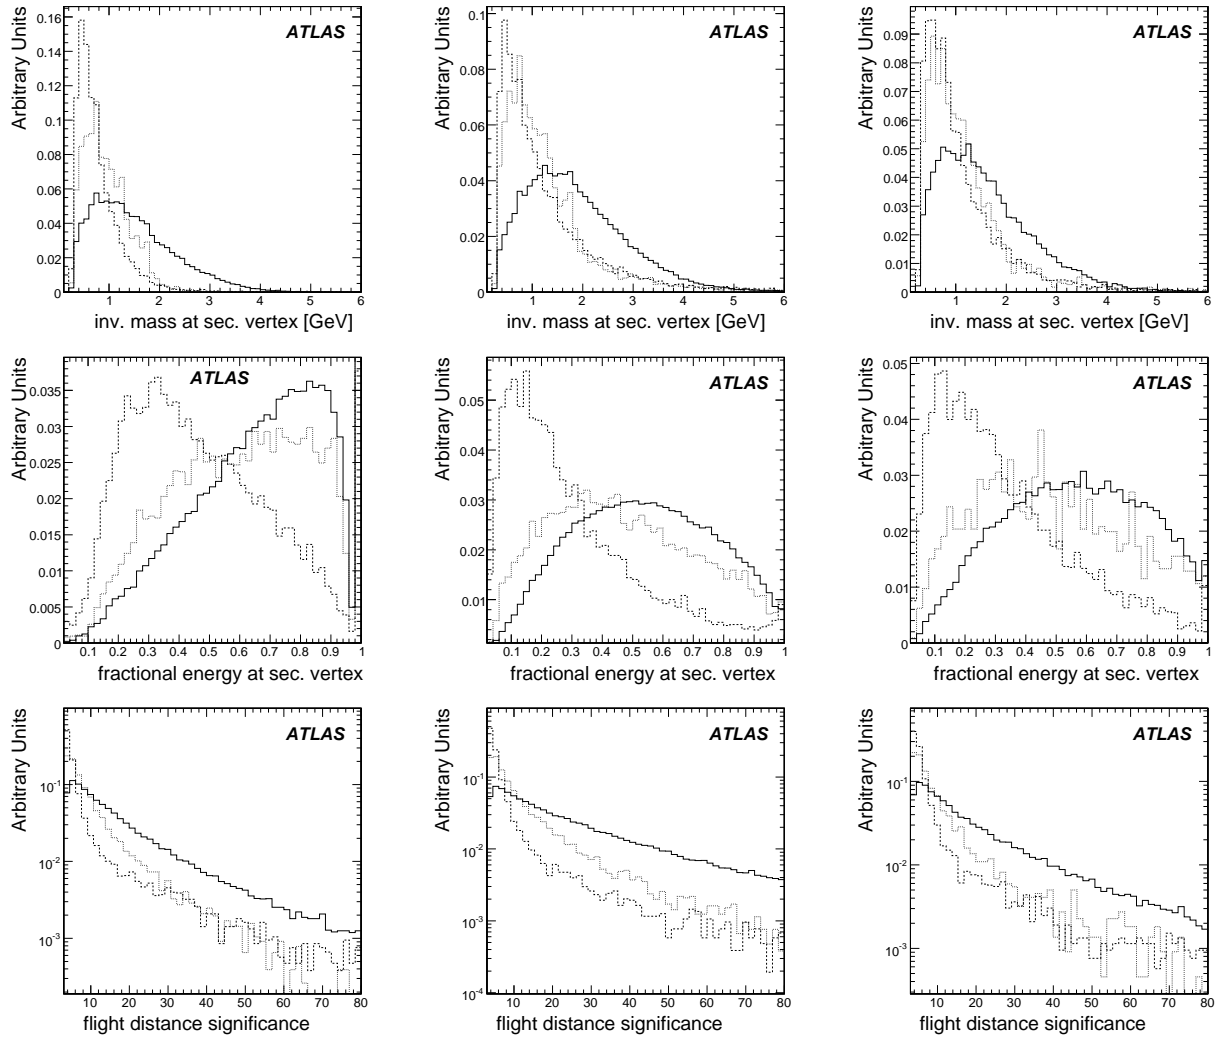

Figure 9: Variables related to the properties of reconstructed secondary vertices as computed by the *BTagVrtSec* algorithm for different jet transverse momenta and pseudorapidities for *b*-quark jets (solid), *c*-quark jets (dotted) and light quark jets (dashed). Left:  $0 < |\eta| < 0.5$ ,  $15 < p_T < 30$  GeV; middle:  $0 < |\eta| < 0.5$ ,  $80 < p_T < 120$  GeV; right:  $2 < |\eta| < 2.5$ ,  $80 < p_T < 120$  GeV. The top row shows the invariant mass of charged particle tracks associated to the reconstructed secondary vertices, the middle row the energy of charged particle tracks associated to the reconstructed secondary vertices divided by the energy of all charged particles in the jet, and the bottom row the flight distance significance as defined in the text.

jet transverse momenta and pseudorapidities for the *BTagVrtSec* algorithm. The flight distance significance, defined as the distance between the primary and secondary vertices divided by its error, is also shown there. The observed dependence of the secondary vertex reconstruction performance on the jet kinematics will directly impact the performance of the *b*-tagging algorithms. This will be discussed in Section 7.

Essentially all *b*-tagging algorithms use the direction of the jet, as reconstructed from calorimeter towers, to assign e.g. the lifetime sign to the impact parameters of charged particle tracks. The jet direction is a reasonably good approximation of the *b*-quark direction, however, for *b*-tagging it is mainly

the direction of the *b*-hadron that matters. The direction of the *b*-hadron flight path can be estimated using information from reconstructed primary and secondary vertices, e.g. for *BTagVrtSec* the line joining the primary and secondary vertices can be used as the *b*-hadron direction if a secondary vertex is present in the jet. The more sophisticated *JetFitter* algorithm delivers by construction an estimate for the *b*-hadron flight direction using information from both the calorimeters and vertices of charged particle tracks. Figure 10 shows a comparison of the resolutions achieved for the azimuth angle  $\phi$  for the different approaches. Using an improved *b*-hadron direction may decrease the contribution of charged particles from the decays of *b*-hadrons to the negative tail of the impact parameter distribution. This contribution mainly comes from a wrong assignment of the lifetime sign if the *b*-hadron direction has not been reconstructed sufficiently precisely. This will facilitate the calibration and improve the *b*-tagging performance.

Figure 10: Angular resolution of the *b*-hadron flight direction in the azimuth angle  $\phi$  as reconstructed with the *JetFitter* and *BTagVrtSec* algorithms (for the latter, the line joining the primary and secondary vertices has been used in the case where a secondary vertex is present), compared with the corresponding resolution as obtained from calorimeter jets. The *WH* ( $H \rightarrow b\bar{b}$ ;  $m_H=120$  GeV) sample was used for this study.

## 6 Combination with Impact Parameter based *b*-tagging Algorithms

The *b*-tagging algorithms presented in the previous sections provide all information needed to be used as stand-alone algorithms. Secondary vertex based *b*-tagging algorithms are, however, limited by the efficiency to reconstruct a secondary vertex inside a jet. To obtain maximum performance, the secondary vertex based algorithms can be combined with other algorithms. *b*-tagging algorithms purely based on the impact parameter significances of charged particle tracks do not have this limitation. They do not offer, however, the amount of topological and kinematical information as the secondary vertex based algorithms.

In ATLAS, the impact parameter information can be used either in two ( $r\phi$  plane only) or three dimensions. The corresponding algorithms and their performance are described in detail in [4]. They calculate a likelihood ratio of the probability density functions for observed track impact parameter

significances  $S$  for tracks coming from *b*-quark jets and light quark jets:  $w_{track} = b(S)/u(S)$ . The jet likelihood ratio (called *jet weight*) is the sum of track ratios:  $w_{jet}^{IP} = \sum_{i=1}^{N_{track}} \ln w_{track,i}$ . Assuming that the tracks are independent, the jet likelihood ratio is an optimal variable for making a decision about the jet origin.

Secondary vertex algorithms were designed in a way facilitating combination with track only based algorithms. They provide likelihood ratios of various parameters for *b*-jets and light jets, which may be simply summed with track likelihood ratios. To preserve an optimal performance, secondary vertex variables have been chosen to be maximally independent on track impact parameters (i.e. the distance between primary and secondary vertex is strongly correlated with track impact parameters and then should be used with care). The combined *jet weight* is then computed as sum of the likelihood ratios of the different algorithms:  $W_{jet}^{combined} = W_{jet}^{SV} + W_{jet}^{IP}$ .

The likelihood ratio approach used in ATLAS makes *b*-tagging an easily scalable procedure. Any new algorithm or new variable can be added in the same way to already existing tagging information. Choice of independent variables (or at least weakly correlated ones) guarantees an optimality of combined procedure.

## 7 *b*-Tagging Performance

In this section, the performance of the algorithms described in this note is discussed. The data samples described in Section 2 have been used for these studies. Jets had to be within the acceptance of the tracking detectors ( $|\eta| < 2.5$ ) and their reconstructed transverse momenta had to exceed 15 GeV:  $p_T^{jet} > 15$  GeV. The performance is shown in terms of *b*-tagging efficiency,  $\epsilon_b$ , and light quark rejection,  $r_{u,c}$  as defined in Section 2. A certain working point is chosen by placing a cut on the weight as computed by the algorithm.

The performance was studied both using only the information as delivered by the secondary vertex based algorithms (denoted *BTagVrtSec* and *JetFitter* as in the previous sections) and after combination with a tagging algorithm based on a combination of transverse and longitudinal impact parameter significances as described in Section 6. The *b*-tagging algorithm purely based on the information from impact

Table 9: The rejection against light quark jets for fixed *b*-tagging efficiencies of 50% and 60% for different data samples without and with applying the purification procedure, denoted as *raw* and *purified*, respectively.

parameter significances of charged particle tracks showing the best performance is called *IP3D* and is used in the following studies. Details about this algorithm can be found in [4]. The results from the combined algorithms are denoted *BTagVrtSec+IP3D* and *JetFitter+IP3D*, respectively. Tables 9 and 10 show the rejection rates against light quark and charm quark jets for different tagging algorithms and data samples.

Figure 11 shows the rejection of light quark (u,d,s) and gluon jets,  $r_u$ , versus the *b*-tagging efficiency  $\varepsilon_b$  for the pure secondary vertex based algorithms and a comparison with the most performant tagging algorithm purely based on three dimensional impact parameter information, *IP3D*. It can be seen that the maximum achievable *b*-tagging efficiency of the vertex based algorithms is limited by the efficiency to reconstruct a displaced vertex or *b*-hadron decay topology. It is higher in the case of *JetFitter* which imposes only very soft requirements on the topology. The performance of the impact parameter based tagging algorithm *IP3D* is better over almost the full range of *b*-tagging efficiencies. There is also a significant difference between *BTagVrtSec* and *JetFitter*, the latter one showing better performance. It has to be noted, however, that *JetFitter* explicitly uses lifetime information (the flight distance significance), which is not used by *BTagVrtSec* to decorrelate the algorithm better from *IP3D*. The right plot of Figure 11 exhibits some steep structures at *b*-tagging efficiencies of about 50% and 70%. These can be related to sudden drops in the rejection rate of the *IP3D* algorithm for these *b*-tagging efficiencies, as can be seen in the left part of Figure 11. This behaviour can be explained mainly by the presence of jets with only a single track associated to them and the finite binning of the reference distributions for the probability density functions of the impact parameter significances as used by the *IP3D* *b*-tagging algorithm (see [4] for details).

Figure 12 shows the rejection against charm quark jets. The rejection against charm quark jets is significantly lower compared to light quark jets because of the real lifetime of charm hadrons and thus similar topology. Here, the vertex based algorithms show a performance that is much closer to the impact parameter based algorithm.

Figures 13 and 14 show the rejections against light quark jets and charm quark jets for the secondary vertex based tagging algorithms after combination with the *IP3D* algorithm, again compared with *IP3D*. This combination results in a significant increase in rejection power, especially for light quark jets.

The dependence of the performance on the jet kinematics is of particular importance. Figures 15 and 16 show the rejection against light quark jets for a fixed *b*-tagging efficiency of 50% versus the jet transverse momentum and jet pseudo rapidity, respectively. Table 11 shows the rejection against light quark jets for a fixed *b*-tagging efficiency of 50% for several regions of jet transverse momenta and pseudorapidities.

The reasons for the observed behaviour are manifold. For larger pseudorapidities, the particles pass through more material and thus the detector resolution is worse. Another reason for degradation of the longitudinal impact parameter at high pseudorapidity is the dramatic increase of the extrapolation distance from b-layer hit to the vertex. The degradation for high jet transverse momenta is caused by an increased fragmentation multiplicity, resulting in an increased combinatorics in the secondary vertex

finding stage when trying to find the tracks stemming from the *b*-hadron decay. Furthermore, the pattern recognition in the track reconstruction becomes more difficult in the very dense environment of jets with very large transverse momenta. The steep fall for low jet transverse momenta is mainly due to the strongly enhanced multiple scattering of low momentum charged particle tracks, leading to significantly degraded impact parameter resolutions. The observed dependence of the *b*-tagging performance on the jet kinematics can be related to the performance of the secondary vertex reconstruction as discussed in Section 5. It can be seen there, that the secondary vertex reconstruction efficiency in *b*-quark jets drops in the same kinematical regions as the resulting *b*-tagging performance, with an increased rate of (fake) vertices in light quark jets.

Two of the most discriminating variables, for both algorithms, are the invariant mass of charged particle tracks associated to the secondary vertex and the fraction of the charged energy at the secondary vertex divided by the total charged energy in the jet. Figure 9 in Section 5 shows these variables for *b*-quark, *c*-quark and light quark jets for various jet transverse momenta and pseudorapidities. The loss of discrimination power in the regions where the degradation of the *b*-tagging performance is observed, is clearly visible. Apart from the kinematic dependence, the *b*-tagging performance also depends critically on the contamination of the light quark jets by displaced tracks stemming from nearby *b*- or *c*-quark jets, as can already be concluded comparing the *b*-tagging performance before and after application of the purification procedure. It is however worth looking at this dependence in more detail, analyzing the *b*-tagging performance as a function of the distance  $\Delta R$  of the light quark jets to the nearest *b*- or *c*-quark or  $\tau$  lepton.

Table 12 shows, both for the pure secondary vertex based algorithms and after combination with the *IP3D* algorithm, that the more the light quark jets are contaminated by *b*- or *c*-hadron decay products (smaller values of  $\Delta R$ ), the stronger the degradation of the *b*-tagging performance is. At very small angles of  $\Delta R$  the light quark-jets can be barely distinguished from the nearby heavy flavour jet. A small kinematical bias (slightly different  $p_T$  and  $\eta$  distribution of the jets for different  $\Delta R$  intervals) should also be taken into account when interpreting these results.

There is a noticeable difference in the behaviour of *JetFitter* compared to *BTagVrtSec*, the second being less robust against building up vertices which catch up contributions from nearby heavy flavour jets. As stated in Section 4.2.2, *JetFitter* uses the jet direction as reconstructed by the calorimeter as a constraint in the fit of the hypothetical *b*-hadron flight axis, thus being more efficient in discarding tracks coming from nearby jets.

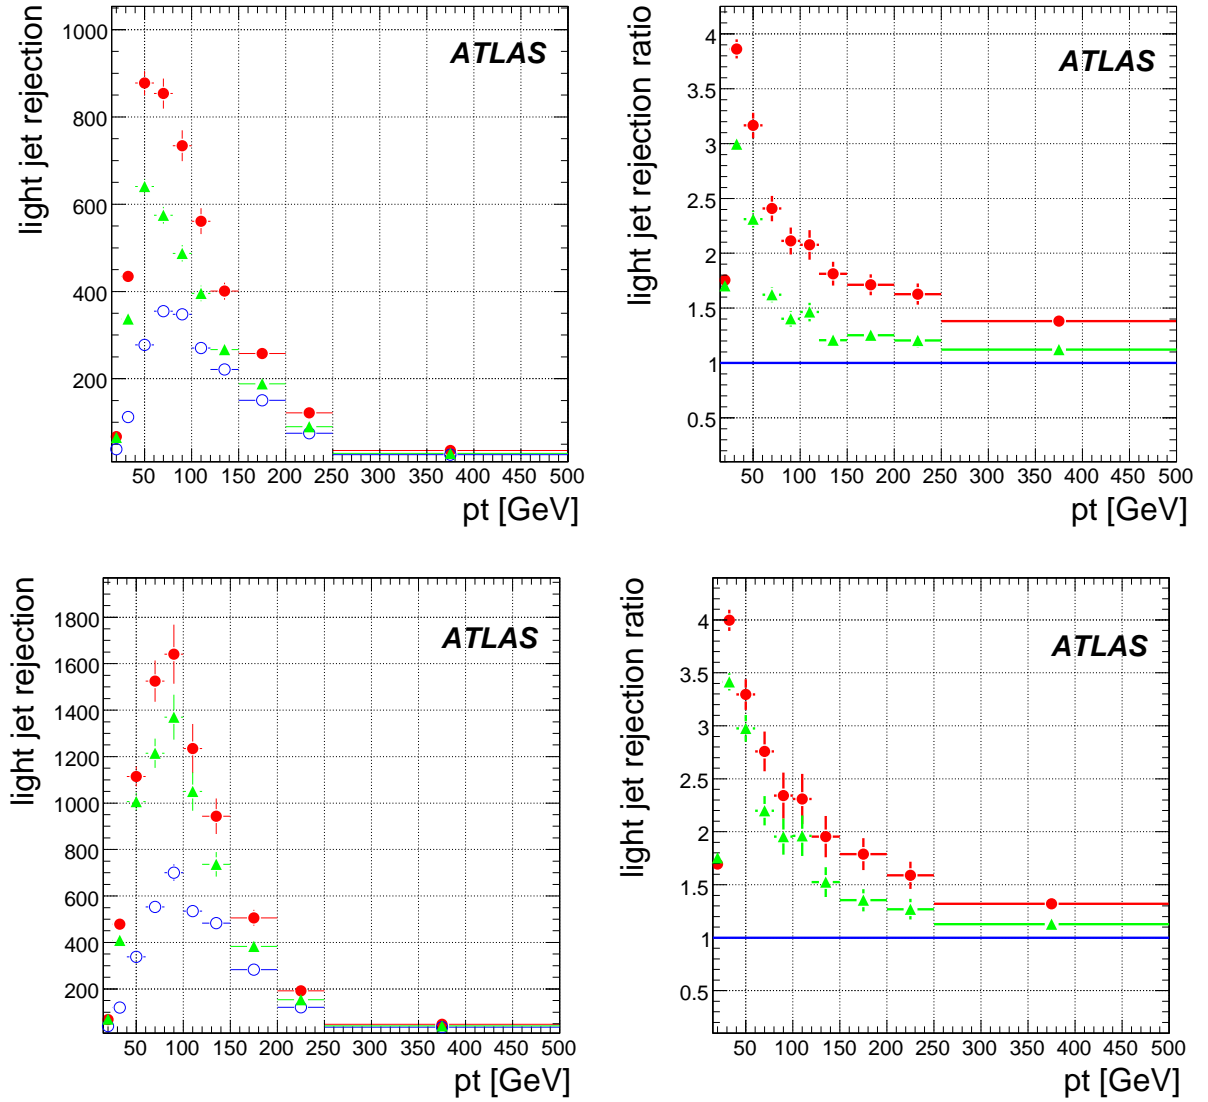

Figure 15: Left: Light jet rejection for a fixed *b*-tagging efficiency of 50% versus the jet transverse momentum for *BTagVrtSec* (triangles, green) and *JetFitter* (full circles, red) after combination with *IP3D*. The pure impact parameter based algorithm *IP3D* is also shown for comparison (open circles, blue); right: The ratio with respect to *IP3D* for *BTagVrtSec* (triangles, green) and *JetFitter* (full circles, red) combined. The plots in the top (bottom) row show the performance without (with) applying the purification procedure. These results have been obtained on the  $t\bar{t}$  and  $t\bar{t}jj$  sample.

## 8 Summary and Outlook

In this note, an overview of vertex reconstruction algorithms used in ATLAS, both for the reconstruction of the primary event vertex and the inclusive reconstruction of secondary decay vertices inside jets, has been given. The focus has been put on applications to the tagging of *b*-quark jets.

Several primary vertex reconstruction algorithms are available in ATLAS. The performance of these algorithms has been studied both for the case where only the hard signal interaction is present and for a luminosity of  $2 \times 10^{33} \text{ cm}^{-2} \text{ s}^{-1}$ , when 4.6 additional pile-up vertices are present on average. It was

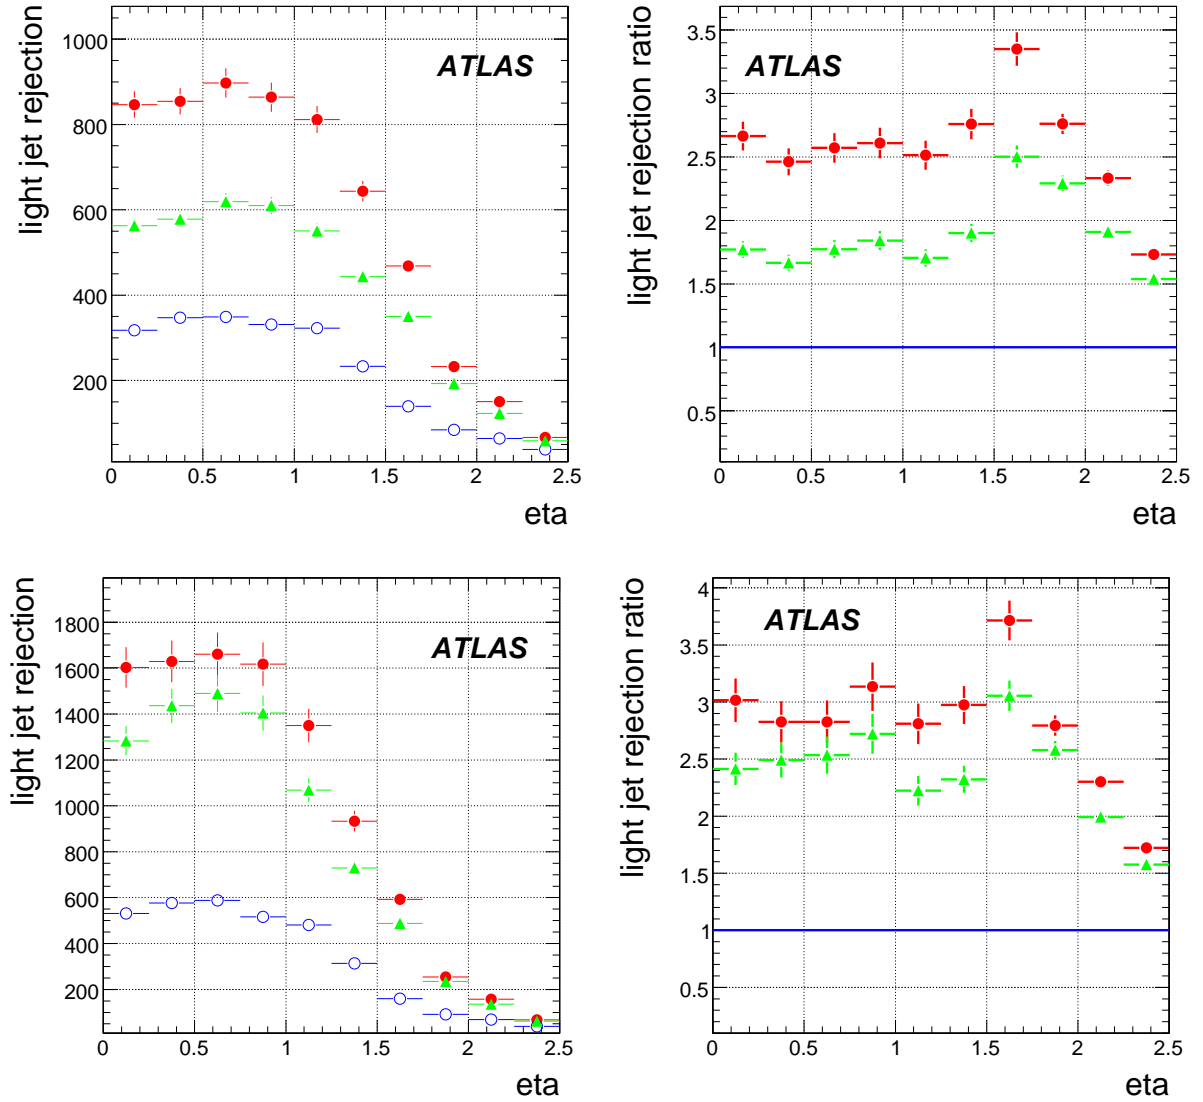

Figure 16: Left: Light jet rejection for a fixed  $b$ -tagging efficiency of 50% versus the jet pseudorapidity for  $BTagVrtSec$  (triangles, green) and  $JetFitter$  (full circles, red) after combination with  $IP3D$ . The pure impact parameter based algorithm  $IP3D$  is also shown for comparison (open circles, blue); right: The ratio with respect to  $IP3D$  for  $BTagVrtSec$  (triangles, green) and  $JetFitter$  (full circles, red) combined. The plots in the top (bottom) row show the performance without (with) applying the purification procedure. These results have been obtained on the  $t\bar{t}$  and  $t\bar{t}jj$  sample.

demonstrated that the presence of additional vertices does not degrade the primary vertex reconstruction precision significantly. A more severe problem is the misidentification of a pile-up vertex as the signal vertex. For the luminosity of  $2 \times 10^{33} \text{cm}^{-2} \text{s}^{-1}$  and the event topologies studied in this note, this misidentification rate can be as high as 5%. This misidentification leads to a significant degradation of the performance of the  $b$ -tagging algorithms that use information of charged particle tracks in the longitudinal direction. Possible procedures to recover a large part of this performance loss have been discussed and will be studied and implemented in the future.

Table 12: The rejection against light quark jets for different  $b$ -tagging efficiencies ( $\epsilon_b$ ) as function of the difference in  $\Delta R$  of the light quark jets to the nearest  $b$ -,  $c$ - or  $\tau$ -jet (top row: *BTagVrtSec*; bottom row: *JetFitter*), for the secondary vertex based  $b$ -tagging algorithms used stand-alone (upper table) and after combination with the impact parameter based tagging algorithm *IP3D* (lower table).

$\epsilon_b$	$0.3 < \Delta R < 0.35$	$0.35 < \Delta R < 0.4$	$0.4 < \Delta R < 0.45$	$0.45 < \Delta R < 0.5$	$0.5 < \Delta R < 0.6$	$0.6 < \Delta R < 0.7$
50%	$12.4 \pm 0.3$ $29 \pm 1$	$28 \pm 1$ $89 \pm 6$	$80 \pm 5$ $244 \pm 27$	$177 \pm 14$ $363 \pm 43$	$231 \pm 11$ $345 \pm 20$	$244 \pm 10$ $327 \pm 16$
60%	$7.3 \pm 0.1$ $17.3 \pm 0.4$	$14 \pm 0.3$ $43 \pm 2$	$8.7 \pm 1$ $30 \pm 6$	$68 \pm 3$ $113 \pm 7$	$91 \pm 3$ $128 \pm 5$	$91 \pm 3$ $119 \pm 4$

$\epsilon_b$	$0.3 < \Delta R < 0.35$	$0.35 < \Delta R < 0.4$	$0.4 < \Delta R < 0.45$	$0.45 < \Delta R < 0.5$	$0.5 < \Delta R < 0.6$	$0.6 < \Delta R < 0.7$
50%	$18.4 \pm 0.5$ $31 \pm 1$	$51 \pm 2$ $141 \pm 12$	$179 \pm 17$ $501 \pm 80$	$467 \pm 62$ $793 \pm 138$	$939 \pm 92$ $1133 \pm 121$	$951 \pm 79$ $1077 \pm 95$
60%	$10.1 \pm 0.2$ $17.0 \pm 0.4$	$23 \pm 1$ $50 \pm 2$	$66 \pm 4$ $158 \pm 14$	$143 \pm 11$ $222 \pm 20$	$265 \pm 14$ $309 \pm 17$	$266 \pm 12$ $302 \pm 14$

Many interesting physics events at the LHC have a lepton with large transverse momentum in the final state, so one may try to decrease the misidentification rate by selecting the reconstructed interaction vertex closest to this lepton. This strategy, however, does not provide a significant improvement in comparison with the standard primary vertex selection algorithm since the presence of a well reconstructed high  $p_T$  lepton increases the weight of the corresponding vertex and then is taken into account automatically.

Two algorithms are available in ATLAS for the inclusive reconstruction of secondary decay vertices in jets, following different approaches. The first algorithm, *BTagVrtSec*, reconstructs explicitly geometrical secondary vertices inside the jet. The second algorithm, *JetFitter*, is based on the specific kinematics of the  $b$ - and  $c$ -hadrons decay chain. The performance of the algorithms has been investigated thoroughly. The  $b$ -tagging performance of both algorithms has been studied using only the information from the secondary vertex algorithms as well as after combination with  $b$ -tagging algorithms based on charged track impact parameters. A strong dependence of the vertex reconstruction and thus  $b$ -tagging performance on the jet pseudorapidity and transverse momentum was demonstrated. As explained in the text, this is caused by physics or instrumental effects.

Several new developments and further improvements are planned for the future. A dedicated reconstruction of  $V^0$  decays and material interactions will also be available in *JetFitter* soon. Together with other improvements, like a modified seeding procedure and the application of multivariate techniques, a significant improvement can be expected for the *JetFitter* based  $b$ -tagging algorithm in the near future. An extension of the *BTagVrtSec* algorithm is able to reconstruct several vertices in a jet. The definition of variables related to the additional information to be used for  $b$ -tagging will be done in the near future and increase the  $b$ -tagging performance. The implementation of another inclusive vertex reconstruction algorithm, the so-called *Topological Vertex Finder* is in progress. It is based on an algorithm originally developed by the SLD collaboration [15].

In the inclusive secondary vertex reconstruction algorithms presented in this note, different cuts are applied at different stages during vertex finding and fitting. Currently, these cuts do not depend on the jet parameters. Due to the strong dependence of the  $b$ -tagging performance on them, however, it seems more appropriate to optimize these parameters depending on the kinematics of the jet under consideration. One quantity worth investigating is the size of the cone around the jet axis within which charged particle tracks are associated to the jet and thus used by the vertex reconstruction and  $b$ -tagging algorithms. For large jet transverse momenta, the cone that contains most of the particles from the decays of heavy

Figure 17: Ratios of the tuned rejections to the default rejection as a function of the jet transverse momentum for a *b*-tagging efficiency of 60%. The left hand side plot shows this ratio for light quark jet rejection, while the right hand side plot shows the ratio for charm jet rejection.

*b*- and *c*-hadrons as well as from fragmentation, will be significantly smaller than for lower transverse momenta. It is thus desirable to choose the size of this track association cone depending on the transverse momentum of the jet. Since this is not restricted to secondary vertex based *b*-tagging algorithms, this point is addressed in detail in [4]. To give an idea of what can be expected from such a parameter tuning, one parameter of the *BTagVrtSec* algorithm has been optimized in bins of the jet transverse momentum. This parameter is a cut on the significance of the displacement of vertex candidates built from pairs of tracks from the primary event vertex. Table 13 shows the values chosen after the optimization procedure.

It can be seen, that the optimal value varies strongly with the jet transverse momentum. Figure 17

Table 13: Optimal values for the significance cut on the displacement of two track vertex candidates from the primary event vertex for the different jet *p<sub>T</sub>* bins.

Jet <i>p<sub>T</sub></i> [GeV]	15-30	30-50	50-80	80-120	120-200	200-400	400-1000
Optimal Cut	3.5	4.5	5.0	6.0	6.5	7.0	7.0

shows the gain in *b*-tagging performance that is achieved by the parameter tuning. It can be seen that the rejection against light quark jets improves by a factor of about two in the region of large jet transverse momenta, whereas the gain in charm jet rejection is more moderate. This parameter tuning will be continued in the future and will be included in the *b*-tagging algorithms.

# Effects of Misalignment on $b$ -Tagging

## Abstract

This note investigates the effects of misalignment on  $b$ -tagging performance using Monte Carlo simulations. Four different alignment sets were considered, two with known random misalignments, one produced with the ATLAS alignment procedures and one with a perfectly aligned detector. Error tuning was investigated to compensate for the larger effective hit errors caused by misalignment. In addition the effects of misalignment on the tracking and vertexing performance were evaluated.

## 1 Introduction

The ATLAS detector has been built to provide high precision tracking and vertexing which are essential for good  $b$ -tagging performance. Misalignment of the detector will degrade the tracking resolution and consequently the performance of the  $b$ -tagging is expected to be sensitive to the alignment of the detector. As well as random misalignments of modules which give an effective smearing of each hit, systematic distortions introduced by the structure of the detector and by the alignment algorithms can have unexpected consequences.

The effects of misalignment on  $b$ -tagging have been studied with Monte Carlo simulations using a number of different alignment sets. These include a set that perfectly aligns the detector, two hand-made sets with known levels of random misalignment and an alignment set produced with the actual alignment algorithms to be used to align the ATLAS detector.

The assignment of correct errors for the hits is important for proper track and vertex reconstruction. Because module misalignments add to the intrinsic error of the module, the errors assigned to the hits need to be adjusted depending on the level of misalignment. Samples were investigated with and without this hit error adjustment.

The note is organized as follows: Section 2 describes the four alignment sets. The error tuning procedure and resulting scale factors used to adjust the hit errors are presented in Section 3. Studies were made with both  $t\bar{t}$  and  $WH(m_H = 120 \text{ GeV})$  samples and a brief description of these samples is given in Section 4. Section 5 describes the effects of misalignment on the tracking and vertexing performance. The effects of misalignment on the  $b$ -tagging performance, as measured by comparing the  $b$ -jet efficiency versus light jet rejection for the different alignment sets, are presented and discussed in Section 6.

## 2 Residual misalignment sets

In order to study the effects of misalignment, a number of different alignment scenarios were considered. The Monte Carlo simulation used in this investigation includes misalignments introduced at the simulation stage. The level of misplacement is representative of the amount of misalignment expected before any attempt to align the detector. The misalignments are of the order of 10–100  $\mu\text{m}$  at the level of individual modules and assembly structures such as layers and disks and misalignments of the order of a few mm at the whole subsystem level. The level of these misalignment was based on known fabrication precisions and survey measurements. [1]. The misalignments introduced are too large to allow for reasonable reconstruction. What is desired is to reconstruct the resulting data sets with alignment corrections that are typical of what is expected in the real detector, after which only small misalignments should remain. Four alignment sets were used in this study:

- **Perfect:** This is the ideal case where the same set of alignments used in the simulation are used in the reconstruction and so one does not see any misalignment.

- **Aligned:** This uses an alignment set produced using the actual track based alignment algorithms developed for the ATLAS detector. It is expected to include any systematic deformations that the alignment procedure itself causes. While some systematic effects were included in the misalignments introduced in the simulation, such as clocking effects where each subsequent layer was rotated by increasing amounts, it does not contain all the systematic deformations which are expected. In particular large scale structures such as layers and discs were treated as rigid objects without any internal deformations such as a twist. Also pixel stave bows which are known to occur were not introduced. So it is possible that this set is still optimistic. This set is a first attempt at the full scale alignment of the inner detector and so should not be considered the final word on what will be seen in the real detector. However, it is considered to be the most realistic case studied here.
- **Random10:** This is a hand-made alignment set that takes the misalignment set used in simulation and randomly shifts the module positions by small amounts. These residual misalignments were introduced at different levels in the hierarchy. Random shifts and rotations were made to individual modules, and whole layers and disks. A small shift and rotation was also made to the whole pixel structure. Since the degradation of the *b*-tagging performance is expected to be dominated by the alignment of the pixel system, only pixel residual misalignments were introduced. The SCT and TRT were corrected perfectly as in the perfect alignment case. Due to movements of higher level structures in this set, some systematic effects may exist. The levels of misalignment are given in Table 1. The axis definitions for the module level uses a local frame where  $x$  and  $y$  are the  $r\phi$  and  $\eta$  measurement directions respectively and  $z$  is out of the plane. For higher levels they correspond to the global frame with  $z$ -axis along the beam direction. *RotX*, *RotY*, *RotZ* are rotations around the corresponding axes. The module level shifts in the  $r\phi$  measurement direction are around  $10\ \mu\text{m}$ . The set attempts to emulate the level of misalignments expected during the early running period. It is not well known what levels of misalignments are expected after certain running periods so this is just an indication rather than being a firm prediction of what is expected at start up. Comparison with the real alignments (“Aligned” set) shows this to be a rather pessimistic scenario.
- **Random5:** As with “Random10”, but with levels of misalignment better by about a factor of 1.5 to 2. This is an estimate of what might be expected after several years of running. Like “Random10”, this set introduces misalignments at the three levels of hierarchy with levels of misalignment given in Table 2.

Table 1: Residual misalignment for “Random10”. Random misalignments were generated with a Gaussian distribution with  $\sigma$  as tabulated. Shifts are in  $\mu\text{m}$  and rotations are in mrad.

Level	$x$	$y$	$z$	<i>RotX</i>	<i>RotY</i>	<i>RotZ</i>
Module	10	30	30	0.3	0.5	0.2
Layer	10	10	15	0.05	0.05	0.1

### 3 Error scaling

#### 3.1 Error scaling procedure

The intrinsic error of a hit will depend on a number of factors such as the cluster width and track direction. These factors are taken into account when calculating the intrinsic error of the hit. In the case of a perfectly aligned detector, if these intrinsic errors are properly determined one expects the pull distribution (the distribution of the hit residuals divided by the calculated intrinsic error) to have a width close to one.

The differences between the real positions of individual hits and those recorded by a misaligned detector lead to an additional error term that must be added in quadrature to the intrinsic error of the hits.

The errors on the hits directly affect whether a hit is associated to a track, the track propagation and track parameter errors and the objects that use tracks as input, such as vertices. Of particular importance to *b*-tagging is the precision of the impact parameter and the vertexing performance. It is therefore necessary to have accurately assigned hit errors.

In this section hits will refer to clusters in the silicon detectors (pixel and SCT) and drift circles in the TRT. To correct the hit errors the diagonal elements of the error matrix are modified using two parameters  $a$  and  $c$ :

$$\sigma'^2 = a^2 \cdot \sigma^2 + c^2 \quad (1)$$

where:

- $\sigma$  is the original error assigned to the hit which is a function of the cluster size and track angle. This should normally be close to the intrinsic resolution if properly determined,
- $a$  is a multiplicative factor on the error, which is meant to compensate for inaccuracies in the intrinsic error determination,
- $c$  is a constant added in quadrature to the error. This is meant to correct effects attributed purely to residual misalignments.

Since each detector component can have significantly different behaviour, the granularity of each detector component has to be taken into account, and therefore different sets of  $(a, c)$  have to be computed separately for the barrel and endcap regions for each detector technology, as well as for the different  $r\phi$  and  $\eta$  measurement directions in the case of the pixel detector.

For the derivation of the  $(a, c)$  pairs, the distributions of hit residuals and their pull distributions are analyzed, and in particular the deviations of the pull widths from the ideal value of 1 are investigated.

Since the scale factor  $a$  is intended to correct the intrinsic resolutions, this is most easily obtained with a perfectly aligned geometry. Naturally, this is not possible with real data, where more in depth

studies will be needed to determine if the assigned intrinsic errors are appropriate. Currently the factor  $a$  is needed as the errors used in the reconstruction do not match those observed in the simulation. It is assumed, however, that the best knowledge from test-beam and simulation will be put into the determination of the intrinsic error such that  $a$  will be close to 1 and any remaining differences would be absorbed into the parameter  $c$ .

The widths of the resulting pull distributions can be used directly as the scaling factors  $a$ . This is iterated a few times, applying the correction, rerunning reconstruction and then determining new values of  $a$ . The iterations are necessary due to correlations between detector components. The factor  $c$  is set to zero when determining the  $a$  factor.

The resulting factors  $a$  are then kept constant when used for the misaligned detector. Several iterations (apply ( $a$ ,  $c$ ) factors, reconstruct sample, analyze pulls) are performed using a misaligned detector, in order to determine the  $c$  factor. It is computed using the formula:

$$c_i^2 = (p_{obs}^2 - 1)a^2\sigma_0^2 + p_{obs}^2c_{i-1}^2 \quad (2)$$

where  $c_i$  and  $c_{i-1}$  are the values of the  $c$  factor obtained in the iteration  $i$  and  $i - 1$ , respectively,  $p_{obs}$  is the hit residual pull width observed at step  $i$ , and  $\sigma_0$  is the average intrinsic detector resolution.

The determination of  $c$  does not rely on any information about the actual detector positions and the procedure can be applied to real data. For this study a sample of high energy single muons was used, while in practice one would need to study the feasibility of extracting the error tuning with a more realistic event sample and track selection.

### 3.2 Error scaling parameters

The resulting parameters after the tuning are shown in Table 3. The values of  $a$  are seen to be well below one for the SCT and TRT. This is due to an overestimate of the intrinsic errors. This is being improved. The value for  $c$  gives some indication of the level of residual misalignment. For the “Random5” and “Random10” sets, the values of  $c$  are higher than what was input for the module shifts. This is possibly due to a larger error being needed to compensate for the effects of the layer and disc movements. It can be seen that the real alignment results in small values of  $c$  compared to the hand-made sets. In the pixel  $r\phi$  measurement direction one gets 3  $\mu\text{m}$  and in the  $\eta$  measurement direction one gets around 15  $\mu\text{m}$  for the “Aligned” set.

Table 3: Error scaling parameters for the different alignment scenarios. The parameter  $a$  was tuned using the “Perfect” case and used for all alignment scenarios.

	All $a$	Perfect $c(\mu\text{m})$	Random10 $c(\mu\text{m})$	Random5 $c(\mu\text{m})$	Aligned $c(\mu\text{m})$
Pixel barrel $r\phi$	1.03	0	31	13	3
Pixel barrel $\eta$	0.97	0	71	34	13
Pixel endcap $r\phi$	1.05	0	30	14	3
Pixel endcap $\eta$	1.08	0	43	11	15
SCT barrel	0.78	0	0	2	7
SCT endcap	0.86	0	6	5	8
TRT barrel	0.82	0	11	3	37
TRT endcap	0.77	0	11	10	19

Table 4: Efficiency of track reconstruction.

Setup	efficiency (%)
Perfect	$97.09 \pm 0.02$
Random10	$95.50 \pm 0.03$
Random10 + error scaling	$97.22 \pm 0.02$
Aligned	$97.07 \pm 0.02$
Aligned + error scaling	$97.04 \pm 0.02$

## 4 Monte Carlo Samples

The performance of *b*-tagging was investigated with  $t\bar{t}$  and  $WH(m_H = 120 \text{ GeV})$  samples which are standard samples used in *b*-tagging performance studies in ATLAS [2]. The main difference between these two samples is that the  $WH$  events have lower jet multiplicities.

The  $t\bar{t}$  sample includes semi-leptonic and di-lepton channels and this sample is used for measuring both *b*-jet and light jet efficiencies. The  $WH(120)$  sample contains two sub samples.  $WH(120) \rightarrow \mu\nu b\bar{b}$  is used to measure *b*-jet efficiencies and  $WH(120) \rightarrow \mu\nu u\bar{u}$  for light jet efficiencies. The samples contained no pile-up.

## 5 Effects of misalignment on tracking and vertexing

The tracking and vertexing performance was studied with the  $WH(120) \rightarrow \mu\nu b\bar{b}$  sample, although the other samples could equally have been chosen. A sample size of 27,000 events was used. This sample was reconstructed using three of the alignment sets described in Section 2: “Perfect”, “Random10” and “Aligned”. All other settings were kept the same. For the “Random10” and “Aligned” sets, samples were investigated with and without error scaling.

### 5.1 Tracking performance

The track reconstruction efficiency was computed for each scenario by comparing true tracks to corresponding reconstructed tracks. Tracks with  $p_T > 1 \text{ GeV}$  and  $|\eta| < 2.5$  were selected. A true track was considered to match a reconstructed track if the true track was the source of at least 50% of the hits associated to the reconstructed track. Next, the efficiency was computed as the ratio of the number of matched tracks to the number of all true tracks. The results for the efficiency for each of the three scenarios are shown in Table 4. The presence of residual misalignment in the “Random10” set causes a loss of about 2% in the efficiency, while the introduction of error scaling completely recovers the loss of performance. The “Aligned” set shows no significant change with respect to the “Perfect” case, with or without error scaling.

The number of fake tracks was also investigated in a similar manner to the track reconstruction efficiency calculation. A track was labeled as “fake” if it had fewer than 50% of its hits from a single true track. The percentage of fake tracks from the total accepted tracks is shown in Table 5 for the different alignment scenarios. The misalignments result in more fakes, and as with the efficiency, this is recovered with the introduction of error scaling.

### 5.2 Vertexing performance

The performance of the primary vertex finding algorithm was also investigated for the same five scenarios of alignment and error scaling. The efficiency for the primary vertex finding was computed as the ratio

Table 5: Ratio of fake tracks to the total number of accepted tracks.

Setup	fake tracks (%)
Perfect	$2.33 \pm 0.02$
Random10	$2.46 \pm 0.02$
Random10 + error scaling	$2.29 \pm 0.02$
Aligned	$2.34 \pm 0.02$
Aligned + error scaling	$2.27 \pm 0.02$

between the total number of reconstructed vertices to the total number of true vertices. It was found that this remains constant, at a value of  $99.68 \pm 0.04\%$ , irrespective of the misalignment scenario considered.

The primary vertex resolution was evaluated by looking at the difference between the reconstructed and the true vertex position. The resulting distributions for  $x$  and  $z$  directions are displayed in Fig. 1. The results for the  $y$  direction were similar to that in the  $x$  direction. The introduction of residual misalignment causes the distributions to become wider as would be expected with a degradation of the hit resolutions. The shift for the hand-made sets is consistent with the shift of the entire pixel detector that was introduced. For the “Aligned” set a shift in  $z$  of about  $90 \mu\text{m}$  is apparent. The alignment procedures do not fully constrain the six degrees of freedom of the whole detector and no attempt was made to correct to the average primary vertex position in the  $z$  direction. Because of this, the alignment procedure can easily result in such a shift when comparing with truth information.

The values for the resolution are computed as the width of a Gaussian fit to the distributions in Fig. 1 and are shown in Table 6. The resolution is degraded by residual misalignment, for both  $x$  and  $z$  directions. Error scaling helps to partially recover the loss of performance for the “Random10” scenario.

Figure 1: Primary vertex resolution, shown for the  $x$  direction (a) and  $z$  direction (b) for the various misalignment scenarios. ES denotes error scaling.

The number of primary vertex outliers was also investigated. Since the shift observed when looking at the resolution should not affect reconstruction, the true vertex position must be corrected by this shift. In the following, a primary vertex was flagged as “outlier” if the distance between the reconstructed vertex and the corrected true vertex position was greater than three sigma ( $30 \mu\text{m}$  in the  $x$  direction and  $150 \mu\text{m}$  in the  $z$  direction).

The percentage of outliers is shown in Table 7, which shows that residual misalignment introduces additional outliers, and therefore indicates a degradation in the primary vertex finding. The number of

Table 6: Primary vertex resolution.

Setup	res. in $x$ ( $\mu\text{m}$ )	shift in $x$ ( $\mu\text{m}$ )	res. in $z$ ( $\mu\text{m}$ )	shift in $z$ ( $\mu\text{m}$ )
Perfect	$11.4 \pm 0.1$	$-0.13 \pm 0.07$	$51.1 \pm 0.4$	$-8.2 \pm 0.3$
Random10	$15.1 \pm 0.1$	$4.2 \pm 0.1$	$63.0 \pm 0.4$	$1.4 \pm 0.4$
Random10 + error scaling	$13.2 \pm 0.1$	$2.6 \pm 0.1$	$56.6 \pm 0.4$	$2.3 \pm 0.4$
Aligned	$13.9 \pm 0.1$	$-0.18 \pm 0.09$	$53.7 \pm 0.4$	$-91.5 \pm 0.4$
Aligned + error scaling	$13.8 \pm 0.1$	$-0.15 \pm 0.09$	$55.4 \pm 0.4$	$-91.6 \pm 0.4$

Table 7: Fraction of primary vertex outliers.

Setup	outliers in $x$ (%)	outliers in $z$ (%)
Perfect	$1.7 \pm 0.1$	$4.1 \pm 0.1$
Random10	$5.5 \pm 0.2$	$8.3 \pm 0.2$
Random10 + error scaling	$2.8 \pm 0.1$	$6.1 \pm 0.2$
Aligned	$3.2 \pm 0.1$	$8.2 \pm 0.2$
Aligned + error scaling	$3.2 \pm 0.1$	$8.0 \pm 0.2$

outliers is however partially diminished by the application of error scaling for “Random10”. For the “Aligned” scenario the corresponding scaling factors are much smaller than for “Random10” and the effect of error scaling on the primary vertex performance is negligible.

## 6 Effects of misalignment on *b*-tagging performance

For the study of the impact of the residual misalignment on the *b*-tagging performance, several data sets were produced with  $WH(m_H = 120 \text{ GeV})$  and  $t\bar{t}$  events. Eight cases were considered corresponding to each specific scenario of residual misalignment (“Perfect”, “Aligned”, “Random10” and “Random5”) with and without error scaling as described in Sections 2 and 3. The performance of the *b*-tagging has been assessed by looking at the rejection rate of light quarks at *b*-jet efficiencies of 50% and 60% using various tagging algorithms: IP2D, IP3D, SV1 and the combined tagger IP3D+SV1. A description of the different taggers can be found in Ref. [2].

For each of the scenarios using  $WH(120)$  samples, 45,000  $WH(120) \rightarrow \mu\nu b\bar{b}$  events and 175,000  $WH(120) \rightarrow \mu\nu u\bar{u}$  events were used. The  $t\bar{t}$  samples contained 50,000 events each with the exception of the “Perfect” scenario without error scaling which had 570,000 events and the “Aligned” scenario with error scaling which had 500,000 events.

### 6.1 Results

Figure 2 shows the *b*-jet efficiency versus light jet rejection for  $t\bar{t}$  and  $WH(120)$  samples for the four misalignment sets with and without error scaling. Rejections for the IP3D and IP3D+SV1 tagger at *b*-tag efficiencies of 50% and 60% are tabulated in Table 8 for  $WH(120)$  and in Table 9 for  $t\bar{t}$ .

The results for the IP3D+SV1 are also summarized in Fig. 3. As expected, the larger the misalignment, the greater the degradation of the *b*-tagging performance. In the case of “Random10”, which represents the highest amount of misalignment (shifts of 10  $\mu\text{m}$  in the pixel  $r\phi$  measurement direction), there is almost a factor 2 drop in performance. For “Random5”, where the level of misalignment is lower (shifts of the order of 5  $\mu\text{m}$ ), the decrease of the light jet rejection rates is lower than in the previous case at around 30% degradation. For the “Aligned” set the loss in performance is around 10 to 20%

Table 8: Light jet rejection rates computed for *b*-jet efficiencies of 50% and 60% for the IP3D and IP3D+SV1 taggers for the various misalignment scenarios with and without error scaling (ES) for *WH*(120) events.

Setup	Rejection rate			
	IP3D (50%)	IP3D (60%)	IP3D+SV1 (50%)	IP3D+SV1 (60%)

Figure 2: Light jet rejection versus  $b$ -tagging efficiency for the four different alignment sets for IP3D+SV1 for  $t\bar{t}$  (left) and  $WH(120)$  (right). ES denotes error scaling.

and lies somewhere between the “Perfect” alignment and the “Random5” set. This is consistent with the level of misalignment suggested by the parameter  $c$  in the error tuning which is  $3 \mu\text{m}$  in the pixel  $r\phi$  measurement direction.

Figure 3: Light jet rejections using IP3D+SV1 tagger for the four misalignment scenarios at  $b$ -tagging efficiency working points of 50% (left) and 60% (right). Results are shown before and after error scaling (ES).

The rejections for  $WH(120)$  are systematically lower than that for  $t\bar{t}$  as observed in other studies [2], however, in general they both show similar trends with misalignment. Some differences are observed with the effects of error scaling which are discussed below. Results are shown mainly for  $t\bar{t}$ , although similar conclusions are reached for both samples.

Figure 4 shows the  $b$ -tag weight for IP3D+SV1 tagger for the different alignment scenarios. The differences between the “Aligned” and “Perfect” sets are difficult to see in such plots but for the larger

misalignments (“Random10” and “Random5”) it is seen that the light jets have slightly larger weights while the  $b$ -jets have lower weights resulting in the loss of discrimination.

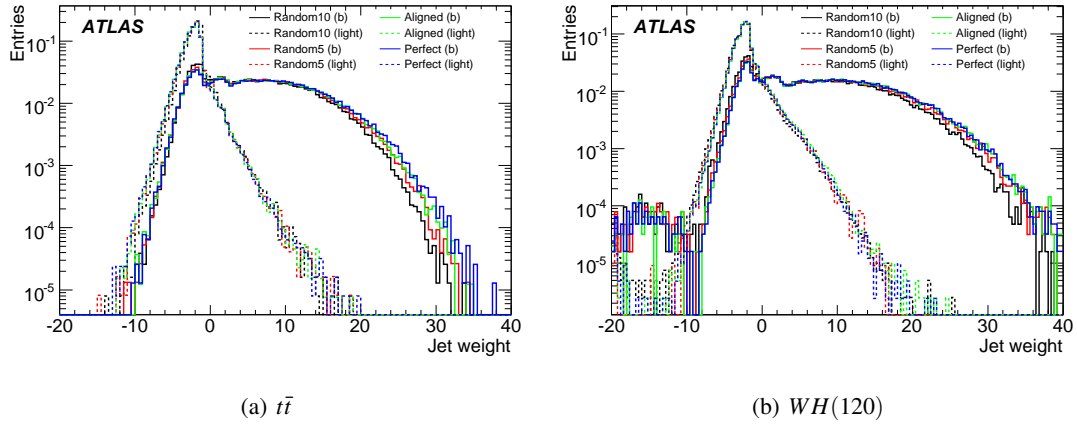

Figure 4: Jet weight distributions for the IP3D+SV1 tagger for the different alignment scenarios with error scaling for  $t\bar{t}$  (a) and  $WH(120)$  (b).

## 6.2 Effects of error scaling

It is observed in Fig. 3 that for the larger misalignment scenarios (“Random10” and “Random5”) the error scaling gives a significant improvement, while for the “Aligned” and “Perfect” case the impact of error scaling is small.

Figure 5 compares the  $b$ -tag weights with and without error scaling. Only the “Random10” results are shown. For the other scenarios the differences were less pronounced. The  $t\bar{t}$  events show some differences in behaviour for the error scaling as compared with the  $WH$  events. For  $t\bar{t}$ , the error scaling results in only a small difference for the light jets while for the  $b$ -jets the differences are more evident. This is in contrast with the  $WH$  events where the light jets show more differences and the  $b$ -jets are less affected.

Figure 5: Jet weight distributions for the IP3D+SV1 tagger comparing with and without error scaling (ES) for “Random10” scenario for  $t\bar{t}$  (a) and  $WH(120)$  (b).

The differences are thought to be associated with the  $p_T$  spectra of light jets and *b*-jets which are different from each other and different for the two event types. The effectiveness of the error scaling is expected to have some  $p_T$  dependence since for lower  $p_T$ , the multiple scattering will dominate and differences in hit errors will be less important. There was insufficient statistics in the samples however to verify if this was indeed the case.

In some cases the use of error scaling results in worse performance. This is discussed further in Section 6.4.

### 6.3 Purified jets

For comparison with other studies [2] purified jets were also studied. Purification excludes labelling jets as light jets when there is a *b*-quark within a cone of 0.8. This gives a more physics independent measure of the performance (although differences will still be seen between samples because of the different  $p_T$  and  $\eta$  distributions of the jets contained in the samples). Table 10 shows the results for purified jets for  $t\bar{t}$ . For *WH* events only standard jets were considered as other studies [2] show similar results with and without purification. Figure 6 compares standard and purified jets for  $t\bar{t}$  events and it can be seen that the rejections are higher for purified jets but the trends are similar for the different alignment scenarios. The degradation of the “Aligned” case with respect to the “Perfect” alignment is more pronounced after purification (19 – 23% degradation) than for the standard jets (10 – 14% degradation). The effects of error scaling showed similar behaviour for both standard and purified jets.

Figure 6: Comparison of light jet rejections using IP3D+SV1 tagger for standard and purified jets in  $t\bar{t}$  events. Left plot: 50% *b*-tag efficiency. Right plot: 60% *b*-tag efficiency.

### 6.4 Comparison of the different taggers

Figure 7 shows the rejections for different taggers for standard jets. The impact parameter based taggers are the most affected by misalignment with the “Aligned” set showing 10 – 20% lower rejections than the “Perfect” case and up to a factor 3 degradation for the largest misalignment. After error scaling, the SV1 tagger shows rather uniform performance for all scenarios considered, with the “Aligned” set giving 10% degraded performance with respect to the “Perfect” case.

Without error scaling (see Fig. 8) the SV1 tagger shows significant differences for the different alignment scenarios. The ratio between rejections with error scaling to those without error scaling is shown in Fig. 9. It can be seen that the error scaling has the most beneficial effect with the larger misalignments (“Random10” and “Random5”) for the SV1 performance. For the “Aligned” scenario the error scaling has little effect while for the “Perfect” case it actually degrades the performance slightly. For the impact parameter based taggers the error scaling has a smaller effect on the *b*-tagging performance and even degrades the performance in  $t\bar{t}$  events.

Figure 7: Comparison of the light jet rejections for the different taggers, IP2D, IP3D, SV1 and the combined tagger IP3D+SV1. Left plot: 50% *b*-tag efficiency. Right plot: 60% *b*-tag efficiency. Results are with error scaling using  $t\bar{t}$  events.

Due to the beneficial effect of the error scaling on the secondary vertexing, the overall performance of the combined tagger (IP3D+SV1) is also improved with error scaling in the case of the “Random10” and “Random5” sets. The error scaling parameter  $c$  is zero for the “Perfect” alignment and small for the “Aligned” set and consequently for both cases the effect of error scaling on the performance of *b*-tagging for the combined tagger is also small. For the “Aligned” case, while the relative difference is smaller than the hand-made sets, the error scaling degrades the performance slightly.

The reason for loss of performance with error scaling for some cases can be explained by the following: since the error scaling will generally increase the errors, it will reduce the impact parameter significance. This is desirable for light jets as it will make them more compatible with zero impact parameter. For *b*-jets, however, it also reduces the significance and so will reduce the *b*-tagging efficiency for a given weight cut, or in other words, one needs a lower weight cut to obtain the same efficiency and hence results in lower rejection for light jets for a given *b*-jet efficiency. The overall effect depends on these two competing effects and so can potentially lead to a loss in performance. While a decrease in performance with error scaling was observed in  $t\bar{t}$  events for the IP2D and IP3D taggers, the opposite was observed for *WH* events. As was already discussed above for the *b*-tag weight in Fig. 5, the error scaling affects the light jets and *b*-jets in the two physics samples differently and this is thought to lead to the differences in the error scaling behaviour seen here.

The effect of error scaling on the secondary vertex tagger will be to recover some secondary vertices which would have otherwise failed quality cuts due to an underestimated error. One will lose some true

Figure 8: As in Fig. 7 but without error scaling.

Figure 9: Ratio of rejections with error scaling to rejections without error scaling. Left plot: 50%  $b$ -tag efficiency. Right plot: 60%  $b$ -tag efficiency.

secondary vertices that are close to the primary vertex as the larger error will make them compatible with the primary vertex, however for similar reasons it will result in fewer fake secondary vertices close to the primary vertex.

## 6.5 Effects of recalibration

The taggers require probability distribution functions for light jets and *b*-jets as described in Ref. [2] and the process of obtaining the set of these reference distributions is known as calibration. The results presented here use the same set of calibrations as used in Ref. [2]. Since misalignments will alter these distributions, it is possible that one can obtain some more discriminating power by recalibrating using the misaligned sample. Methods for obtaining these calibrations from real data are explored in Ref. [3].

To investigate whether recalibrating results in any gain in performance, a new set of reference distributions was obtained for each sample with and without error scaling. In practice one should use independent samples to calibrate and to test the performance, however, here the reference distributions were obtained with the same or a subset of the sample used to measure the performance.

As seen in Fig. 10 recalibration gives better performance, although after error scaling the difference between the fixed calibration and recalibration is only marginal.

One might expect that recalibration may compensate any miscalculation of the errors in a similar way to the error scaling. This is only partially the case as can be seen in Fig. 11, where the relative improvement with error scaling is reduced when recalibrating.

Figure 10: Comparison of the light jet rejection obtained for the IP3D+SV1 tagger using a fixed calibration or recalibrating for each separate sample. Left plot: 50% *b*-tag efficiency. Right plot: 60% *b*-tag efficiency.

## 7 Conclusion

The effect of misalignment on the tracking performance, as measured by tracking efficiency and fake rates, was small, and error scaling recovered the performance almost to the level that was seen with the perfect alignment. The degradation of the primary vertex was more significant, with resolutions

Figure 11: Ratio of rejections with error scaling to rejections without error scaling. Results are shown for the IP3D+SV1 tagger. Left plot: 50% *b*-tag efficiency. Right plot: 60% *b*-tag efficiency. Compares using a fixed calibrations and recalibrating for each separate sample.

about  $2.5 \mu\text{m}$  degraded and an increase in the number of outliers. The “Aligned” set showed similar performance to the “Random10” despite better *b*-tagging performance.

The performance of *b*-tagging was clearly degraded with misalignment and the amount of degradation was found to be roughly proportional to the amount of random displacement of modules. Systematic effects are expected to also play an important role, however, the random displacement was the only aspect that was quantified in this study by the parameter  $c$  obtained in the error scaling procedure. In order to disentangle the contributions from random and systematic effects it would be necessary to create dedicated residual misalignment sets with known systematic distortions.

The impact parameter based taggers were observed to be the most affected by misalignment and the introduction of error scaling brought little or even negative benefit to the *b*-tagging performance in the case of  $t\bar{t}$  events. Error scaling was important for the performance of the secondary vertex finding, and without it, for larger misalignments the degradation for the secondary vertex based tagger was significant. With error scaling most of the degradation was recovered and the secondary vertex tagger showed uniform performance for all alignment scenarios considered. The behaviour of the combined tagger, IP3D+SV1, follows what one might conclude from the behaviour of the separate taggers, that is, it benefits from error scaling but shows a degradation with misalignment even after error scaling.

The “Aligned” set was the most realistic misalignment scenario studied here and the results were encouraging with rather moderate degradation in the *b*-tagging performance. In purified jets from  $t\bar{t}$ , the degradation was more evident with 19% loss of rejection at 50% *b*-tagging efficiency. However, in a more realistic environment, as seen by looking at standard jets, the amount of degradation was only 10%. At 60% *b*-tagging efficiency, the loss of rejection was slightly larger with 23% degradation for purified jets and 14% degradation for standard jets. For WH events the loss of rejection was similar with around 18% degradation at 50% *b*-tagging efficiency and 11% degradation at 60% *b*-tagging efficiency.

The amount of residual misalignment remaining after applying the actual alignment procedures resulted in only a small loss of performance and so misalignments are not expected to cause a major problem for doing *b*-tagging in ATLAS.

# Soft Muon $b$ -Tagging

## Abstract

$b$ -jets can be identified by taking advantage of the presence of a muon coming from the semi-leptonic decay of the  $b$  hadrons. This note describes a soft muon tagging algorithm and its performance when applied to different Monte Carlo physics samples in ATLAS. A  $b$ -jet tagging efficiency of about 10% (including the inclusive  $b \rightarrow \mu \nu X$  branching ratio of  $\approx 20\%$ ) is achieved for a light jet rejection of better than 300. The effect of pile-up events and cavern background on the performance is also considered and is found to be significant but manageable.

## 1 Introduction

Soft-lepton tagging relies on the semi-leptonic decays of  $b$  and  $c$  hadrons. Indeed the presence of a muon is enhanced in  $b$ -jets thanks to the significant semi-leptonic decay branching ratio of  $b$  hadrons ( $BR(b \rightarrow \mu \nu X) \approx 11\%$ ), and of  $c$  hadrons produced by the  $b$  hadron decay (sequential semi-leptonic decay,  $BR(b \rightarrow c \rightarrow \mu \nu X) \approx 10\%$ ). A soft muon tagger, while intrinsically limited by the small semi-leptonic branching ratio, offers a good alternative or complement to the more performant lifetime taggers. Thanks to its good purity and low correlation with lifetime taggers, it can be used to do cross-calibrations of the two types of tagger [1], or to enhance the lifetime tagger performance by combining the two. Finally, it permits derivation of specific jet energy corrections [2].

The properties of the soft muons and of the various backgrounds are shown in Section 2. The algorithm is then described in detail in Section 3 while its performance applied to different Monte Carlo samples is discussed in Section 4.

## 2 Properties of muons from semi-leptonic decays and their backgrounds

There are three sources of background from particles within light jets: muons coming from the decay of light hadrons (mostly pions), hadrons managing to go through the calorimeter and reaching the muon spectrometer (“punch-through”), and hits caused by the neutron gas that will be surrounding the detector during data taking, producing fake tracks in the muon spectrometer (“cavern background”).  $c$ -jets are also a source of background as far as  $b$ -tagging is concerned. Figures 1, 2, 3, and 4 show, respectively, the distance to the closest jet  $\Delta R = \sqrt{\eta^2 + \phi^2}$ , the muon transverse momentum, the impact parameter, and the transverse momentum relative to the closest jet axis  $p_T^{rel}$ , for muons from (direct)  $b$  decays, sequential  $b \rightarrow c \rightarrow \mu \nu X$  decays,  $c$  decay, light hadron decays, and fake muons, in jets of  $E_T > 15\text{GeV}$  and  $|\eta| < 2.5$  in  $t\bar{t}$  events.  $p_T^{rel}$  is defined as the muon momentum in the plane orthogonal to the jet axis, where the jet axis is corrected for the presence of a muon by adding the muon momentum to the jet momentum. Contributions from true muons are estimated at the generator level while fake muons are estimated with the full simulation and defined as a reconstructed muon associated with a jet while no muon of momentum larger than 2 GeV was found at the generator level within  $\Delta R = 0.6$  of that same jet. Note that the distinction between fake muons and muons from light hadron decays is somewhat arbitrary since the latter can also be produced in the calorimeter as part of the hadronic shower; such muons are present in the full simulation but are not distinguished from fake muons because long-lived particles and showers are taken care of by GEANT and the full GEANT information was not available in the present study. Muons produced by direct  $b$  hadron decays have a significantly larger transverse momentum than the various backgrounds, especially muons from light hadron decays; additionally, since light hadrons such as charged pions and charged kaons have a long lifetime, those muons tend to have a large impact

parameter. Those two properties will be used to reject this important background efficiently. Thanks to the *b* hadrons high mass, muons from direct *b* decays tend to be more boosted in a plane transverse to the jet axis, *i.e.* have a larger  $p_T^{rel}$  than the backgrounds. This property is used in the tagger to further separate *b*-jets from light jets through a likelihood technique. It is important to note that muons from sequential *b* decay are much more difficult to separate from background since they have a much softer spectrum both in  $p_T$  and  $p_T^{rel}$  than those from direct *b* decay. Finally, Fig. 5 shows that the  $p_T^{rel}$  distribution in  $t\bar{t}$  and  $WH$  events is very similar. Indeed the  $p_T^{rel}$  variable is not very correlated with the jet  $E_T$  or pseudo-rapidity. Thus it is not very dependent on the process producing the *b*-jets.

Figure 1: Distribution of  $\Delta R = \sqrt{\Delta\eta^2 + \Delta\phi^2}$  between closest jet and muons from *b* hadron decays, *c* hadron decays, light hadron decays, and fakes, in jets of  $E_T > 15\text{GeV}$  and  $|\eta| < 2.5$  in  $t\bar{t}$  events. The red line shows the cut applied for the basic selection described in Section 3. All histograms in Fig. 1 to 5 are normalized to unity.

### 3 Description of the algorithm

The algorithm works in three steps, described in the following sections:

- The standard muon reconstruction algorithms are used to identify muons.
- Muons satisfying some basic requirements are then associated to jets.
- Finally, a 1-dimensional likelihood ratio using the  $p_T^{rel}$  variable discriminates further signal from background.

#### 3.1 Muon reconstruction

Two complementary muon reconstruction algorithms are used by the soft-muon tagger: so-called “combined” muons, which correspond to a track fully reconstructed in the muon spectrometer and matched with a track in the inner detector; and “tagged” muons, which cannot reach the muon middle and outer

Figure 2: Transverse momentum distribution of muons from *b* hadron decays, *c* hadron decays, light hadron decays, and fakes, in jets of  $E_T > 15\text{GeV}$  and  $|\eta| < 2.5$  in  $t\bar{t}$  events. The last bin includes overflows. The red line shows the cut applied for the basic selection described in Section 3.

Figure 3: Impact parameter distribution of muons from *b* hadron decays, *c* hadron decays, light hadron decays, and fakes, in jets of  $E_T > 15\text{GeV}$  and  $|\eta| < 2.5$  in  $t\bar{t}$  events. The last bin includes overflows. The red line shows the cut applied for the basic selection described in Section 3.

Figure 4: Distribution of the transverse momentum relative to the jet axis of muons from *b* hadron decays, *c* hadron decays, light hadron decays, and fakes, in jets of  $E_T > 15\text{ GeV}$  and  $|\eta| < 2.5$  in  $t\bar{t}$  events. The last bin includes overflows.

Figure 5: Distribution of the transverse momentum relative to the jet axis of muons from *b* hadron decays and from background sources, in jets of  $E_T > 15\text{ GeV}$  and  $|\eta| < 2.5$  for  $t\bar{t}$  events and  $WH$  events. The last bin includes overflows.

stations and are identified by matching an inner detector track with a segment in the muon inner stations only. The ATLAS muon spectrometer is able to fully reconstruct muons of momentum larger than about 5 GeV, providing a precise measurement of its momentum, allowing – in combination with the inner detector track – a very good rejection of the combinatoric background in the dense environment of jets. Muon spectrometer tracks that fail to be combined with an inner detector track are not used by the soft-muon tagger because of the contamination from fakes and muons from light hadron decays. Tagged muons are less pure than combined muons but allow one to recover some efficiency in the crucial low momentum range. Thus both combined muons and tagged muons are used by the soft-muon tagger. For more details of muon reconstruction and identification, see Ref. [3].

### 3.2 Jet-muon association and basic selection

Muons are associated with the closest jet (in  $\eta \times \phi$ ) in the event (only jets with  $E_T > 15$  GeV and  $|\eta| < 2.5$  are considered) and the jet-muon pair is required to satisfy  $\Delta R(\text{jet-muon}) < 0.5$ . Additionally, muons are required to satisfy the following requirements:

- Impact parameter with regard to the primary vertex  $|d_0| < 4$  mm
- $p_T > 4$  GeV
- Matching between the muon spectrometer and inner detector tracks of  $\chi^2/dof < 10$

### 3.3 Likelihood ratio

Muons from semi-leptonic *b*-decays are further separable because of their particular kinematics. As shown in Section 1, the muon transverse momentum relative to the jet ( $p_T^{rel}$ ) is a good discriminant variable, and it is used in a likelihood ratio to discriminate between the *b* and light jet hypotheses. No attempt was made to specifically discriminate between *b*- and *c*-jets. The  $p_T^{rel}$  probability density functions were estimated on fully simulated  $t\bar{t}$  and  $WH \rightarrow \mu\nu b\bar{b}/WH \rightarrow \mu\nu u\bar{u}$  samples of several hundred thousand events and are shown in Fig. 6 and 7 for tagged and for combined muons separately. Here pile-up and cavern background are omitted. The normalized variable  $p_T^{rel}/(p_T^{rel} + 0.5 \text{ GeV})$  is used instead of  $p_T^{rel}$  in order to facilitate the smoothing of the probability density functions. The likelihood is found to be less discriminating for tagged muons than for combined muons because muons at low momentum tend to be produced by  $b \rightarrow c \rightarrow \mu X$  sequential decays, which also tend to yield a smaller  $p_T^{rel}$  as shown in the previous section. This is visible in the probability density function as a second peak at a value of  $\approx 0.5$  (compared to  $\approx 0.7$  for direct  $b \rightarrow \mu X$  decays). Each likelihood is normalized with the probability (estimated on the same fully simulated samples) that a reconstructed muon be associated with a jet of a given flavor. For each type of reconstructed muon (tagged or combined), the likelihood ratio  $Q$  can be written as follows:

$$Q = \frac{\epsilon_b^0 \times L(p_T^{rel}|b)}{\epsilon_l^0 \times L(p_T^{rel}|l)}$$

where  $\epsilon_b^0$  ( $\epsilon_l^0$ ) is the fraction of *b*-jets (light jets) that contain a muon satisfying the basic selection and  $L(p_T^{rel}|b)$  ( $L(p_T^{rel}|l)$ ) is the probability density function for a *b*-jet (light jet). It was found that  $\epsilon_b^0/\epsilon_l^0 \approx 6.6$  for tagged muons and  $\epsilon_b^0/\epsilon_l^0 \approx 44.4$  for combined muons, reflecting the fact that combined muons are purer and contribute to a large fraction of the efficiency.

Several muons can be associated with a jet. In such a case, the muon with highest transverse momentum is considered. At this point, no attempt has been made to use the information given by the presence of an additional muon in the jet.

Figure 6: Probability density function used in the algorithm likelihood for the  $p_T^{rel}$  variable, for the tagged muons.

Figure 7: Probability density function used in the algorithm likelihood for the  $p_T^{rel}$  variable, for the combined muons.

## 4 Performance

The algorithm performance was estimated on  $t\bar{t}$  and  $WH \rightarrow \mu\nu b\bar{b}/WH \rightarrow \mu\nu u\bar{u}$  Monte Carlo samples of several hundred thousand events. The jet flavor is determined at the generator level by matching reconstructed jets with quarks considered after final state radiation (for details, see Ref. [4]). Figures 8 and 9 show the *b*-tagging efficiency and the light jet tagging rate, respectively, with and without a cut on the likelihood ratio, as a function of jet  $E_T$  and pseudorapidity in  $t\bar{t}$  events. An average *b*-tagging efficiency of 10% is reached for a cut on the likelihood ratio of  $\ln Q > 3.05$ , which corresponds to rejecting all tagged muons and selecting combined muons with  $p_T^{rel} > 360$  MeV. No requirement on the *b* decay is made, so that the *b*-tagging efficiency includes the semi-leptonic branching ratios as well as the jet-muon association efficiency, the detector acceptance, and the muon reconstruction efficiency and selection. Likewise, the light jet tagging rate includes both light hadron decay muons and fake muons. The *b*-tagging efficiency tends to decrease as the jet  $E_T$  increases, mostly because of a drop in the tracking efficiency of the inner detector in highly collimated jets. Not surprisingly, the light jet tagging rate increases significantly with the jet  $E_T$ . After the basic selection stage, light hadron decays account for 8% (1.6%) of combined muons (tagged muons) present in tagged light jets in  $t\bar{t}$  events.

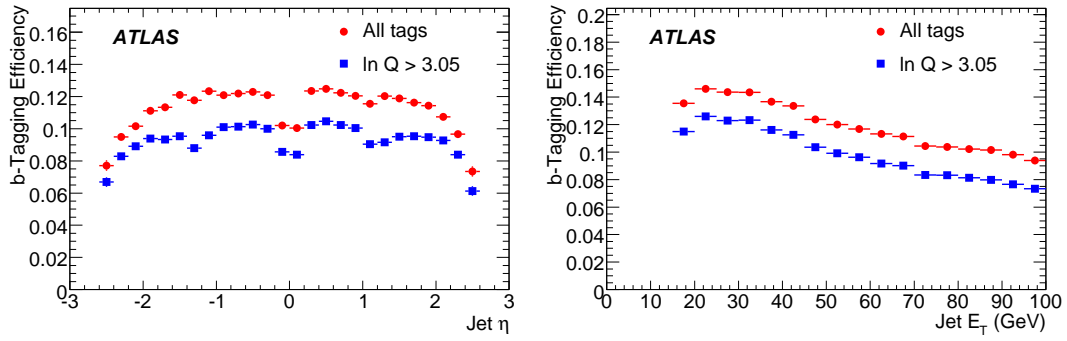

Figure 8: Probability for a *b*-jet to be tagged by the soft-muon tagger as a function of jet pseudorapidity (left) and transverse energy (right: the last bin includes overflows) without and with a requirement on the likelihood ratio corresponding to an average *b*-tagging efficiency of 10%.

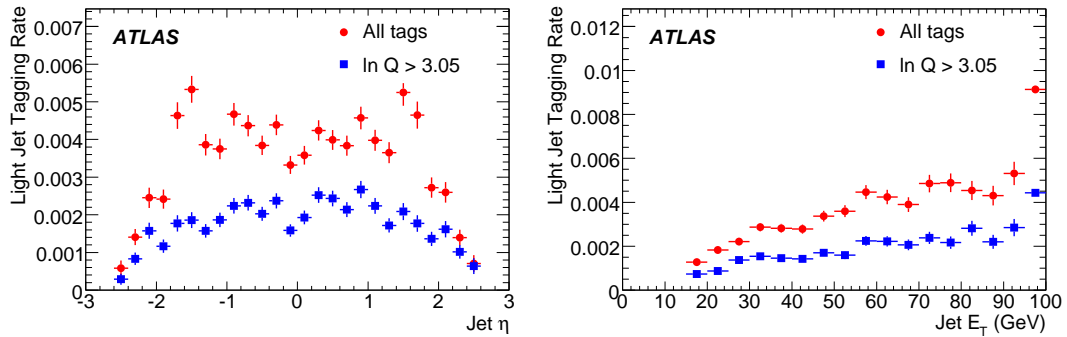

Figure 9: Probability for a light jet to be tagged by the soft-muon tagger as a function of jet pseudorapidity (left) and transverse energy (right, the last bin includes overflows) without and with a requirement on the likelihood ratio corresponding to an average *b*-tagging efficiency of 10%.

Figures 10 and 11 show the *b*-tagging efficiency vs light jet rejection (the inverse of the light jet tagging rate) for different cuts on the likelihood ratio. Figure 10 compares the performance in  $t\bar{t}$  and  $WH$  events. The rejection for a given efficiency is slightly better in  $t\bar{t}$  events than in  $WH$  events, due to the fact that jets in  $t\bar{t}$  events are more central, while the tagger performance is degraded in the forward region of the detector. The soft-muon tagger reaches a rejection of about 300 in  $WH$  events and 380 in  $t\bar{t}$  events for an efficiency of 10%.

Figure 11 shows the effect of pile-up (the superposition of several events occurring within the same bunch crossing) and cavern background on the tagger performance. Here, only jets matched to the hard-scatter process quarks are considered in order to make a fair comparison of the algorithm performance with and without cavern background and pile-up. Indeed, soft jets from pile-up events tend to have a lower light jet tagging rate and would bias the comparison. For a luminosity of  $2 \times 10^{33} \text{cm}^{-2} \cdot \text{s}^{-1}$ , pile-up and cavern background decrease the rejection by about 15% (for a given efficiency of 10%), which is significant but not dramatic.

Figure 10: *b*-tagging efficiency vs light jet rejection estimated in  $t\bar{t}$  and  $WH$  (without pile-up/cavern background).

Performance will have to be evaluated in data, using techniques similar to those developed at the Tevatron [5]. The muon reconstruction efficiency can be measured using a tag-and-probe method applied to  $J/\psi$  and  $Z$  samples. The light jet tagging rate may be measured using jet events, although disentangling background from heavy-flavor muons is a complex issue. Jet samples may also be used to test the likelihood probability distribution functions against data. Those issues have not been studied in the context of soft muon tagging in ATLAS yet.

## 5 Conclusion

The soft-muon tagger developed for the ATLAS detector shows excellent performance across a large jet  $E_T$  spectrum, with a light jet rejection of more than 300 for a *b*-tagging efficiency of 10%. The event pile-up and the cavern background appear to have a significant but not dramatic effect on the performance, with a decrease of about 15% on the light jet rejection at a luminosity of  $2 \times 10^{33} \text{cm}^{-2} \cdot \text{s}^{-1}$ .

Figure 11: *b*-tagging efficiency vs light jet rejection estimated on a  $t\bar{t}$  sample with and without pile-up/cavern background.

# Soft Electron $b$ -Tagging

## Abstract

The presence of an electron coming from the semi-leptonic decay of a  $B$  hadron can be used to tag  $b$ -jets. This note describes a soft electron tagging algorithm and its performance when applied to ATLAS Monte Carlo simulation data. Jets are built from the energy reconstructed in the electromagnetic and hadronic calorimeters with a cone algorithm. Electrons, reconstructed by a track-seeded algorithm, are sought among charged tracks associated to the jets. The tagging of jets originating from  $b$  quarks is based on kinematics and on the identification capabilities of the inner tracker and the electromagnetic calorimeter. The performance of the electron identification and  $b$ -tagging procedure are presented. A  $b$ -jet tagging efficiency of about 7% (including the inclusive  $b \rightarrow e\nu X$  branching ratio of  $\sim 20\%$ ) is achieved for a light jet rejection of better than 100.

## 1 Introduction

A variety of interesting physics processes at LHC, such as the  $H \rightarrow b\bar{b}$  decay for an intermediate Higgs boson mass range, top physics or searches for new physics require efficient identification of  $b$ -quarks. The performance of  $b$ -tagging algorithms in ATLAS are studied in Ref. [1]. The semi-leptonic decays of heavy quarks provide a clean signature used to identify the flavour composition of jets. The semi-leptonic decay modes are  $b \rightarrow \ell$ ,  $c \rightarrow \ell$  and the cascade decay  $b \rightarrow c \rightarrow \ell$ . Electrons produced in  $b$  decays (through direct and cascade decays) can be detected using the electromagnetic calorimeter and the inner detector. Since these electrons are non-isolated and with low transverse momentum, excellent electron/hadron separation capability is required. As a  $b$ -flavour tag, the lepton tag is not competitive with the lifetime tag because the branching ratio is low for such decays (about 20% for  $B$ -meson decays to leptons, including cascade decays, per lepton family) and is limited by the efficiency to reconstruct and identify electrons within jets. Still this method can be used with the vertex algorithms to provide a complement to the overall  $b$ -tagging performance and for cross-checks and calibration.

The note is organised as follows. Monte Carlo data samples used in this analysis are described in Section 2. The jet and track selections are described in Section 3. The electron identification algorithm is described in Section 4. The  $b$ -tagging algorithm and its performance are described in Section 5.

## 2 Monte Carlo samples

The samples used in this study contain events with electrons in jets from Higgs boson associated production  $WH$ , with  $W \rightarrow \mu\nu$ . We take the mass of the Higgs boson to be  $m_H = 120$  GeV. The signal sample consists of  $H \rightarrow b\bar{b}$  events and the background sample of  $H \rightarrow u\bar{u}$  events. Another sample of  $H \rightarrow b\bar{b}$  events is enriched in true electrons with a filter at the generation level. This filter is defined as follows: both  $b$  quarks (before final state radiation, FSR) are required to have a transverse momentum  $p_T^b > 15$  GeV and a pseudorapidity  $|\eta_b| < 2.5$ ; at least one true electron with  $p_T^e > 1$  GeV is required to be found in a cone  $\Delta R < 0.4$  around each  $b$ -quark direction (before FSR). This sample will be used only in Section 4 to model signal electrons with enough statistics.

All samples have been generated using the PYTHIA 6.403 [2] Monte Carlo event generator. More details on the Monte Carlo generators used can be found in [3]. Data have been passed through a full detector simulation based on GEANT4. No pile-up has been included but its effect on performance, based on previous studies, is mentioned below where relevant.

The signal electrons come from direct ( $b \rightarrow e$ ) and cascade ( $b \rightarrow c \rightarrow e$ ) semi-leptonic decays of  $B$ -hadrons. Apart from the previous sources, there are also some other sources<sup>1</sup>, mainly  $b \rightarrow \tau \rightarrow e$  and  $b \rightarrow (J/\psi, \psi') \rightarrow e^+e^-$ . The background electrons arise from  $\pi^0$  Dalitz decays,  $\gamma$ -conversions occurring in the inner detector and decays of light hadrons. The fraction of electrons from photon conversions becomes substantial at large pseudo-rapidities and large transverse momenta.

Distributions of true transverse momentum,  $p_T$ , and pseudo-rapidity,  $\eta$ , for electrons and pions are shown in Fig. 1 for the samples considered. Table 1 shows the mean values of the true transverse mo-

Figure 1: Normalized distributions of true transverse momentum  $p_T$  (left) and pseudo-rapidity  $\eta$  (right) are shown for signal electrons (hatched histograms), electrons from conversions (dotted line histograms) and pions (plain histograms).

mentum distributions for signal and background electrons and pions in the two samples.

Table 1: The mean true  $p_T$  (in GeV) for electrons and pions in various data samples.

sample	electrons				pions
	$B$ hadrons	$D$ hadrons	$\gamma$ -conversions and $\pi^0$ Dalitz	other sources

$H \rightarrow u\bar{u}$	-	-	5.2	4.2	7.1

### 3 Jet and track selection

The reconstruction of the various objects needed for  $b$ -tagging and the estimation of its performance are summarized in this section. The reconstruction of soft electrons will be detailed in the next section.

We follow the default jet reconstruction and labelling procedure described in Ref. [1]. Jets are reconstructed in the calorimeters using a standard cone algorithm with a size of  $\Delta R = 0.4$ . Jets with  $p_T > 15$  GeV and  $|\eta| < 2.5$  are considered for  $b$ -tagging. To assess quantitatively the  $b$ -tagging performance, Monte-Carlo information is used to determine the type of parton (a quark-based labelling) from which a jet originates. Jets are labelled as  $b$ -jets if a  $b$  quark with  $p_T > 5$  GeV (after FSR) is found in a cone  $\Delta R = 0.3$  around the jet direction. The labelling for  $c$ -jets (and  $\tau$ -jets) is done in the same way. By light jets we denote all other reconstructed jets.

<sup>1</sup>The corresponding branching ratios [4] are  $Br(b \rightarrow \ell^-) = (10.71 \pm 0.22)\%$ ,  $Br(b \rightarrow c \rightarrow \ell^+) = (8.01 \pm 0.18)\%$ ,  $Br(b \rightarrow \bar{c} \rightarrow \ell^-) = (1.62^{+0.44}_{-0.36})\%$ ,  $Br(b \rightarrow \tau \rightarrow e) = (0.419 \pm 0.055)\%$  and  $Br(b \rightarrow (J/\psi, \psi') \rightarrow e^+e^-) = (0.072 \pm 0.006)\%$ .

Figure 2: Track multiplicity in jets (left) and jet transverse momentum (right) for *b* jets (hatched histograms) and light jets (solid line). Only jets having at least one *good quality track* with  $p_T > 2$  GeV are considered.

For the soft electron *b*-tagging algorithm, a track-based electron reconstruction algorithm is used and will be described in the next section. In order to be able to identify track candidates as electrons, strict track selection criteria are applied and called hereafter *good track quality cuts*. To reduce the number of fake candidates in jets, only tracks with  $p_T > 2$  GeV are considered. The inner detector coverage extends to pseudo-rapidity values of  $\pm 2.5$ , except for the transition radiation tracker (TRT) which extends up to  $\pm 2$ . This sub-detector is crucial in the identification procedure, so the track selection requires  $|\eta| < 2$ . Tracks are required to have at least nine precision hits (pixels and SCT), at least two hits in the pixel detector, at least one hit in the vertexing layer (the so-called *b*-layer) and an unsigned transverse impact parameter at the perigee smaller than 1 mm. The TRT may record either of two types of hits, ‘low-energy’ hits which are used for track reconstruction and ‘high-energy’ hits which are used for electron identification. Selection criteria thus require at least 20 low-energy hits and at least one high-energy hit in the TRT detector along the track. After this selection, only about 50% of initial tracks remain. About 50% of actual *b*-jets and 60% of light jets, in the WH sample, have no *good quality track* associated. Figure 2 shows the multiplicity of *good quality track* inside jets and the jet transverse momenta. For jets having at least one *good quality track* the mean multiplicity is 3.8 (3.3) for *b*-jets (light jets). Light jets, which include ISR, FSR and underlying events, have a softer transverse momentum than *b* jets, which are originated from the *H* decay, with a mean  $p_T$  of 51 GeV against 57 GeV, but with a large spread, an RMS of  $\sim 35$  GeV.

The fraction of jets containing electrons with a *good quality track* is given in Table 2 for signal and background samples.

Table 2: Fraction of jets (in %) with an electron at the generator level that also have a *good quality track*, for the signal and background samples.

Sample	$\gamma$ -conversions and $\pi^0$ Dalitz	<i>B</i> hadrons	<i>D</i> hadrons	Other sources
$H \rightarrow b\bar{b}$	1.6	3.4	2.2	0.3
$H \rightarrow u\bar{u}$	1.3	$< 10^{-4}$	$< 10^{-4}$	0.1

## 4 Electron reconstruction and identification

The standard electron reconstruction procedure [5] is based on calorimeter clusters, with a subsequent association to tracks. While this method is efficient for high-energy isolated electrons, such as those arising from *W* or *Z* decays, it is not effective for electrons inside hadronic jets, such as those from semi-leptonic decays. Indeed hadron and electron showers tend to overlap in collimated jets so that electron cluster characteristics are obscured. An alternative procedure takes full advantage of the tracking capabilities of the inner detector as well as the granularity of the electromagnetic calorimeter. The method relies on the extrapolation of reconstructed charged particle trajectories into the electromagnetic calorimeter. The most common background processes for producing electron-like showers in the calorimeters were described in Section 2. Because the development of showers is different for electrons and hadrons, the electron identification algorithm incorporates variables that describe the shower shapes, quality of the match between the track and its corresponding cluster, and the fraction of high-energy hits in the transition radiation tracker. This algorithm is used also for the reconstruction of low  $p_T$  electrons in *J/ψ* events [6].

### 4.1 Electron reconstruction

All the tracks that pass the *good track quality cuts*, described in the previous section, are extrapolated to the second (also known as middle) sampling layer of the electromagnetic calorimeter. Around this position a cluster of size  $\Delta\eta \times \Delta\phi = 0.125 \times 0.125$  ( $5 \times 5$  cells in this sampling layer) is built. The cell with the maximum energy is sought within a small  $\eta$  and  $\phi$  window ( $0.075 \times 0.075$ ) around the extrapolation point. Shower shapes are estimated with respect to this cell. The contribution of neighbouring hadronic showers is therefore reduced.

A set of *preselection* criteria are applied to decrease the number of fake candidates per jet:

- The ratio of energy reconstructed in the core of the shower in the first sampling layer to the total shower energy reconstructed in the core of the cluster, must fulfil  $E_1(\text{core})/E(\text{core}) > 0.03$ .  $E_1(\text{core})$  is the energy reconstructed in a window of size  $\Delta\eta \times \Delta\phi = 0.009375 \times 0.1$  in the first sampling layer ( $3 \times 1$  cells).  $E(\text{core})$ , the core energy in the cluster, is computed in the following windows:  $0.075 \times 0.3$  ( $3 \times 3$  cells) in the presampler,  $0.046875 \times 0.2$  ( $15 \times 2$  cells) in the strips,  $0.125 \times 0.125$  ( $5 \times 5$  cells) in the middle,  $0.15 \times 0.125$  ( $3 \times 5$  cells) in the back. This ratio tends to be larger for electrons than for hadrons due to the different development of hadronic and electromagnetic showers. This quantity is discussed in detail in the following section.
- Similarly, the fraction of energy reconstructed in the core of the shower in the third sampling layer to the energy reconstructed in the core of the cluster,  $E_3(\text{core})/E(\text{core})$ , must be smaller than 0.5.  $E_3(\text{core})$  is the energy reconstructed in a window of size  $\Delta\eta \times \Delta\phi = 0.15 \times 0.075$  in the third sampling layer ( $3 \times 3$  cells). This ratio is larger for hadrons than it is for low-energy electrons which almost never reach this layer and is discussed in the following section.
- The ratio of the energy  $E$  reconstructed in the electromagnetic calorimeter over the momentum  $p$  of the track reconstructed in the inner detector is required to fulfil  $E/p > 0.7$ .

These *preselection* criteria cut out less than 5% of signal electrons. Finally, candidates which are also reconstructed as originating from a conversion are vetoed, corresponding to a loss of 9% of all signal and background tracks.

Position and energy corrections are applied in the precise reconstruction of the electromagnetic cluster and are described in [7]. These corrections have been tuned for high-energy clusters and are not optimal for low-energy electrons. In Fig. 3 the ratio between the reconstructed and the true electron

Figure 3: Ratio between reconstructed and true energy as a function of the electron pseudo-rapidity  $|\eta|$  (left) and ratio of the reconstructed to true momentum for electrons (right).

energies is shown as a function of  $|\eta|$  for signal electrons from the  $H \rightarrow b\bar{b}$  sample. It can be seen that the corrections over-estimate the electron energy. Moreover, as electrons are embedded in jets, there is a contamination from other hadrons in the energy determination which is not visible with the isolated electrons from a  $J/\psi$  sample [6]. Work is on going to improve the energy reconstruction at low energy.

By default the four-momentum of an electron is defined as the energy reconstructed in the calorimeter, whereas the direction is taken from the associated track. Since in this note the main physics processes lead to electron transverse momenta of less than 15 GeV, the momentum measured in the tracker is used instead of the energy unless stated otherwise. The reconstructed momentum of the electron is shown in Fig. 3. The track reconstructs the momentum of the electron close to its true value for most candidates. The small downward shift of the peak from unity and the tail towards lower values are due to photon bremsstrahlung. Future developments in ATLAS will ensure an optimal combination of calorimeter and tracker measurements in the energy definition.

## 4.2 Electron identification variables

The hadronic calorimeter has a granularity of  $\Delta\eta \times \Delta\phi = 0.1 \times 0.1$  which is too large to disentangle the energy deposit of an electron inside a jet. In the electromagnetic calorimeter, electrons are narrow objects while jets tend to have a broader profile, allowing a discrimination. For this purpose, we use the finer granularity ( $\Delta\eta \times \Delta\phi = 0.05 \times 0.025$ ) of the third sampling layer of the electromagnetic calorimeter. The ratio  $E_3(\text{core})/E(\text{core})$ , defined above, is larger for pions than for electrons and is clearly discriminating as can be seen in Fig. 4.

Electromagnetic showers deposit most of their energy in the second sampling layer of the electromagnetic calorimeter. The following variables are used:

- The lateral shower shape  $R_\eta$  (cf. Fig. 5 on left) is given by the ratio of the energy reconstructed in a window of size  $0.075 \times 0.175$  ( $3 \times 7$  cells of the middle sampling layer) to the energy reconstructed in  $0.175 \times 0.175$  ( $7 \times 7$  cells).
- The lateral width  $\omega_{\eta 2} = \sqrt{\frac{\sum E_c \times \eta^2}{\sum E_c} - \left(\frac{\sum E_c \times \eta}{\sum E_c}\right)^2}$  (cf. Fig. 5 on right) is calculated in a window of size  $0.075 \times 0.125$  ( $3 \times 5$  cells of the middle sampling layer) using the energy weighted sum over all cells, which depends on the particle impact point inside the cell.

The first layer, with its very fine granularity in pseudo-rapidity, can be used to detect sub-structures within a shower and thus isolated  $\pi^0$ 's and  $\gamma$ 's can be discriminated against efficiently. For all variables computed in the first sampling layer, two cells in  $\phi$  are summed.

Figure 4: Ratio  $E_3(\text{core})/E(\text{core})$  (see text) for electrons in the  $H \rightarrow b\bar{b}$  sample (hatched histogram) and for charged pions in the  $H \rightarrow u\bar{u}$  sample (solid line). The distributions are normalized to unit area.

Figure 5: Lateral shower shape  $R_\eta$  (left) and lateral width  $\omega_{\eta 2}$  (right) in the second layer of the electromagnetic calorimeter (see text for details). The distributions are shown for electrons in the  $H \rightarrow b\bar{b}$  sample (hatched histograms) and for charged pions in the  $H \rightarrow u\bar{u}$  sample (solid lines). The distributions are normalized to unit area.

The ratio  $E_1(\text{core})/E(\text{core})$ , defined above, is larger for electrons than for hadrons as can be seen in Fig 6.

The lateral shower shape in the strips is now exploited.

- The total shower width in strips  $\omega_{\text{tot}}$  is determined in a window  $\Delta\eta = 0.0625$  (corresponding to 20 strips in the barrel for instance). It is calculated from:  $\omega_{\text{tot}} = \sqrt{\sum E_i \times (i - i_{\text{max}})^2 / \sum E_i}$ , where  $i$  is the strip number and  $i_{\text{max}}$  the strip number of the first local maximum. This width is shown for electrons and pions in Fig. 7.
- The shower width using three strips around the one with the maximal energy deposit is shown in Fig. 7 on the right. It is given by the following formula:  

$$\omega_{s3} = \sqrt{\sum E_i \times (i - i_{\text{max}})^2 / \sum E_i}$$
, where  $i$  is the number of the strip and  $i_{\text{max}}$  the strip number of the most energetic one.

The pion and jet rejection can be significantly improved by ensuring consistency between the electromagnetic calorimeter and the inner detector information.

Figure 6: Ratio  $E_1(\text{core})/E(\text{core})$  (see text) for electrons in the  $H \rightarrow b\bar{b}$  sample (hatched histogram) and for pions in the  $H \rightarrow u\bar{u}$  sample (solid line). The distributions are normalized to unit area.

Figure 7: Total shower width  $\omega_{\text{tot}}$  (left) and shower width in three strips  $\omega_{s3}$  (right) in the first layer of the electromagnetic calorimeter. The distributions are shown for electrons in the  $H \rightarrow b\bar{b}$  sample (hatched histograms) and pions in the  $H \rightarrow u\bar{u}$  sample (solid lines). The distributions are normalized to unit area.

First, the angular matching between the track and the electromagnetic cluster is checked (cf. Fig. 8):  

$$|\Delta\eta| = \frac{\sum_{i=i_m-7}^{i=i_m+7} E_i \times (i - i_m)}{\sum_{i=i_m-7}^{i=i_m+7} E_i},$$
 which gives the difference between the track and the shower positions in units of distance between the strips, where  $i_m$  is the impact cell for the track reconstructed in the inner detector and  $E_i$  is the energy reconstructed in the  $i$ -th cell in the  $\eta$  direction, at constant  $\phi$  given by the track parameters.

Subsequently, the energy  $E$  measured in the electromagnetic calorimeter is compared to the momentum  $p$  measured in the inner detector (cf. Fig. 9 on the left). In the case of an electron, the momentum should match the energy. The large tails at high values of the ratio in the signal distribution are due to soft bremsstrahlung.

A further reduction of the charged hadron contamination is obtained by rejecting tracks having a low fraction of high-energy hits in the TRT. Figure 9 (right) shows the ratio  $N_{\text{HTR}}/N_{\text{straw}}$  between the number of high threshold hits  $N_{\text{HTR}}$  and the total number of TRT hits  $N_{\text{straw}}$ .

Figure 8: Angular matching between charged tracks extrapolated to the electromagnetic calorimeter and electromagnetic clusters in pseudo-rapidity ( $|\Delta\eta|$ ). The distributions are shown for electrons in the  $H \rightarrow b\bar{b}$  sample (hatched histogram) and for pions in the  $H \rightarrow u\bar{u}$  sample (solid line). The distributions are normalized to unit area.

Figure 9: Ratio  $E/p$  between the energy of the electromagnetic clusters and the momentum of reconstructed charged tracks (left) and fraction  $N_{\text{HTR}}/N_{\text{straw}}$  of high-energy hits in the TRT (right). The distributions are shown for electrons in the  $H \rightarrow b\bar{b}$  sample (hatched histograms) and for pions in the  $H \rightarrow u\bar{u}$  sample (solid lines). The distributions are normalized to unit area.

### 4.3 Rejection of electrons from $\gamma$ -conversions and Dalitz decays

A significant source of low- $p_T$  electron tracks in jets are photon conversions and Dalitz decays. Such tracks might be identified by the algorithm as signal electron tracks. The *good quality track* cuts help in part to suppress that type of background. In case of  $\gamma$ -conversions and Dalitz decays,  $e^+e^-$  pairs with small invariant mass are observed in the detector. To find them the conversion finding algorithms can be used. Ref. [8] details the last developments on the reconstruction of such electrons. Unfortunately, these were not available for the electron reconstruction algorithms at the time of this study. As detailed in Section 4.1, about 9% of signal electrons are mis-identified as conversions. Based on previous studies [9], for an electron efficiency  $\varepsilon_e = 80\%$ , the rejection factor of electrons from conversions and Dalitz decays is  $\sim 3$  with the conversion package and  $\sim 2$  without.

## 5 $b$ -tagging algorithm

The variables described in the previous section have been shown to be efficient in distinguishing electron tracks from non-electron tracks or electron tracks from  $\gamma$ -conversions and Dalitz decays.

In order to construct a  $b$ -tagging algorithm we combine these variables with additional variables to exploit the specific features of  $b$ -jets. First we take advantage of the fact that the electron is coming from a  $b$  quark and thus can have a significant transverse impact parameter  $d_0$ . Figure 10 shows the corresponding distributions. In addition, because of the  $B$  hadron's high mass, electrons from direct

Figure 10: Transverse impact parameter for electrons in the  $H \rightarrow b\bar{b}$  sample (hatched histogram) and for pions in the  $H \rightarrow u\bar{u}$  sample (solid line). The distributions are normalized to unit area.

bottom decays tend to be more boosted in a plane transverse to the jet axis, *i.e.* have a larger  $p_T^{rel}$  than the backgrounds, as shown in Fig. 11.  $p_T^{rel}$  is defined as the electron momentum in the plane orthogonal to the jet axis.

Figure 11: Distribution of the track transverse momentum  $p_T^{rel}$  relative to the jet axis for signal electron tracks in  $b$  jets (hatched histogram) and for pion tracks in light jets (solid line).

The combination of all variables is performed in two steps; first for variables independent of the jet and second including a jet dependent variable as explained in Section 5.1. Finally the performance of the algorithm will be detailed in Section 5.2.

## 5.1 *b*-tagging procedure

A likelihood-ratio method is used to combine the variables described in the previous section along with the electron track impact parameter  $d_0$ . This likelihood ratio uses information only on the characteristics of the electron and is independent of the parameters of the jet. The discriminating variables are compared to pre-defined normalized distributions (probability density functions) for both the electron and the pion hypotheses. We use the signal sample of  $H \rightarrow b\bar{b}$  filtered for electrons and part of the  $H \rightarrow u\bar{u}$  background samples. The variables show a significant dependence on pseudo-rapidity and a less pronounced one on transverse momentum. In  $\eta$  the changes correspond to varying granularities, lead thickness and material in front of the electromagnetic calorimeter. The separation between the distributions obtained for electrons and pions can vary also with  $\eta$ . Therefore probability density functions are defined in five  $|\eta|$  bins: (0-0.8), (0.8-1.37), (1.37-1.52), (1.52-1.8), (1.8-2).

Figure 12: Discriminating function  $D_{\text{track}}$  for electrons in the  $H \rightarrow b\bar{b}$  sample (hatched histogram) and for pions in the  $H \rightarrow u\bar{u}$  sample (solid line). The distributions are normalized to unit area.

For each *good quality* track the discriminating function  $D_{\text{track}}$  is calculated as:

$$D_{\text{track}} = \frac{\prod_i P_e(x_i)}{\prod_i P_e(x_i) + \prod_i P_h(x_i)}, \quad (1)$$

where  $x_i$  denotes the value of the  $i$ -th variable for a given track,  $P_e(x_i)$  is the probability obtained from the single variable  $x_i$  that the track originates from a signal electron,  $P_h(x_i)$  is the probability that the track originates from a hadron, and  $i$  runs through all the variables used by the algorithm. Distributions of  $D_{\text{track}}$  obtained for signal electrons and background pions are shown in Fig. 12.  $D_{\text{track}}$  tends to 1 for electrons and tends to 0 for pions. The identification of a candidate track as originating from a signal electron track is based on the value of  $D_{\text{track}}$ . Those tracks for which  $D_{\text{track}}$  is below a given threshold are rejected. Typically, for an electron identification efficiency of 80%, a pion rejection factor of about 200 can be achieved in  $H \rightarrow u\bar{u}$  events.

For each *good quality* track in the jet the value of the discriminating function for electron identification,  $D_{\text{track}}$ , defined previously in Eq. 1, has been calculated. For each jet, the track with the highest value  $\max(D_{\text{track}})$  is chosen and this single track will now be used to estimate the discriminating function  $D_{\text{jet}}$  for the jet. In addition to the variables used for electron identification based on the inner detector and electromagnetic calorimeter information, the track transverse momentum  $p_T^{\text{rel}}$  relative to the jet axis, shown in Fig. 11 is included. For each jet the discriminating function  $D_{\text{jet}}$  is calculated using the selected track as:

$$D_{\text{jet}} = \max(D_{\text{track}}) \times \frac{P_e(p_T^{\text{rel}})}{P_e(p_T^{\text{rel}}) + P_h(p_T^{\text{rel}})}, \quad (2)$$

where  $P_e(p_T^{rel})$  is the probability obtained from the single variable  $p_T^{rel}$  that the track originates from a *b*-jet and  $P_h(p_T^{rel})$  is the probability that the track originates from a light jet. Distributions of  $D_{jet}$  obtained for *b*- and light jets are shown in Fig. 13. For a given threshold  $D_{jet}^{thr}$ , a jet with  $D_{jet} > D_{jet}^{thr}$  is tagged as a *b*-jet.

Figure 13: Discriminating function  $D_{jet}$  for *b*-jets in the  $H \rightarrow b\bar{b}$  sample (hatched histogram) and light jets in the  $H \rightarrow u\bar{u}$  sample (solid line). The distributions are normalized to unit area.

## 5.2 Performance of the *b*-tagging algorithm

The *b*-tagging efficiency is defined as  $\varepsilon_b = N_b^t / N_b$  where  $N_b^t$  is number of the tagged *b*-labelled jets and  $N_b$  is the total number of jets labelled as *b*-jets. The definition includes the semi-leptonic branching ratios as well as the detector acceptance and the electron reconstruction and identification efficiencies. The jet rejection factor is calculated as  $R_{lightjet} = N_j / N_j^t$ , where  $N_j$  is the number of light jets and  $N_j^t$  is the number of light jets tagged by mistake as *b*-jets.

Figure 14 shows the rejection of light jets as a function of the *b*-tagging efficiency  $\varepsilon_b$ . The rejection factors achieved against light jets are presented in Table 3. For a *b*-tagging efficiency  $\varepsilon_b = 7\%$  on

Figure 14: Rejection factor of light jets  $R_{lightjet}$  versus *b*-tagging efficiency  $\varepsilon_b$ .

inclusive *b*-jets, the light jet rejection factor is about 110. This operating point corresponds to a 61% *b*-tagging efficiency on semi-electronic *b*-jets.

Table 3: Light jet rejection factors  $R_{\text{light jet}}$  for various *b*-tagging efficiencies  $\varepsilon_b$  on inclusive jets. Errors are statistical only.

$\varepsilon_b$ (%)	$R_{\text{light jet}}$
8	$80 \pm 1$
7	$110 \pm 2$
6	$160 \pm 3$

This study has been performed on Monte Carlo simulated data which do not include pile-up effects. Based on previous study [10], a further degradation of the light jets rejection factor by 10% (30%) is expected when on average 4.6 (23) minimum-bias events per beam-crossing are added.

Figure 15 shows the light jet rejection as a function of the jet  $p_T$  and  $|\eta|$  for a total *b*-tagging efficiency  $\varepsilon_b = 7\%$ . Performance are estimated in five bins in  $|\eta|$  and in seven bins in  $p_T$ . The rejection of light jets does not depend significantly on jet  $p_T$  over the range 30-80 GeV. For lower  $p_T$ , jets are wider and an electron can escape outside the cone of  $\Delta R = 0.4$  and this leads to lower rejections for the same *b*-tagging efficiency. For higher jet energies, the jet is narrower and showers coming from the particles in the jet overlap more and thus it is more difficult to separate the electrons, leading to a drop in rejection. A loss in the jet rejection factor can also be observed in the region  $1.37 < |\eta| < 1.52$  corresponding to the crack between the barrel and the end-caps of the electromagnetic calorimeter. Even though soft electrons are reconstructed only within  $|\eta| < 2$ , some sensitivity is retained for jet axes just beyond the cut-off as shown in Fig.15.

Figure 15: Light jet rejection factor as a function of jet  $p_T$  (left) and jet  $|\eta|$  (right) for a *b*-tagging efficiency  $\varepsilon_b = 7\%$ .

Table 4 shows the fraction of jets tagged of a given type of track for  $\varepsilon_b = 7\%$ . Most *b*-jets are tagged by true electron tracks; in particular by signal electrons in  $\sim 65\%$  of cases. Light jets are tagged in  $\sim 25\%$  of cases by electrons from  $\gamma$ -conversions and Dalitz decays. Light jets are also tagged in  $\sim 60\%$  of cases by pions.

## 6 Conclusion

Soft electron tagging relies on the semi-leptonic decays of bottom and charm hadrons. It is therefore intrinsically limited by the branching ratios to electrons: about 20% of *b*-jets will contain a soft electron,

Table 4: Fraction of jets (%) in the  $WH$  sample tagged by a specified type of track for  $\varepsilon_b = 7\%$ . The “ $e$  from  $*$ ” column corresponds to electrons from conversions and Dalitz decays. Statistical errors on these numbers are negligible.

Jet type	Fraction of jets tagged by a specified type of track [%]						
	all $e$	$e$ from $b$	$e$ from $c$	$e$ from $*$	other $e$	$\pi$	others
$b$	67.6	42.0	19.4	3.6	2.6	23.9	8.5
light	27.2	0.2	0.4	25.5	1.1	58.7	14.1

including cascade decays of bottom to charm hadrons. However, when a signal electron is present the algorithm is quite efficient. In addition, tagging algorithms based on soft leptons have low correlations with the track-based  $b$ -tagging algorithms, which is very important for checking and cross-calibrating performance with data.

The study presented here was based on a sample of  $WH$  events which have two high  $p_T$  and well separated jets. A  $b$ -jet tagging efficiency of about 7% (including the inclusive  $b \rightarrow e\nu X$  branching ratio of  $\sim 20\%$ ) is achieved for a light jet rejection better than 100. The efficiency of the soft electron identification is high, since two-thirds of the  $b$ -jets are tagged by the true electron. Work is ongoing to prepare similar analyses with other Monte Carlo simulated samples with different topologies as well as to prepare the measurement with real ATLAS data.

# ***b*-Tagging Calibration with $t\bar{t}$ Events**

## **Abstract**

This note describes various studies of  $b$ -jet reconstruction and  $b$ -tagging in simulated ATLAS  $t\bar{t}$  events. The performance of several jet algorithms on  $t\bar{t}$  event  $b$ -jets is studied. Techniques for measuring the  $b$ -tagging efficiency directly from data  $t\bar{t}$  events, using both tag counting and explicit  $b$ -jet selection, are described and compared. Finally, the optimisation of  $b$ -tagging for  $t\bar{t}$  events, using both Monte Carlo and data samples, is discussed. Both semileptonic and dilepton  $t\bar{t}$  decay channels are considered, for an initial integrated luminosity of  $100\text{ pb}^{-1}$ .

## **1 Introduction**

The identification of  $b$ -jets is of crucial importance to many physics analyses at the LHC, including top physics and the search for new particles including Higgs bosons. The performance of  $b$ -tagging algorithms will have to be understood using real data, as Monte Carlo will only give an approximate description of the tracking and vertexing performance of the detector, at least initially. Light jet rejection factors can be measured in inclusive jet samples (where the heavy flavour content is small), but pure samples of  $b$ -jets are required to measure the  $b$ -jet tagging efficiency. One solution, already widely used at the Tevatron, exploits dijet events in which one of the jets is  $b$ -tagged using a soft lepton tag [1].

At the LHC, the large  $t\bar{t}$  production cross-section offers an alternative source of  $b$ -jets, in a distinctive topology which is relatively easy to trigger on and isolate, providing at least one of the  $W$ -bosons from the top decays leptonically. Providing the top quark is assumed to have Standard Model properties (in particular that  $\text{Br}(t \rightarrow Wb) = 1$ ), each  $t\bar{t}$  event has two  $b$ -jets, together with at least one high- $E_T$  lepton, missing energy and additional high- $E_T$  jets from hadronically decaying  $W$ -bosons. The environment (high jet multiplicity, high- $E_T$   $b$ -jets) is also much closer to that which  $b$ -tagging efficiency measurements are typically needed than in dijet events.

The  $b$ -tagging efficiency can be extracted from  $t\bar{t}$  events in two ways—either by counting events with different numbers of tagged jets, or by reconstructing the  $t\bar{t}$  decay topology in order to identify a pure sample of  $b$ -jets. Both techniques are explored in this note, which is organised as follows. Section 2 briefly describes the Monte Carlo simulation samples and common event selection which is used throughout, and Section 3 discusses reconstruction of  $b$ -jets in  $t\bar{t}$  events, as an essential preliminary to studies of  $b$ -jet tagging. The counting and  $b$ -jet selection methods are discussed in Sections 4 and 5. Finally, Section 6 discusses the possibilities for optimising  $b$ -tagging performance specifically for  $t\bar{t}$  events, using both Monte Carlo and data.

## **2 Datasets and event selection**

All studies were performed using ATLAS Monte Carlo production samples as discussed in more detail in [2] and [3]. Semileptonic and dileptonic  $t\bar{t}$  decays were generated with MC@NLO with Herwig hadronisation. AcerMC with Pythia hadronisation was used as an alternative. The background in the semileptonic channel is dominated by  $W$ +multijet production, which was simulated with ALPGEN (including  $Wb\bar{b}$  and  $Wc\bar{c}$ ), and single top production, simulated with AcerMC. In the dilepton channel (used only for the counting method  $b$ -tagging efficiency determination), additional backgrounds from  $Z$ +jets (simulated with ALPGEN) and diboson production (simulated with Herwig) are also important. Background coming from QCD multijet events has not been studied, as this background is difficult to simulate

$t\bar{t}$ (except all hadronic)	Electron channel 45232	Muon channel 45232		Dilepton channel 45232

Table 1: Numbers of events from  $t\bar{t}$  production expected with  $100 \text{ pb}^{-1}$  in the lepton+jets and dilepton channels. The cut efficiency w.r.t. the previous line is shown in parenthesis. The fully hadronic decay  $t\bar{t}$  contribution is not included but is expected to be small. Contributions from non- $t\bar{t}$  background are not included.

and samples were not available. The normalisation of such background (if significant) will eventually have to be extracted from data.

Systematic errors have been evaluated following the prescriptions discussed in detail in [2] and [4] wherever possible. The sensitivity to incorrect  $b$ -tagging of non- $b$  jets was assessed by doubling and setting to zero the corresponding jet tagging efficiencies, separately for light quark and charm jets. The jet energy scale was varied by  $\pm 5\%$ . The Monte Carlo event generation sensitivity was assessed by using AcerMC instead of MC@NLO, including samples with modified ISR, FSR and parton shower cutoff  $Q^2$ . The backgrounds from  $W$ +multijet events and single top production were independently doubled and set to zero. In all cases, the effect of these variations was computed without adjusting parameters of the analysis (*e.g.* acceptance factors and background estimates) to compensate for changes made to the input Monte Carlo samples.

The analyses make use of isolated high  $E_T$  electrons and muons (with  $E_T > 20$  GeV) and jets (with  $E_T > 20$  GeV or higher depending on the particular analysis), selected according to standard ATLAS object definitions and fiducial cuts [2]. In the semileptonic channel, events are required to have exactly one high  $E_T$  lepton, at least four jets and missing transverse energy of at least 20 GeV. In the dilepton channel, two leptons of opposite charge and a missing transverse energy of at least 20 GeV are required; in the  $e^+e^-$  and  $\mu^+\mu^-$  channels, the  $Z$ +jets background was further reduced by vetoing events with dilepton mass between 81 and 101 GeV and by requiring a missing transverse energy of at least 35 GeV. In both cases, at least one lepton in the event was required to pass the ATLAS level-1, level-2 and event filter triggers, using trigger signatures appropriate for the 20 GeV offline lepton  $E_T$  cuts. For electrons, the signatures e25i and e60 were used (the e60 trigger improves the efficiency at high lepton  $E_T$ ), and for muons, the signature mu20i was used. Further studies of the ATLAS trigger performance on  $t\bar{t}$  events can be found in [5].

The resulting estimated event yields at various stages of the event selection are shown in Table 1 for  $100 \text{ pb}^{-1}$ . Non- $t\bar{t}$  backgrounds are not included. The individual analyses apply further specific selection cuts as discussed below. The effects of the tighter selections used only by the tag counting analysis described in Section 4 are also shown in Table 1. The hadronic  $W$  mass window cut was applied by selecting the pair of jets with invariant mass closest to the  $W$  mass and requiring this to be within  $\pm 20$  GeV of the nominal value; a top mass cut was applied similarly by adding the jet giving a reconstructed top mass closest to the nominal, and requiring it to be within  $\pm 30$  GeV of the top mass.

All studies were performed with the default ATLAS  $b$ -tagging algorithm (IP3D+SV1), which uses

a likelihood weight  $w$  constructed from the results of the IP3D impact parameter and SV1 secondary vertex-based taggers [6]. This likelihood weight is large for *b*-jets and small for light and *c*-quark jets. For jets from top decay with  $E_T > 20$  GeV, a cut  $w > 4$  gives a *b*-jet tagging efficiency of around 70 % per jet and a light jet rejection of 50 while a  $w > 7$  cut gives an efficiency of 60 % and a rejection of 200, though these values are somewhat dependent on jet  $E_T$  and  $\eta$ . Detailed studies of the expected *b*-tagging performance can be found in [6] (e.g. in Table 1 therein). For the purposes of comparison, *b*-tagging efficiency measurements have been done at reference efficiencies of 50, 60 and 70 %. Various other cut values are used internally by the selections in the individual analysis methods. When considering Monte Carlo truth information, jets have been labelled *b*, *c* and light using the standard ATLAS jet matching and labelling procedures [6].

### 3 *b* jet reconstruction in $t\bar{t}$ events

The choice of jet reconstruction algorithm is an important issue for top physics analysis in ATLAS, where good resolution for the reconstruction of the original quark energy and direction is mandatory. These questions are explored below, using various jet algorithms and parameter choices. The analysis uses a sample of 250k semileptonic  $t\bar{t}$  events generated with MC@NLO and passed through the standard top selection as discussed in Section 2. The choice of jet algorithm also affects the *b*-tagging performance, as studied in detail elsewhere [6].

The standard reconstruction outputs jet collections made with the Cone (with  $\Delta R = 0.4$  and  $\Delta R = 0.7$ ) and  $k_T$  (with  $D = 0.4$  and  $D = 0.6$ ) jet algorithms, each based on either Precluster Projective Towers (‘Tower’) or Topological Cell Clusters (‘Topo’) (see [7] for more information on jet reconstruction in ATLAS). For this study, these standard jet reconstruction algorithms and parameter choices have been complemented by additional Cone and  $k_T$  jets with a larger variety of  $\Delta R$  and  $D$  parameters. To compare all these jet algorithm and parameter choices in a controlled environment, re-reconstruction of jets was performed at the AOD level, using ‘Topological Cell Clusters’ calibrated by ‘Local Hadron Calibration’ (see [8] and [9] for details about the different strategies used to exploit and calibrate calorimeter information). All parameters except for the  $D$  parameter ( $k_T$ ) or  $\Delta R$  (Cone) were left unchanged with respect to the standard jet algorithms.

It should be noted that these re-reconstructed jets do not contain the calorimeter energy corrections applied in the standard calibration procedure described in [7] and [8]. Therefore a comparison of the overall performance between the different jet algorithms with different parameters is valid, but no direct comparison between corrected and non-corrected jets should be made.

#### 3.1 Jet energy and angle resolution

Reconstructed jets are matched to quarks from the  $t\bar{t}$  decay following the standard procedure [6]. The results are shown in Fig. 1.

The top plots of Fig. 1 show the width of the distributions  $(E_{quark} - E_{jet})/E_{quark}$  (i.e. the energy resolution) as a function of  $E_{quark}$ , for both  $k_T$  and Cone. To calculate the width, a Gaussian is fitted to the individual distributions. The distributions show the expected behaviour. The smallest width is obtained for the jet sizes 0.4, 0.5 and 0.6, for both Cone and  $k_T$ . However, the differences between the different jet algorithms are small, so no strong conclusions can be drawn from them.

The two lower plots of Fig. 1 show an investigation of the angular resolution. The mean distance between the initial quark and the resulting jet in  $\Delta R$  is plotted as function of  $E_{quark}$  for Cone and  $k_T$ . The expected behaviour is that for bigger jet sizes the deviations between the jet axis and the flight direction of the initial quark should increase; this behaviour is observed in Fig. 1. It can also be seen that for larger jets and higher quark energies, the  $k_T$  jet algorithm performs better than Cone.

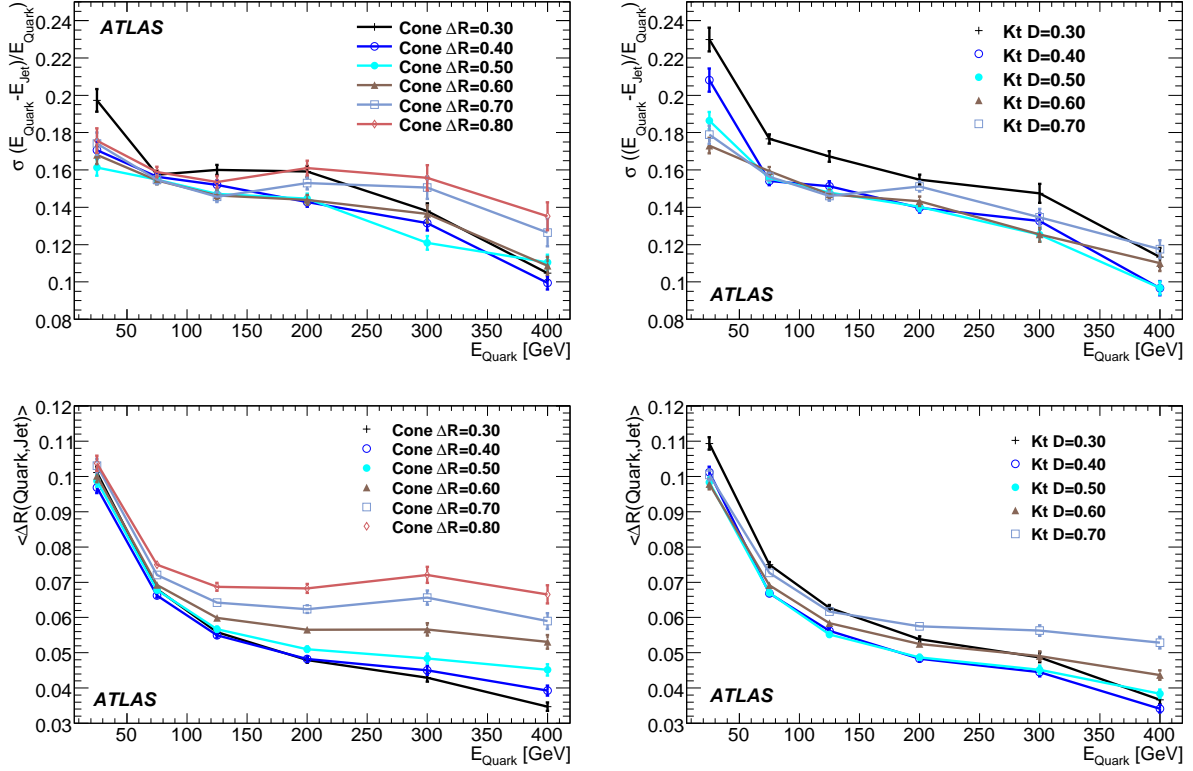

Figure 1: Studies of  $b$ -jet resolution: width of  $(E_{\text{quark}} - E_{\text{jet}})/E_{\text{quark}}$  and average of  $\Delta R(\text{Quark, Jet})$  for Cone and  $k_T$  with different jet sizes.

The choice of the Cone algorithm with  $\Delta R = 0.4$  that was driven by the need to reconstruct properly  $W$  hadronic decays [10] has been found to be an appropriate choice for the  $t\bar{t}$  signal. Background studies that will be performed in the near future will complete the picture.

## 4 $b$ -tagging efficiency measurement via tag counting

Conceptually, in the absence of background, the simplest way to determine the  $b$ -tagging efficiency in  $t\bar{t}$  events is to count the number of events with different numbers of  $b$ -tagged jets; this allows both the  $b$ -tagging efficiency and the  $t\bar{t}$  production cross-section to be measured simultaneously. This method is discussed in detail below, with an emphasis on the  $b$ - (and  $c$ -) tagging efficiency measurements. More information on  $t\bar{t}$  cross-section measurement can be found elsewhere [4].

In the following analysis, the event selection has been slightly tightened from that used elsewhere, in order to reduce the background. Jets are required to have  $E_T > 30$  GeV. In the lepton+jets channel, the single top background is significantly reduced by applying a cut on the  $W$  and top reconstructed masses, as described in Section 2.

### 4.1 Method

Top pair-production events give rise to two  $b$ -jets in the final state. Assuming for pedagogical purposes that every selected event contains two  $b$ -jets in the detector acceptance and that only  $b$ -jets can be tagged,

then it is clear that the expected number of events with one  $b$ -tagged jet is proportional to  $N2\varepsilon_b(1 - \varepsilon_b)$  while the expected number of events with two  $b$ -tagged jets is proportional to  $N\varepsilon_b^2$ , where:

- $\varepsilon_b$  is the  $b$ -tagging efficiency, i.e. the probability to tag a  $b$ -jet
- $N$  is the number of selected  $t\bar{t}$  events prior to any  $b$ -tagging requirement, which is proportional to the  $t\bar{t}$  production cross-section.

It can be seen that it is possible to estimate both the  $b$ -tagging efficiency and the  $t\bar{t}$  production cross-section from the observed number of events with one and two  $b$ -tagged jets.

In reality,  $c$ -jets and light jets (either from the hadronic  $W$  decay or from ISR/FSR) are present and contribute to the number of tagged jets in the event. Moreover not all  $b$ -jets coming from the top decays end up being selected, whilst a small number of  $b$ -jets are produced through gluon radiation. To take these effects into account, the event flavour content is estimated from Monte Carlo with a large simulation  $t\bar{t}$  sample. The factors  $F_{ijk}$  are defined as the fractions of selected events (prior to any  $b$ -tagging requirement) with  $i$   $b$ -jets,  $j$   $c$ -jets, and  $k$  light jets ( $i, j, k = 0, 1, 2, 3, \dots$ ). The *expected* number of events with  $n$  tagged jets  $\langle N_n \rangle$  can be written as the sum over all possible combinations of  $i$   $b$ -jets,  $j$   $c$ -jets, and  $k$  light jets, as a function of  $b$ -,  $c$ -, and light jet tagging efficiency:

$$\langle N_n \rangle = (L \cdot \sigma_{t\bar{t}} \cdot A_{pre-tag}) \cdot \sum_{i,j,k} F_{ijk} \sum_{i'+j'+k'=n} A_i^{i'} \cdot \varepsilon_b^{i'} \cdot (1 - \varepsilon_b)^{i-i'} \cdot A_j^{j'} \cdot \varepsilon_c^{j'} \cdot (1 - \varepsilon_c)^{j-j'} \cdot A_k^{k'} \cdot \varepsilon_l^{k'} \cdot (1 - \varepsilon_l)^{k-k'} \quad (1)$$

where  $A_i^{i'}$  is the number of arrangements  $i!/(i'!(i-i')!)$ , the prime subscript corresponding to the number of *tagged* jets of a given flavour;  $\sigma_{t\bar{t}}$  is the total production cross-section;  $A_{pre-tag}$  is the acceptance for  $t\bar{t}$  events prior to any  $b$ -tagging requirement (including trigger efficiency, lepton reconstruction and ID efficiency, *etc.*) and  $L$  is the integrated luminosity. The assumption that there is no correlation between tags in a given event is discussed later and is treated as a systematic uncertainty.

Finally, the following likelihood can be written:

$$L = \Pi(\text{Poisson}(N_n, \langle N_n \rangle)) \quad (2)$$

where  $N_n$  is the *observed* number of events with  $n$  tags. In practice only events with one, two, or three tags in the lepton+jets channel and one or two tags in the dilepton channel are taken into account in the likelihood. Events with no tag suffer from significant background, whilst there are few events with more than three (two in the dilepton channel) tags. In the lepton+jets channel, both  $b$ - and  $c$ -tagging efficiencies are allowed to fluctuate in the fit together with the  $t\bar{t}$  cross-section (hence three variables and three constraints); the light jet tagging efficiency is fixed in the fit and must be measured elsewhere. In the dilepton channel, the  $c$ -jet tagging efficiency is also fixed (hence two variables and two constraints).

Tables 2 and 3 show the  $F_{ijk}$  values for the lepton+jets and dilepton channels, estimated from a sample of 265k  $t\bar{t}$  events. It is interesting to note that the ‘nominal’ combination (two  $b$ -jets and two light jets for the lepton+jets channel; two  $b$ -jets for the dilepton channel) represents only about one third of the events, due to the presence of ISR/FSR light jets and  $c$ -jets from  $W$  decays. The significant presence of  $c$ -jets in the lepton+jets channels allows the  $c$ -jet tagging efficiency to also be measured.

Figures 2 and 3 show the expected yield of events in the lepton+jets and dilepton channels for an integrated luminosity of  $100 \text{ pb}^{-1}$ , as a function of the number of tagged jets. A  $b$ -jet is considered tagged if its  $b$ -tagging weight  $w$  is greater than 7.

The method was applied to a sample of  $t\bar{t}$  events corresponding to about  $400 \text{ pb}^{-1}$  of data and independent of those used to estimate the acceptance factors. Table 4 compares the measured efficiencies and cross-section to their true value for three different  $b$ -tagging purity levels. No bias is visible within the available statistics. The small deviation for the cross-section measurement in the dilepton channel is explained by the lack of statistics in the sample used to estimate the  $F_{ijk}$  factors; this issue is discussed

Number of light jets	1	2	3	4	any
2 $b$ -jets, 1 $c$ -jet	15.9 %	10.6 %	3.00 %	0.85 %	30.5 %
2 $b$ -jets, 0 $c$ -jet	-	24.4 %	13.8 %	3.74 %	42.8 %
1 $b$ -jet, 1 $c$ -jet	-	6.46 %	2.38 %	0.74 %	9.75 %
1 $b$ -jet, 0 $c$ -jet	-	-	7.60 %	3.21 %	11.6 %
0 $b$ -jet, 1 $c$ -jet	-	-	0.38 %	0.11 %	0.49 %
0 $b$ -jet, 0 $c$ -jet	-	-	-	0.46 %	0.65 %

Table 2: Fractions of selected events with a certain number of  $b$ ,  $c$  and light jets in the lepton+jets channel for the counting method. Only the dominant contributions are shown.

Number of light jets	0	1	2	3	any
2 $b$ -jets, 1 $c$ -jet	1.02 %	0.73 %	0.27 %	<0.1 %	2.08 %
2 $b$ -jets, 0 $c$ -jet	35.2 %	20.9 %	6.64 %	1.39 %	64.3 %
1 $b$ -jet, 1 $c$ -jet	1.68 %	1.08 %	0.46 %	0.22 %	3.54 %
1 $b$ -jet, 0 $c$ -jet	-	18.9 %	6.26 %	1.66 %	27.2 %
0 $b$ -jet, 1 $c$ -jet	-	0.29 %	0.11 %	<0.1 %	0.40 %
0 $b$ -jet, 0 $c$ -jet	-	-	1.11 %	0.31 %	1.50 %

Table 3: Fractions of selected events with a certain number of  $b$ ,  $c$  and light jets in the dilepton channel for the counting method. Only the dominant contributions are shown.

later together with other systematic uncertainties. With  $100 \text{ pb}^{-1}$ , a statistical precision of 2.7% (4.2%) can be achieved on the  $b$ -tagging efficiency, and 2.4% (4.8%) on the  $t\bar{t}$  cross-section, respectively in the lepton+jets channel and dilepton channel. In the lepton+jets channel, the statistical uncertainty on the  $c$ -tagging efficiency is rather large, because this measurement is mostly determined by the number of events with three tagged jets.

## 4.2 Backgrounds

In the lepton+jets channel, the main backgrounds are  $W$ +jets and single top. Other sources of background are  $Z$ +jets (where one lepton fails to be identified),  $WW/WZ/ZZ$ +jets, and QCD processes (which has

		$\varepsilon_b$ (%)		$\varepsilon_c$ (%)		$\sigma_{t\bar{t}}$ (pb)
		true	meas.	true	meas.	
Lepton+jets	$w > 4$	72.1	71.7 $\pm$ 0.7	22.3	21.9 $\pm$ 1.5	841 $\pm$ 9
	$w > 7$	60.4	59.8 $\pm$ 0.8	12.8	13.8 $\pm$ 1.3	844 $\pm$ 10
	$w > 10$	48.1	47.4 $\pm$ 0.9	6.7	8.2 $\pm$ 1.4	832 $\pm$ 13
Dilepton	$w > 4$	72.9	72.9 $\pm$ 1.0	-	-	882 $\pm$ 17
	$w > 7$	61.1	60.5 $\pm$ 1.2	-	-	883 $\pm$ 19
	$w > 10$	48.4	47.9 $\pm$ 1.3	-	-	883 $\pm$ 25

Table 4: Counting method: tagging efficiencies and cross-section measured on a control sample and compared to their true value for three levels of  $b$ -tagging purity, for the lepton+jets and dilepton channels. The  $t\bar{t}$  production cross-section was assumed to be 833 pb. The uncertainties are statistical only and correspond to about  $400 \text{ pb}^{-1}$  of data.

Figure 2: Yield expected for an integrated luminosity of  $100 \text{ pb}^{-1}$  in the lepton+jets channel as a function of the number of tagged jets. The expected background from  $W/Z$ +jets, single top, and diboson production is also shown.

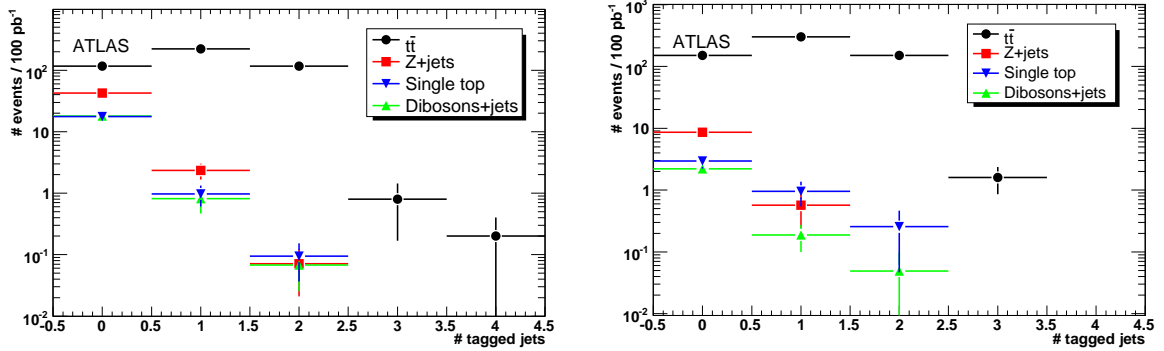

Figure 3: Yield expected for an integrated luminosity of  $100 \text{ pb}^{-1}$  in the dilepton+jets channels (left:  $ee/\mu\mu$ ; right:  $e\mu$ ) as a function of the number of tagged jets. The expected background from  $Z$ +jets and single top is also shown.

not been studied, as discussed in Section 2). Figure 2 shows the total background due to  $W/Z$ +jets, single top, and diboson+jets production and Fig. 4 (left) shows the expected signal over background ratio as a function of the number of tagged jets. Events with one, or more than one, tagged jets have good purity, with signal over background ratios of 14.4 and 26.8 respectively, but the background does need to be taken into account. The estimated background is subtracted from each sub-sample.

In the dilepton+jets channel, the main source of background is  $Z$ +jets production (but in the  $e\mu$  channel, only  $Z \rightarrow \tau\tau \rightarrow e\mu\nu\nu$  is significant).  $WW/WZ/ZZ$ +jets and single top also contribute. Figure 3 shows the total background due to  $Z$ +jets and diboson+jets production. The purity of the dilepton+jets sample (especially of the  $e\mu$  channel) is good enough for the background estimate not to be an issue. Figure 4 shows that the expected signal over background ratio for events with exactly one tagged jet

Channel Source	Lepton+Jets			Dilepton	
	$\epsilon_b$	$\epsilon_c$	$\sigma_{t\bar{t}}$	$\epsilon_b$	$\sigma_{t\bar{t}}$

Table 5: Relative systematic and statistical uncertainties (in percent) for the lepton+jets channel for a  $b$ -tagging efficiency of  $\epsilon_{\text{true}} = 0.6$  and jet  $E_T > 30 \text{ GeV}$ .

is 80 in the  $ee$  and  $\mu\mu$  channels and 175 in the  $e\mu$  channel; the background is completely negligible for events with two or more tagged jets. It is remarkable that the  $e\mu$  0-tagged jet sub-sample is also quite pure and could be used in the fit to improve its statistical power, provided a reliable background estimate is available.

Figure 4: Signal over background ratio vs the number of tagged jets in the lepton+jets channel (left) and in the dilepton  $ee/\mu\mu$  and  $e\mu$  dilepton+jets channels (right).

### 4.3 Systematic uncertainties

Table 5 summarizes the resulting systematic uncertainties for the counting method in the lepton+jets and the dilepton channels. Some effects specific to this method are discussed in detail below.

The acceptance factors  $F_{ijk}$  depend upon the definition of jet flavour, which is arbitrary to some ex-

tent. By default, reconstructed jets are matched to the closest heavy quark (after FSR) in  $\Delta R = \sqrt{\eta^2 + \phi^2}$ ; the jet is attributed the quark flavour if  $\Delta R < 0.3$  (in case of ambiguity, *b* quarks have priority over *c* quarks). Jets that are not associated to any *b* or *c* quark are considered light jets. Another possibility is to match jets with hadrons, following the same procedure. It was checked that the choice of matching hadrons or quarks has a negligible effect on the definition of jet flavour. To assess the systematic uncertainty, the cut was shifted from 0.2 to 0.5 (nominal cut: 0.3) and the  $F_{ijk}$  factors were re-estimated for each value. The shift observed on the same pseudo-experiments was taken as systematic effect.

The counting method assumes that there is no correlation between *b*-tags within an event, while some detector effects or the reconstructed primary vertex might induce such a correlation. To check this assumption, events with two reconstructed *b*-jets in the detector acceptance were selected. The covariance between the tagging of the two *b*-jets is:

$$\text{cov}(\text{tag}_1, \text{tag}_2) = \frac{N^{2b\text{-tags}}}{N} - \varepsilon_b^2$$

(where  $N^{2b\text{-tags}}$  is the number of events with two tagged *b*-jets,  $N$  is the total number of events, and  $\varepsilon_b$  is the true *b*-tagging efficiency). It was found that  $\text{cov}(\text{tag}_1, \text{tag}_2) = (8.8 \pm 27) \cdot 10^{-4}$ , which is consistent with 0; the statistical uncertainty corresponds to a bias on the measured efficiency of 0.2 %, which is conservatively taken as systematic uncertainty.

Backgrounds are subtracted in each sub-sample and a 100% uncertainty is assumed. In the lepton+jets sample, for  $100 \text{ pb}^{-1}$ , 106 events from  $W/Z$ +jets are expected to populate the lepton+jets 1-tag sub-sample and 34.6 the 2-tag sub-sample. In the dilepton channel, 4.4 events with one tagged jet are expected for all three channels (mostly in the  $ee$  and  $\mu\mu$  channels), resulting in a small uncertainty.

A 5% uncertainty on the jet energy scale, a 1% additional uncertainty on the *b*-jet energy scale, and a 2 GeV uncertainty on the top mass, are also taken into account.

The statistical uncertainty on the  $F_{ijk}$  factors was estimated by comparing the results given by two different training samples. It is not negligible in the dilepton+jets channel (3 %). However it could easily be reduced by employing a larger  $t\bar{t}$  sample (1M events would suffice); thus it was not included in the total uncertainty.

The cross-section measurement is very sensitive to the jet multiplicity, which is driven mostly by ISR and FSR. This uncertainty appears also in the comparison of the two MC generators since the hadronisation models (Herwig in one case, Pythia in the other) need to be tuned in data and display important differences. In order to avoid to count twice the uncertainty on jet multiplicity, only the largest of the two estimates (ISR/FSR and MC generators) was considered in the total systematic uncertainty.

Systematic uncertainties on  $\sigma_{t\bar{t}}$  that are not specific to this analysis are discussed elsewhere [4]. Uncertainties relative to integrated luminosity and event selection prior to *b*-tagging (namely, lepton identification efficiency, trigger efficiency and pdf's) amount to 5 % and 2.8 %, respectively.

#### 4.4 Tag counting results

With  $100 \text{ pb}^{-1}$  of data, the counting method allows the *b*-tagging efficiency at a working point of  $\varepsilon_{\text{true}} = 0.6$  to be measured with a relative precision of  $\pm 2.7(\text{stat.}) \pm 3.4(\text{syst.}) \%$  in the lepton+jets channel, and  $\pm 4.2(\text{stat.}) \pm 3.5(\text{syst.}) \%$  in the dilepton channel. A better understanding of ISR/FSR could significantly reduce the systematic uncertainty.

The uncertainty on the  $t\bar{t}$  production cross-section is somewhat larger in both channels, with  $\pm 2.4(\text{stat.})_{-14.7}^{+12.7}(\text{syst.}) \pm 5(\text{lum.}) \%$  in the lepton+jets channel, and  $\pm 4.8(\text{stat.})_{-7.7}^{+7.2}(\text{syst.}) \pm 5(\text{lum.}) \%$  in the dilepton channel, mostly because of the uncertainties on the jet multiplicity (ISR/FSR), jet energy scale, and background estimate, uncertainties that can be improved in the long term and have been assessed conservatively here.

The lepton+jets channel also allows the  $c$ -tagging efficiency to be measured. Unfortunately it is very sensitive to light jet contamination, and the uncertainty on light jet rejection and jet multiplicity makes any precision measurement impossible. Isolating a purer  $c$ -jet sample through some kinematic selection might help but has not been attempted here.

## 5 Selecting $b$ jet samples in data

Going beyond the  $b$ -tagging efficiency measurement from the counting method discussed above, the kinematics and topology of semileptonic  $t\bar{t}$  events also allow pure samples of  $b$ -jets to be identified directly. Providing this selection is done without biasing any properties of the selected  $b$ -jets, they can then be used to measure the  $b$ -tagging efficiency, simply by studying the distribution of the tagging discriminant variable(s) in the selected jets. With enough statistics, this technique should also allow the measurement of the tagging efficiency as a function of other variables (e.g. jet  $E_T$  and  $\eta$ ).

Obtaining a pure sample of identified  $b$ -jets requires full reconstruction of the  $t\bar{t}$  decay chain, assigning four jets in the event to the two  $b$ -jets coming directly from the  $t \rightarrow Wb$  decays and the jets from hadronic  $W \rightarrow qq$  decay. For any given event, many different assignments are possible, especially when spectator jets (not from the  $t\bar{t}$  decay) are also present. The correct combination can be determined by making use of kinematic information, including the reconstruction of the hadronic and leptonic top masses for each considered combination, and the classification can be further improved by requiring a  $b$ -tag for *one* of the jets assigned to the  $t \rightarrow Wb$  decay, providing the other presumed  $b$ -jet is left unbiased.

Three similar techniques have been explored for making this jet identification, all of which consider each combinatorial jet assignment and try to determine which one is correct:

- A ‘topological’ selection based on the reconstructed masses for each combination.
- A ‘likelihood’ selection, exploiting reconstructed top mass, jet momentum and angular information.
- A ‘kinematic’ selection based on applying a kinematic fit to each combination and choosing the one with the best  $\chi^2$  value.

All of these methods start from the selection of semileptonic  $t\bar{t}$  events discussed in Section 2, *i.e.* events with a high- $E_T$  lepton, significant missing energy and at least four jets. None of the methods result in a sample which is 100 % pure in  $b$ -flavoured jets, so background subtraction techniques are needed to derive pure samples on a statistical basis. The three methods, their associated background subtraction techniques, and their application to the measurement of the  $b$ -tagging efficiency for the standard IP3D+SV1 tagger, are discussed in Sections 5.1, 5.2 and 5.3 below. Comparisons of their performance in terms of  $b$ -jet sample selection and  $b$ -tagging efficiency measurement are then given in Sections 5.4 and 5.5.

### 5.1 Topological selection

The topological selection of  $b$ -jets from the basic sample has two stages: reconstruction of  $t\bar{t}$  pairs, followed by fitting the top mass distributions to extract the  $b$ -jet sample and estimate the remaining background. To improve the purity, an explicit  $b$ -tag is required on the jet from the hadronic top decay, whilst the  $b$ -jet from the leptonic top is left unbiased, and is used to form the sample of  $b$ -jets for measuring the tagging efficiency.

An attempt is made to reconstruct both hadronic and leptonic top decays in each event. First, the invariant mass of every pair of jets is calculated to look for combinations consistent with coming from the decay  $W \rightarrow jj$ . Combinations satisfying  $60 < m_{jj} < 100$  GeV are retained, and combined with a third

jet to form a candidate  $t \rightarrow bW \rightarrow bj\bar{j}$  decay. One jet from the  $W$  decay and the candidate  $b$ -jet must have jet  $E_T > 40$  GeV, and the second  $W$  decay jet must have  $E_T > 20$  GeV. To reduce background, this candidate  $b$ -jet is required to have a  $b$ -tagging weight of  $w > 3$ , corresponding to an efficiency of about 74 % for genuine  $b$ -jets from top decay. Additionally, the two  $W$  jets are both required to have  $b$ -tagging weights of  $w < 3$ , to reduce the probability that the  $b$ -jet from the top decay is included in the  $W$ . No mass requirements are placed on the hadronic top candidate at this stage.

A leptonic top is then reconstructed from one of the other jets and a reconstructed leptonic  $W$  decay. The leptonic  $W$  is formed from the identified lepton and a neutrino, whose transverse momentum ( $p_x, p_y$ ) is taken to be equal to the missing transverse momentum vector of the event. The longitudinal momentum of the neutrino is inferred using the constraint of the known  $W$  mass, which leads to a quadratic equation for  $p_z$  which has either two or no solutions. In the case of two solutions, the one with the smaller  $p_z$  is chosen. If there is no solution, the measured missing  $E_T$  is scaled down, preserving its direction, until a solution is possible. The reconstructed  $W$  is then combined with another jet which was not used in making the hadronic  $W$ , which is assumed to be the  $b$ -jet from the leptonic top decay. This jet is required to have  $E_T > 20$  GeV. No requirements are placed on the  $b$ -tagging weight for this jet, which is instead enhanced in  $b$ -flavour due to the topological reconstruction of the  $t\bar{t}$  event.

This procedure is performed for all possible combinations of jets in each event. In an event with four jets, several assignments of jets to the hadronic top  $b$ -jet, leptonic top  $b$ -jet and  $W$  decay jets are possible, constrained by the requirements made on the  $b$ -tagging weights for the jets assigned to the hadronic top decay. In events with more than four jets, some jets will be left unassigned, and are assumed to be spectator jets from initial or final state radiation or the underlying event. As the number of jets in the event increases, the number of combinations satisfying all the requirements increases very rapidly, from typically one or two combinations in events with four jets to an average of nine combinations for events with six or more jets. The combination with the largest scalar sum of the  $p_T$  of the two tops is retained for further analysis. In  $100 \text{ pb}^{-1}$  of fully-simulated  $t\bar{t}$  events plus  $W$ +jets background, 3028 events are selected, of which 80 % are semileptonic  $t\bar{t}$  events with  $t \rightarrow b\ell\nu$  or  $b\bar{\ell}\bar{\nu}$ , with the background being dominated by  $t\bar{t}$  with  $b \rightarrow b\tau\nu$  (11 %) and  $W$ +jets (6 %), together with smaller contributions from dilepton and single top events.

### 5.1.1 Mass fitting

After all these selections, only one assignment of jets and leptons to the hadronic and leptonic top decays remains. The resulting distributions of reconstructed hadronic and leptonic top masses are shown in Fig. 5. Clear top mass peaks are seen in both distributions, though with significant combinatorial background and a small contribution from  $W$ +jet and single top background events. Contributions from non- $t\bar{t}$  events (denoted class 1), events where both tops are incorrectly reconstructed (class 2), events where one top (hadronic or leptonic) is correctly reconstructed and the other is not (classes 3 and 4), and events where both tops are correctly reconstructed (class 5) are shown separately. For these purposes, a top decay is considered correctly reconstructed if the associated  $b$ -jet is actually labelled as a  $b$ -jet by the Monte Carlo truth analysis, and the direction of the reconstructed top decay is within  $\Delta R$  of 0.5 (2.0) for the hadronically (leptonically) decaying top. The hadronic top mass distribution in Fig. 5 shows peaks for classes 3 and 5, and the leptonic top mass shows peaks for classes 4 and 5, though with a considerably worse mass resolution. Both distributions also show some ‘peaking’ structure in the combinatorial backgrounds.

The analysis aims to extract a pure sample of  $b$ -jets from the reconstructed leptonic top decay. The leptonic top is chosen since it does not suffer from combinatorial background within the top decay itself—by contrast, in the hadronic top decay with three jets combined to give the top mass, a mis-assignment of jets to  $W$  decay and  $b$  will give the same top mass, with only the reconstructed hadronic  $W$  mass changing. Since the resolution on the latter quantity is relatively poor, many reconstructed  $b\bar{j}$

Figure 5: Reconstructed hadronic (left) and leptonic (right) top masses for the selected jet combination, showing the contributions from correctly reconstructed  $t\bar{t}$  events, combinatorial and non- $t\bar{t}$  background, normalised to  $100 \text{ pb}^{-1}$ . The numbers refer to the classes discussed in the text.

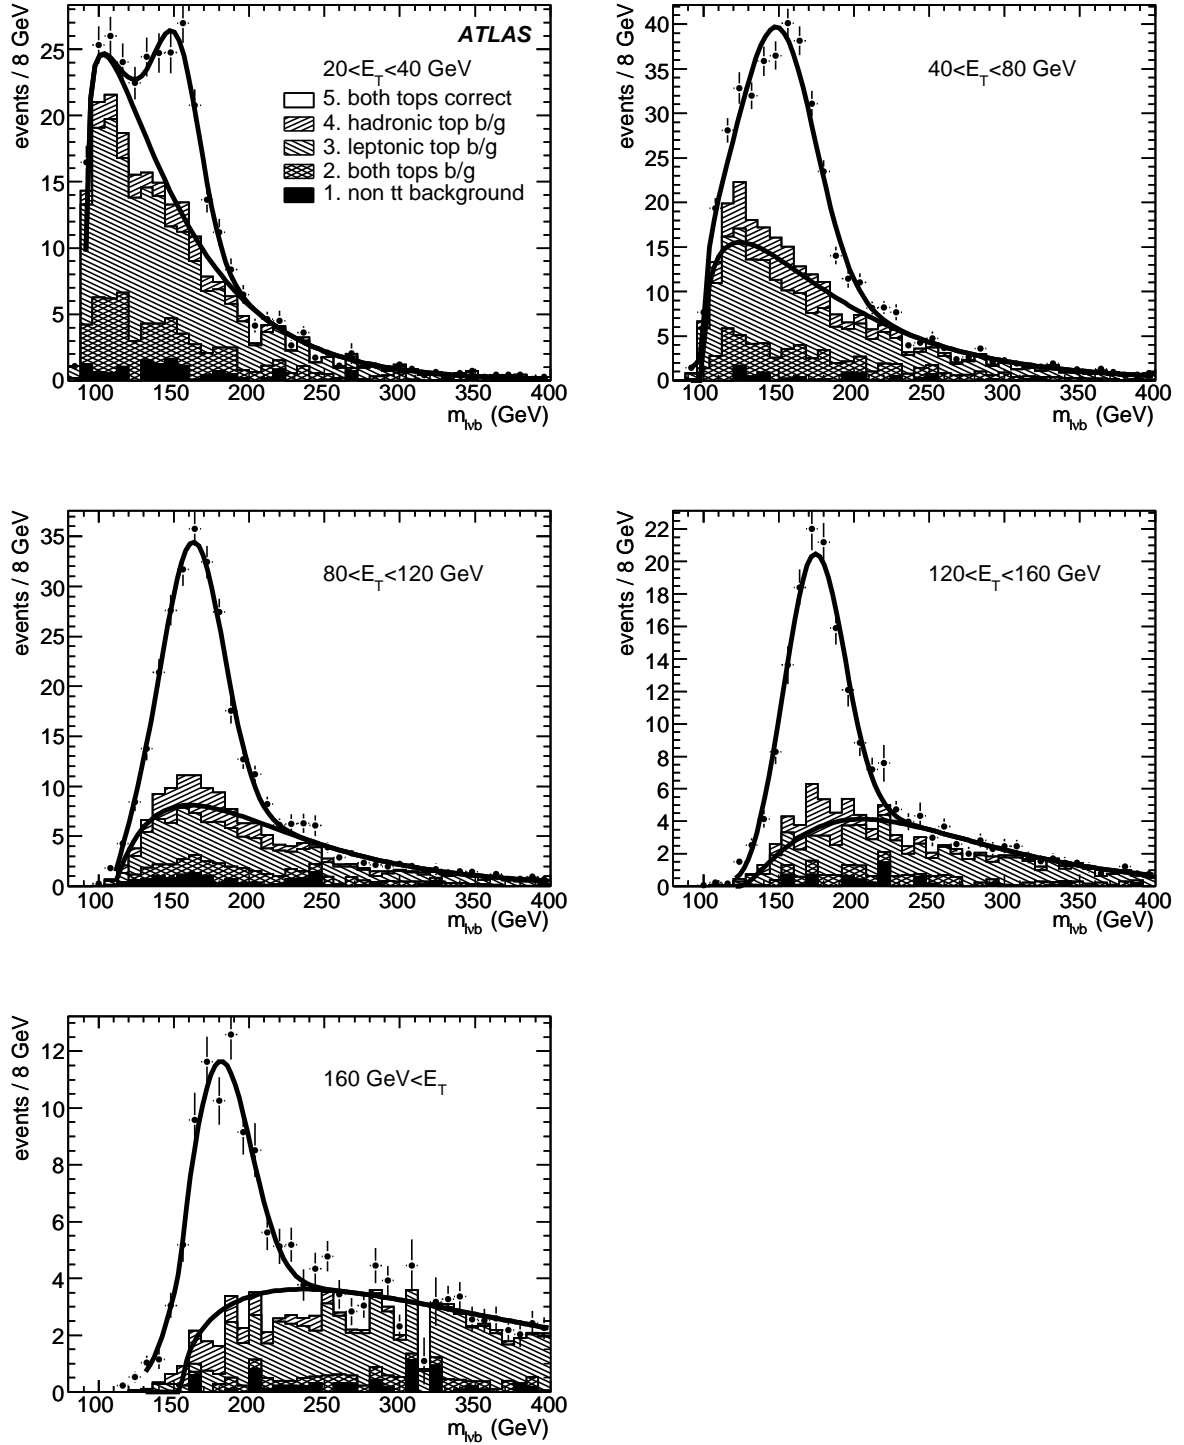

combinations are compatible with the  $W$  mass, and the  $W$  mass requirement gives little discrimination. In the leptonic top decay, the  $W$  has no decay jets, and this problem does not arise.

The resolution on the reconstructed leptonic top mass is poor, and there is a large combinatorial background. This is reduced by first requiring that the hadronic top mass is in the signal region ( $140 < m_{\text{jjj}} < 190 \text{ GeV}$ ), and then dividing the sample into five sub-samples according to the reconstructed  $E_T$  of the leptonic top  $b$ -jet, as the level of background depends strongly on this jet energy. The resulting leptonic top mass distributions can be seen in Fig. 6, where it can be seen that the top signal is significantly enhanced, especially for high leptonic top jet  $E_T$ . Events from classes 4 and 5 have correctly reconstructed leptonic tops, where the leptonic top jet is pure  $b$  flavour, whilst the other events are combinatorial background, with a mixture of jet flavours (they can include  $b$ -jets from the hadronic top, and jets which are not unambiguously from a single parton, containing some particles from the decay of  $B$  hadrons).

In order to correct for this background of event classes 1–3 under the leptonic top mass peak, both its size and flavour composition must be determined. This is done on a statistical basis using the sideband region with high  $m_{b\ell\nu}$  to normalise the background contribution, and a control sample to determine the shape of its mass distribution. The control sample is generated from events where the reconstructed hadronic top mass satisfies  $200 < m_{\text{jjj}} < 400 \text{ GeV}$ , and where the leptonic top  $b$ -jet satisfies a cut on the  $b$ -tagging weight of  $w < 4$ . These samples are dominated by events in classes 2 and 3, and provide a reasonable model of the background shapes in the signal sample.

The amount of background under the signal is then extracted using a simultaneous fit to both signal and control sample leptonic top mass distributions. The control sample is described using a fit function  $F_b(m_{b\ell\nu})$  given by:

$$F_b(m_{b\ell\nu}) = E((m_{b\ell\nu} - c_0)/400), \quad (3)$$

where  $E(x)$  is given by:

$$E(x) = \begin{cases} c_1 x^{c_2} \exp(-c_3 x) & \text{if } x > 0 \\ 0 & \text{if } x < 0 \end{cases} . \quad (4)$$

The signal is described by a fit function  $F_s(m_{b\ell\nu})$  consisting of a scaled background function plus a Gaussian representing the signal, given by:

$$F_s(m_{b\ell\nu}) = c_4 F_b(m_{b\ell\nu}) + c_5 G((m_{b\ell\nu} - c_6)/c_7) . \quad (5)$$

The parameter  $c_4$  represents the ratio of class 1–3 background contributions in signal to control samples, and  $c_5$  the amount of top signal with fitted mean  $c_6$  and RMS width  $c_7$ . All eight parameters are extracted in a simultaneous  $\chi^2$  fit to the signal and control sample mass distributions, thus determining the shape of the background under the signal peak from the control sample, and the normalisation of the background from the sideband of the signal distribution at high  $m_{b\ell\nu}$ . Separate fits are performed in each leptonic top jet  $E_T$  bin, and the results are shown in Fig. 6. The fits are performed over the mass range  $b_1$  and  $b_2$ , where  $b_1$  is set to 90, 90, 110, 120, and 130 GeV for the 20–40, 40–80, 80–120, 120–160 and 160–200 GeV jet  $E_T$  bins, reflecting the differing kinematic cut-off in each jet mass bin.

### 5.1.2 Background subtraction

The sample of leptonic top  $b$ -jets is divided using the reconstructed leptonic top mass into a signal region defined by  $s_1 < m_{b\ell\nu} < s_2$  where  $s_1 = c_6 - 2c_7$  and  $s_2 = c_6 + 2c_7$  (*i.e.*  $m_{b\ell\nu}$  within  $\pm 2\sigma$  of the fitted top mass peak position) and a sideband region with  $m_{b\ell\nu}$  outside this range. The distribution of the  $b$ -tagging weight in the signal region contains contributions both from pure  $b$ -jets (events of classes 4 and 5), and from the mixture of flavours forming the combinatorial background under the signal peak. This latter mixture is well described by the jets in the sideband region, so its effect is corrected for by subtracting the  $b$ -tagging weight distribution in the sideband region, scaled according to the expected normalisation derived from the mass fit discussed in Section 5.1.1. The scale factor  $S$  is given by:

$$S = \frac{\int_{s_1}^{s_2} F_b(m_{b\ell\nu}) dm_{b\ell\nu}}{\int_{b_1}^{s_1} F_b(m_{b\ell\nu}) dm_{b\ell\nu} + \int_{s_2}^{b_2} F_b(m_{b\ell\nu}) dm_{b\ell\nu}} \quad (6)$$

and varies between around 4 for the 40–80 GeV bin to 0.3 for the 160–200 GeV bin. Once this scaled background has been subtracted, the resulting  $b$ -tagging weight distribution in the signal region is statistically compatible with that expected from pure  $b$ -jets. The uncertainty on the amount of background to subtract in each bin of the  $b$ -tagging weight distribution has two components: the uncertainty on the number of background events in each bin in the sideband distribution, scaled by  $S$ , and the uncertainty on  $S$  itself, which is correlated across all bins. The latter is calculated using equation 6 together with the full correlation matrix for the parameters  $c_0$  to  $c_6$  which are used in the background function  $F_b(m_{b\ell\nu})$ .

In order to check that this selection does not introduce a bias, the  $b$ -tagging weight distribution of true  $b$ -jets in the selected signal region was checked, and found to be compatible with that of all  $b$ -jets within the  $\eta$  and  $E_T$  acceptance. Hence this selected sample of  $b$ -jets can be safely used to measure the  $b$ -tagging efficiency.

### 5.1.3 Topological selection results

The results of applying this analysis procedure to full simulation events (including background) are shown as the ‘Topological’ entries in Table 6 in Section 5.4. For each leptonic top jet  $E_T$  bin, the number of jets selected in the window  $s_1 < m_{b\ell\nu} < s_2$ , the number remaining after subtracting the scaled sideband background, and the purity of the selected sample are given, together with the background-subtracted

sample *b*-flavour purity, *i.e.* the fraction of the background-subtracted sample which is made up of *b*-flavour jets according to the Monte Carlo truth information. It can be seen that in all cases the flavour purity is compatible with unity within errors, showing that the background subtraction procedure is working well and producing a statistically pure sample of *b*-jets. Table 6 also shows the results integrated from 40–200 GeV. The sample size and purity in the 20–40 GeV jet  $E_T$  bin is not sufficient to make a sensible measurement of the *b*-tagging efficiency, and this bin is not considered in what follows.

Using this *b*-jet selection, the *b*-tagging efficiency corresponding to any cut on the *b*-tagging weight can be obtained by integration of the *b*-tagging weight distribution, *i.e.* calculating the fraction of the background-subtracted weight distribution above the cut value. This efficiency is shown as a function of *b*-tagging weight cut for each *b*-jet  $E_T$  bin in Fig. 7 as the points with error bars. The solid histogram shows the same distribution for an unbiased sample of pure *b*-jets in  $t\bar{t}$  events without any event selection, derived using Monte Carlo truth information. If the method is correct, the two distributions should agree within errors. The statistical errors on the measured *b*-tagging efficiency (which are highly correlated between bins) have two components: the binomial errors due to the fluctuations in numbers of events passing the cut for signal and background, and the uncertainty due to the background subtraction scale factor  $S$ . Figure 7 also shows the difference  $\delta = \epsilon_{\text{meas}} - \epsilon_{\text{true}}$  between the estimated and true efficiency, which should be compatible with zero if the method is working well. This is seen to be the case except for very high *b*-tagging efficiencies in the two highest jet  $E_T$  bins, where the statistics are limited. The combined efficiency curve for *b*-jet  $E_T > 40$  GeV is shown in Fig. 8(a). These results are derived by weighting the individual *b*-tagging efficiencies measured in each energy bin by the *b*-jets  $E_T$  distribution in  $t\bar{t}$  events.

The method has been validated using ensemble tests based on sets of Monte Carlo subsamples of various integrated luminosities, derived from a sample of  $1793 \text{ pb}^{-1}$ . Studies of the distributions of fit results, estimated uncertainties and pulls show that the uncertainty on the *b*-tagging efficiency returned from the fit underestimates the true uncertainty by about 20 %. They also show that the fit shows significant biases and does not always converge correctly for samples of  $100 \text{ pb}^{-1}$ . With  $200 \text{ pb}^{-1}$  of data, the fit results are unbiased and the fit converges in 98 % of the test samples; hence this is considered the minimum amount of data for which this technique can be used.

Figure 8(b) shows the absolute uncertainty returned by the tagging measurement as a function of the efficiency itself, scaled to an integrated luminosity of  $200 \text{ pb}^{-1}$ . At  $\epsilon_{\text{true}} = 0.6$ , the statistical error is about 0.038, corresponding to a relative error of  $\sigma_{\epsilon_{\text{true}}}/\epsilon_{\text{true}} = 6.4 \%$ .

Systematic uncertainties have been evaluated as discussed in Section 4.3, with the exception that no uncertainties were evaluated for *b*-jet labelling, Monte Carlo statistics and the top quark mass, which are not relevant for this analysis. The systematic errors are summarised in Table 7.

## 5.2 Likelihood-based selection

The likelihood selection uses templates based on event and jet kinematic variables to determine the best assignment of jets to  $t\bar{t}$  decay products within an event. These same likelihoods are also used to select events for which the jet assignments are most likely to be correct.

Templates are constructed using several kinematic variables to provide discrimination between ‘correct’ and ‘incorrect’ permutations. To maximize discrimination, templates are constructed separately for each jet multiplicity. All possible permutations of assignments of jets to final-state quarks are considered, and, for each permutation within each event, the leptonic and hadronic top quark and hadronic *W* boson are reconstructed, using the reconstructed momenta. The permutation is labelled ‘correct’ if the jets used to reconstruct the particle (*t*, *W*, *b*-quark, or light quark from *W* decay) are correctly matched to the quarks arising from the hard-scatter vertex. To limit the number of jet-parton assignment combinations, events with more than six jets are rejected.

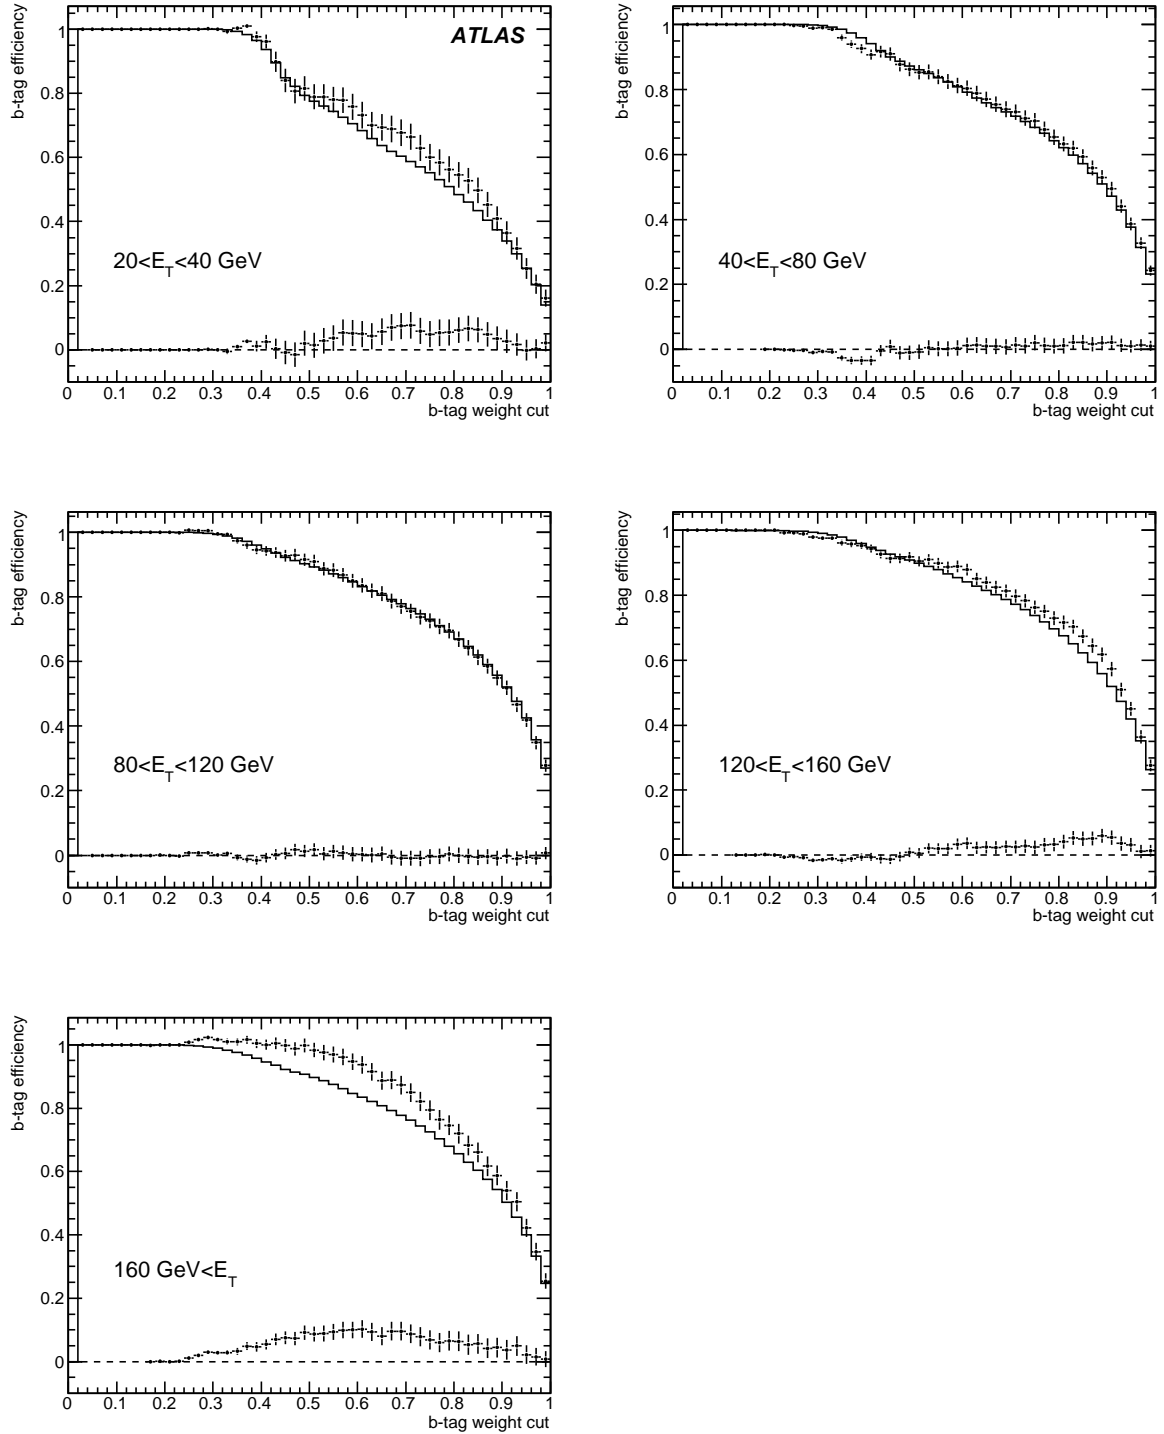

Figure 7:  $b$ -tagging efficiency vs. weight cut for different  $b$ -jet  $E_T$  ranges, as measured by the topological  $b$ -jet analysis (upper points with error bars, statistics of full simulation sample), and compared to the true efficiency from unbiased  $b$ -jets (histogram). The difference between the two is shown as the lower points with error bars.

Figure 8: (a) *b*-tagging efficiency vs. cut on *b*-tagging weight  $w$ , as measured from the topological *b*-jet selection (points with error bars), and derived from Monte Carlo truth information in all *b*-jets in  $t\bar{t}$  events (histogram), for  $948 \text{ pb}^{-1}$  of simulated  $t\bar{t}$  plus background events; (b) Estimated statistical uncertainty on the measured *b*-tagging efficiency as a function of tagging efficiency, for  $200 \text{ pb}^{-1}$ .

The 18 variables used in the likelihood are described below. The two templates based on the hadronic *t*-quark are shown in Fig. 9.

**1-4. hadronic *W* boson and top quark  $p_T$  and mass.** The two light quark four-momenta are added together to obtain the hadronic *W* boson four-momentum. The *b*-quark four-momentum is then added to obtain the hadronic top quark momentum.

**5-6. leptonic top quark  $p_T$  and mass.** The transverse momentum of the neutrino is taken to be the negative of the total transverse momentum of the event. The *z*-component of the neutrino momentum is unknown, so is determined by assuming the mass of the *W* boson (80.403 GeV) and solving the resulting quadratic equation. Since there are two solutions, the smaller solution is chosen. If the root is imaginary, the real part is used. The energy of the neutrino is taken from the neutrino momentum assuming the neutrino is massless. The leptonic top quark four-momentum is then determined from the lepton, neutrino and associated *b*-quark jet.

**7-18. hadronic and leptonic *b*-jets and 2 jets from *W*-decay: rank,  $E_T$ , and  $\Delta\phi(b_{had}, \text{lep})$ .** For each of the four jets assigned to the hadronic *W* quarks and the two *b*-quark, kinematic variables are used to construct additional templates. The jets are ranked by  $E_T$ , with rank one denoting the jet with the highest  $E_T$ . This jet rank, along with jet  $E_T$  and the separation in  $\phi$  between the jet and the lepton ( $\Delta\phi(\text{jet}, \text{lep})$ ) are used as additional templates.

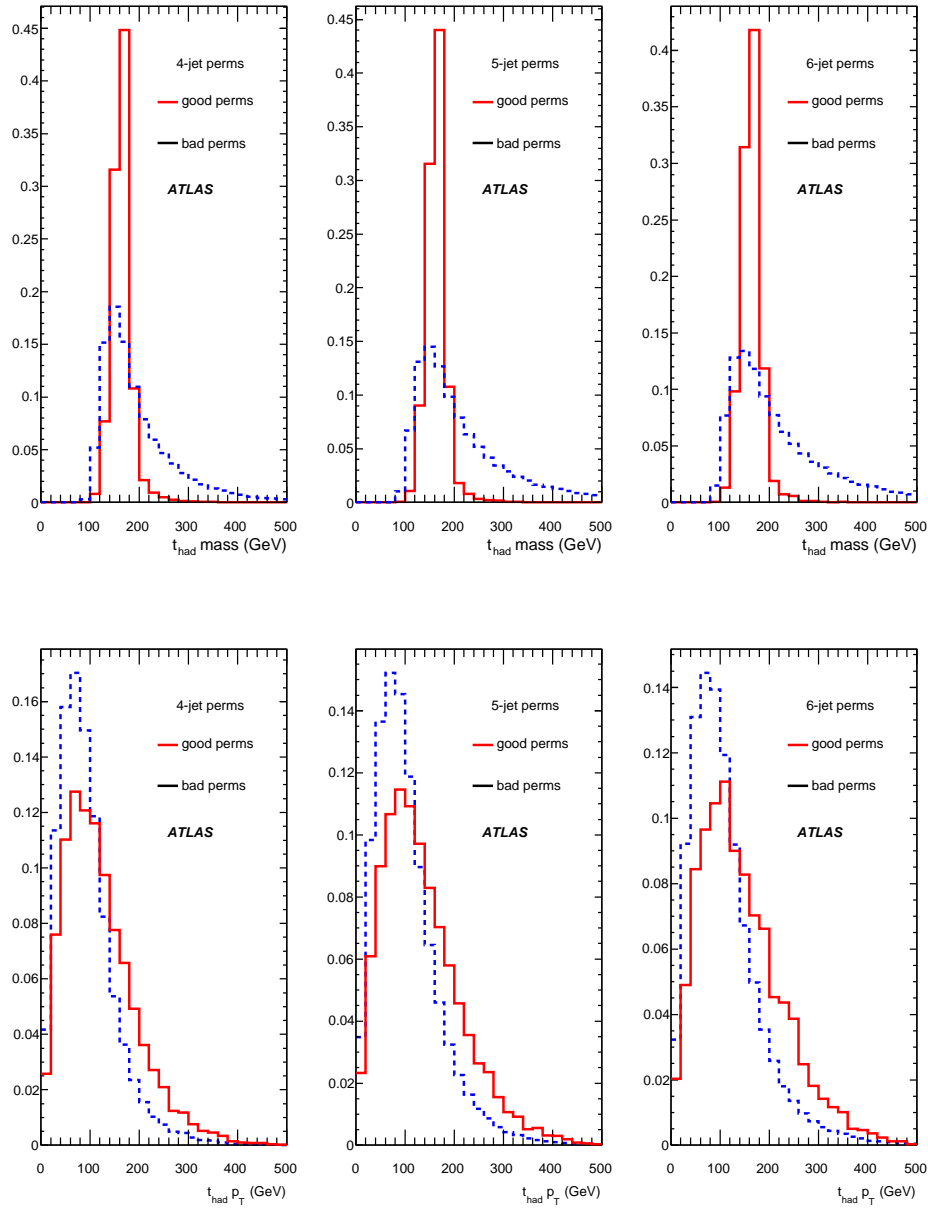

Figure 9: Templates for the likelihood-based selection, using (a) hadronic  $t$ -quark mass and (b) hadronic  $t$ -quark  $p_T$ .

### 5.2.1 Event selection

The  $b$ -purity of the basic sample selected as discussed in Section 2 is enhanced by requiring one jet to be  $b$ -tagged, with an IP3D+SV1 weight  $w > 6$ . Then a discriminant value  $\mathcal{D}$  is calculated for each jet combination in the event using the templates, which are taken to be likelihood distribution functions for each variable. The ‘correct combination’ templates are used to get the ‘ $s$ ’ values for the  $i^{th}$  variable, and

Figure 10: Discrimination between correct and incorrect permutations, best permutation chosen for each event, for entire range of  $\mathcal{D}$ , and for  $\mathcal{D} \geq 0.985$ . Events are chosen which have at least 1  $b$ -tagged jet.

the ‘incorrect combination’ templates are used to get the ‘ $b$ ’ values. They are combined according to:

$$\mathcal{D} = \frac{\prod_i (s_i/b_i)}{1 + \prod_i (s_i/b_i)}. \quad (7)$$

In each event, the combination with the largest value of  $\mathcal{D}$  is retained. The resulting distributions are shown in Fig. 10, normalised to  $100 \text{ pb}^{-1}$ . The contributions from the correct combination, incorrect combinations and non- $t\bar{t}$  events are shown separately. As can be seen from the right-hand plot, very high discriminant values are required to select a sample with high purity.

The  $b$ -jet purity is shown vs. the number of selected events in Fig. 11, for several ranges of jet  $E_T$ . Higher purity samples can be obtained by tightening the cut on  $\mathcal{D}$ , but at the expense of selection efficiency. A cut of  $\mathcal{D} > 0.985$  was chosen for these studies assuming  $100 \text{ pb}^{-1}$  samples, which could be raised to improve the purity once the data sample size allows.

### 5.2.2 Background subtraction

Assuming the cuts used to discriminate between correct and incorrect jet-parton assignments reduce the background from non- $t\bar{t}$  events to a negligible level, the primary background to be considered arises from jets incorrectly assigned to  $b$ -quarks. These jets can be from light,  $c$ , or  $s$ -quarks from  $W$  decay, and from ISR/FSR jets. To estimate the effect of the background on the  $b$ -tagging efficiencies, it is necessary to determine the tagging rate of jets in background events, as well as the fraction of signal (and hence background) events in the data sample. Using Monte Carlo truth information to determine the true flavour of the jet assigned to the leptonic top decay (and assumed to be a  $b$ -jet), signal ( $S$ ) and background ( $B$ )

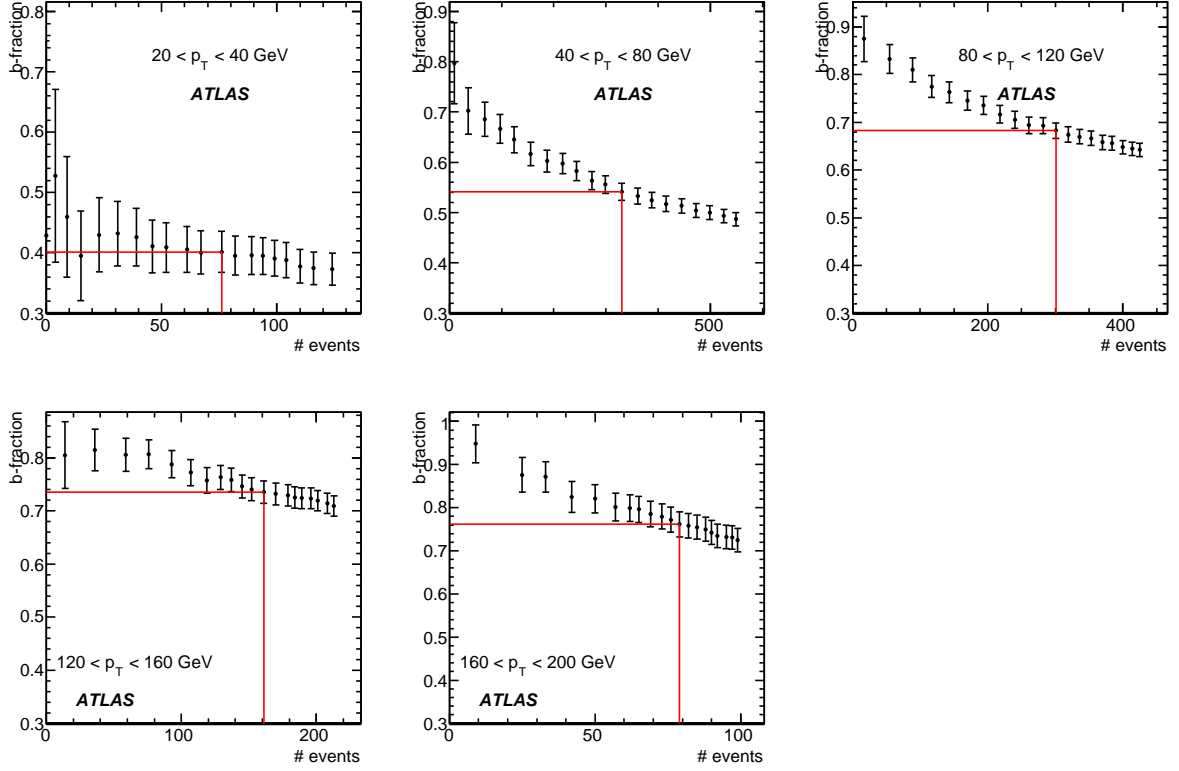

Figure 11: Likelihood selection:  $b$ -jet purity vs. number of selected events (discriminant cut value ranging from 0.975 to 1) for each  $b$ -jet  $E_T$  bin.

templates are formed, binned by discriminant value. Using these templates, a likelihood is constructed to find the fraction  $f_{sgn}$  of signal events. The likelihood formed from data ( $D$ ) and templates is:

$$\ln \mathcal{L}(f_{sgn}) = \sum_i^{\#bins} -D_i \ln (f_{sgn} S_i + (1 - f_{sgn}) B_i), \quad (8)$$

where  $D_i$  is the number of data events in the  $i^{th}$  bin, and  $S_i$  and  $B_i$  are the values of the  $i^{th}$  bins of signal and background templates. The associated background  $b$ -tagging efficiencies are determined using events passing a looser discriminant cut ( $\mathcal{D} > 0.9$ ), since the tag rate for jets in the background do not depend strongly on the value of this cut. These are shown for several ranges of jet  $E_T$  in Fig. 12. The average of the  $b$ -tagging efficiencies of non- $b$ -jets over all jet  $E_T$  bins is used, giving  $\epsilon_{btag}^{bkgd} = 0.021 \pm 0.004$ . Once the  $b$ -tagging efficiencies for background events and  $f_{sgn}$  are obtained, the following equation is used to solve for  $\epsilon_{btag}^{b-jets}$ :

$$\epsilon_{btag}^{b-jets} = \frac{1}{f_{sgn}} \left( \epsilon_{btag}^{all jets} - (1 - f_{sgn}) \epsilon_{btag}^{bkgd} \right) \quad (9)$$

### 5.2.3 Results for $b$ -tagging efficiency measurement

The  $b$ -tagging efficiencies are determined for events binned in  $b$ -jet  $E_T$ , with bin sizes chosen to match the kinematic and topological methods. To simulate the  $100 \text{ pb}^{-1}$  sample, histograms have been scaled

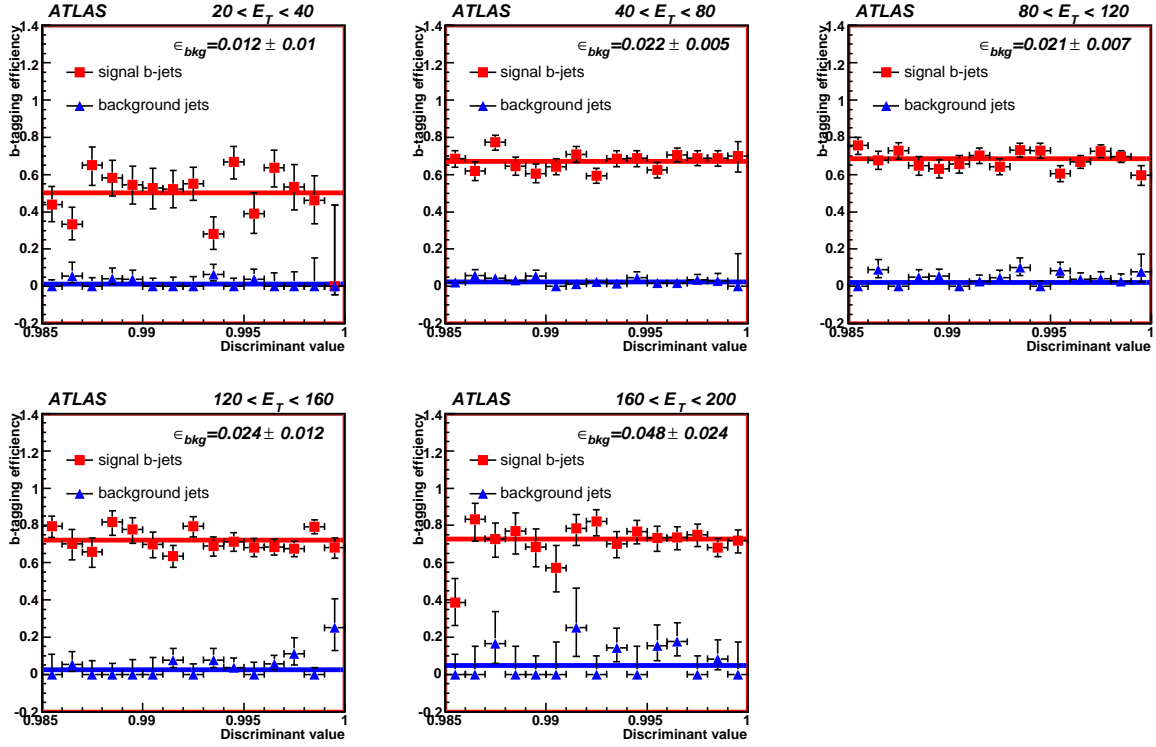

Figure 12:  $b$ -tagging efficiencies for signal ( $b$ -jets), and tag rate for light and  $c$ -jets (background) for events passing a discriminant cut of 0.9. Each plot was done for a different range of jet  $E_T$ .

to the number of events expected in the sample. The sample purities are shown for the  $E_T$ -binned sample in Table 6 for comparison with the other methods, and the  $b$ -tagging efficiencies are shown in Fig. 13. The average of  $b$ -tagging efficiencies for jet  $E_T > 40$  GeV is  $0.674 \pm 0.086$ , consistent with the actual value of 0.658.

Ensemble testing was done using 100 pseudo-experiments, verifying the same central value and error. The pull distribution of the 100 pseudo-experiments has a width of 0.60 standard deviations, so the error (0.086) is scaled by 0.60 to get an expected statistical error 0.05 for the  $100 \text{ pb}^{-1}$  sample. The low pull width arises because, for some pseudo-experiments in the ensemble, likelihood fits of signal fractions are close to 0 or 1. Failing to determine asymmetric errors properly for these pseudo-experiments results in an overestimation of the error.

Systematic uncertainties are determined for the effects discussed in Section 4.3, using the full available MC statistics for all except the effect of background events in the sample. Ensemble testing was used to evaluate this error, using double the expected number of events and no background events. In general, the systematic errors are large for the cuts chosen for the  $100 \text{ pb}^{-1}$  sample. These are expected to improve once data samples are available and the discriminants are optimised, especially once the sample size allows tighter jet  $E_T$  and discriminant cuts to be used in order to reduce the background from non- $t\bar{t}$  and wrong combinations.

### 5.3 Kinematic selection

This section describes the selection of a high purity  $b$ -jet sample through the use of a kinematic fit and cuts based on the resulting fit  $\chi^2$ . Other selection criteria, including the use of a  $b$ -tag on the hadronic top

Figure 13: Likelihood method: simulation of  $b$ -tagging efficiencies vs.  $E_T$  for a  $100 \text{ pb}^{-1}$  sample using the best permutation for events selected with a discriminant cut. The solid line shows the true  $b$ -tagging efficiencies from the full MC sample using truth information. ( $b$ -tag weight=6.0, discriminant cut 0.985)

$b$ -jet are also used to enhance the purity. As with the other methods described above, it is difficult to get high purity whilst maintaining sufficient statistics, and a data-based background subtraction procedure is employed to derive an effective pure  $b$ -jet sample.

### 5.3.1 Kinematic fit and performance

The analysis uses the kinematic fit HITFIT [11], originally developed at DØ. A  $W$  mass constraint is included and the two reconstructed tops are constrained to have the same mass. The top mass can also be constrained. For this study the mean top mass obtained with the unconstrained fit (172 GeV) was used as a constraint in subsequent fits. The mean top mass obtained from the fit was 172 GeV. Both neutrino solutions are considered and the one with the lower  $\chi^2$  is used. The fit requires calibrations of the jet energy to the parton energy and resolutions of the jets and leptons, which were determined by comparing reconstructed quantities with the Monte Carlo truth information.

Only the four largest  $E_T$  jets in the event were used in the kinematic fit, giving rise to 12 permutations which were each fitted. The correct combination is not always in the four leading jets. In 49 % of the events passing the basic semileptonic event selection discussed in Section 2, the four jets from the  $t\bar{t}$  system are reconstructed and pass the jet selection cuts. Out of the events where all four jets are reconstructed 44 % contain the  $t\bar{t}$  jets in the four leading jets, rising to 92 % of events if the first six jets are used. However, this leads to a large increase in combinatorial background and was not considered

further.

Figure 14: Kinematic selection: Distribution of the  $\chi^2$  for the permutation with the minimum  $\chi^2$  showing contributions of the signal and backgrounds with standard selection cuts (left plot), and with additional requirements according to selection  $S_3$  described in the text (right plot).

From the four leading jets, the permutation with the lowest  $\chi^2$  was chosen, and events where this  $\chi^2$  was below a particular cut value were retained. If the four leading jets are four jets from the  $t\bar{t}$  system, then the correct permutation is the one with the lowest  $\chi^2$  in 58 % of the cases. Figure 14 (left) shows the  $\chi^2$  distribution for the selected combination, including the contributions from correct and wrong combinations in  $t\bar{t}$  events, and from  $W$ +jets and single top backgrounds. It can be seen that the fraction of correct combinations is not high, even for low  $\chi^2$  values. Several additional selections beyond the ‘standard cuts’  $S_0$  defined above were tried in order to enhance the purity as follows. Selection  $S_1$  requires a  $b$ -tag with weight  $w > 5$  on the jet assigned as the hadronic  $b$ -jet; the effect of this is mainly to reduce the  $W$ +multijet background. Selection  $S_2$  adds a  $b$ -tag veto ( $w < 5$ ) on both jets assigned to the hadronically decaying  $W$ . Selection  $S_3$  also requires there are six or less jets with  $E_T > 20$  GeV, and selection  $S_4$  requires that the hadronic top  $p_T$  satisfies  $p_T > 150$  GeV. The relative reduction of wrong combinations and background can be seen in the  $\chi^2$  distribution after selection  $S_3$  as shown in Fig. 14 (right).

Figure 15 shows the results of these additional selections, in terms of the fraction of jets assigned as the leptonic top  $b$ -jet which are really  $b$ -jets, and the number of selected events for  $100 \text{ pb}^{-1}$ . Purities of up to 90 % are reachable, but at the cost of low selection efficiency. To retain a reasonable number of events, a signal sample is defined using selection  $S_3$  with a cut  $\chi^2 < 10$ , which leaves around 600 events for  $100 \text{ pb}^{-1}$ .

### 5.3.2 Background subtraction

As for the topological method, a background control sample is used to estimate the composition of the remaining background in the sample of selected jets from data. The use of the kinematic fit excludes most events with masses outside the top mass window, so it is not possible to use top mass sidebands to estimate the background composition. However, events with high  $\chi^2$  are predominantly wrong combinations (see Fig. 14). The wrong-combination fraction can be enhanced by selecting events that pass the standard selection  $S_0$  and requiring that one of the jets assigned to the  $W$  is tagged as a  $b$ -jet ( $w > 5$ ). The  $\chi^2$  distribution of this control sample follows closely that of the wrong combination background in the selected jet sample. The shape of the  $\chi^2$  distribution is used to predict the amount of combinatorial

Figure 15: Left: The purity (fraction of true  $b$  jets) of the jet assigned as the  $b$ -jet on the leptonic side as a function of the  $\chi^2$  cut. Right: The corresponding number of events. The different selection criteria are described in the text.

background in the signal sample, normalising the two samples in the region  $30 < \chi^2 < 100$ . Any test distribution (*e.g.* the  $b$ -tagging weight) extracted from the signal sample can then be corrected for this contribution of background events, taking the shape of the test distribution in background from the region of the control sample with  $\chi^2 > 30$ . This background subtraction method is very similar to that discussed in Section 5.1, with the high  $\chi^2$  region playing the role of the top mass sideband, and the control sample with a  $b$ -tagged jet from the  $W$  decay corresponding to the sample with high hadronic top mass in the topological selection.

### 5.3.3 Results for $b$ -tagging efficiency measurement

The results of applying this selection to simulated data including background and scaling the event count to  $100 \text{ pb}^{-1}$  are shown in Table 6. The purity in the 20–40 GeV jet  $E_T$  bin is rather low, and the background from the significant contribution of single top is not well-estimated. As for the topological analysis, this bin is not used for calculating the  $b$ -tagging efficiency. The combined  $b$ -tagging weight distribution for the other bins ( $E_T > 40$  GeV) is shown in Fig. 16. The  $b$ -tagging efficiency corresponding to any given cut can be calculated by integration, and the corresponding statistical errors for various tag working points can be seen in Table 7.

## 5.4 Comparison of selection methods

The performance of the different  $b$ -jet selection methods are compared in Table 6, which shows the number of jets selected as a function of jet  $E_T$ , the effective number of jets after background subtraction procedures have been performed, the corresponding purity of the original sample, and the  $b$ -jet fraction of the final background-subtracted sample, which should be compatible with one.

The different selections have roughly similar overall performance, with the topological selection giving relatively more jets at high  $E_T$ , and the kinematic selection more at low  $E_T$ . All selections allow a sample of several hundred  $b$ -jets to be selected in  $100 \text{ pb}^{-1}$  of data, although the selections of low  $E_T$   $b$ -jets (20–40 GeV) suffer from large backgrounds.

Figure 16: Kinematic selection: (Left): The  $b$ -tag weight distribution for the uncorrected sample (unfilled histogram), for the estimated background sample (filled histogram) and the corrected distribution calculated from the difference (data points). Right: The  $b$ -tag weight distribution for the corrected sample (data points) compared with the distribution for true  $b$ -jets (histogram). Both plots are normalised to  $100 \text{ pb}^{-1}$ , but use  $967 \text{ pb}^{-1}$  of simulated data.

### 5.5 Comparison of efficiency measurements

The performance of the different  $b$ -tagging efficiency measurements is compared in Table 7, which shows the statistical and significant systematic errors for a true tagging efficiency of 0.6 for all methods. The systematic errors have been evaluated as discussed in [2] and Section 2. The differences in systematic uncertainties reflect the different uses made of Monte Carlo information by the various methods. The expected statistical errors for other tagging efficiencies, and the simpler IP2D tagging algorithm, are shown (where available) in Table 8.

With  $100 \text{ pb}^{-1}$  of data, the counting method can measure the overall  $b$ -tagging efficiency to a precision of better than 5 %, and, particularly as the luminosity increases through  $200 \text{ pb}^{-1}$  several alternative approaches are possible that also enable the efficiency dependence on other variables (*e.g.* jet  $E_T$ ) to be studied.

## 6 Optimisation of $b$ -tagging for $t\bar{t}$ events

The ATLAS multivariate  $b$ -tagging algorithms rely heavily on likelihood reference distributions for light- and  $b$ -quark jets derived from Monte Carlo simulation. The default reference distributions are produced using a mixture of physics processes. In principle, using reference histograms from Monte Carlo  $t\bar{t}$  events alone could lead to an improvement in tagging performance on  $t\bar{t}$  events. The selection of a pure sample of  $b$ -jets from  $t\bar{t}$  data offers an opportunity to tune the  $b$ -tagging algorithms directly on data, reducing the dependence on Monte Carlo simulation. Both these topics are discussed below.

Jet $E_T$ range (GeV)	Selected jets	Effective jets	Purity (%)	Estimated $b$ flavour purity (%)
Topological				
20–40	144	51	54	$99 \pm 8$
40–80	340	189	67	$92 \pm 3$
80–120	223	138	78	$98 \pm 3$
120–160	122	92	84	$98 \pm 3$
160–200	75	54	86	$108 \pm 4$
40–200	819	515	60	-
Likelihood				
20–40	52	24	47	$86 \pm 6$
40–80	225	130	58	$94 \pm 3$
80–120	204	143	70	$97 \pm 3$
120–160	110	91	83	$89 \pm 3$
160–200	54	40	73	$104 \pm 5$
40–200	593	403	68	-
Kinematic				
20–40	164	102	53	$74 \pm 6$
40–80	284	182	73	$93 \pm 4$
80–120	113	78	88	$107 \pm 5$
120–160	38	30	90	$103 \pm 5$
160–200	17	13	94	$107 \pm 6$
40–200	451	302	79	$98 \pm 3$

Table 6: Summary of  $b$ -jet selection method performance, showing the number of selected  $b$ -jets, the number of jets after background subtraction, the selected sample purity, and estimated  $b$ -jet purity of the final sample after background subtraction, for each selection method. The results correspond to  $100 \text{ pb}^{-1}$  of MC@NLO  $t\bar{t}$  Monte Carlo plus backgrounds from  $W$ +jets,  $Wb\bar{b}$ ,  $Wc\bar{c}$  and single top production.

Systematic	Counting		Topological	Likelihood	Kinematic
	lepton+jet	dilepton			
Light jets and $\tau$	0.1	0.7	0.5	5.2	0.6

IP2D	0.7			5.6	5.1	5.0

Table 8: Expected statistical errors (relative errors in %) on the  $b$ -tagging efficiency for  $200 \text{ pb}^{-1}$  measured using each technique, for IP3D+SV1 and IP2D taggers at various working points.

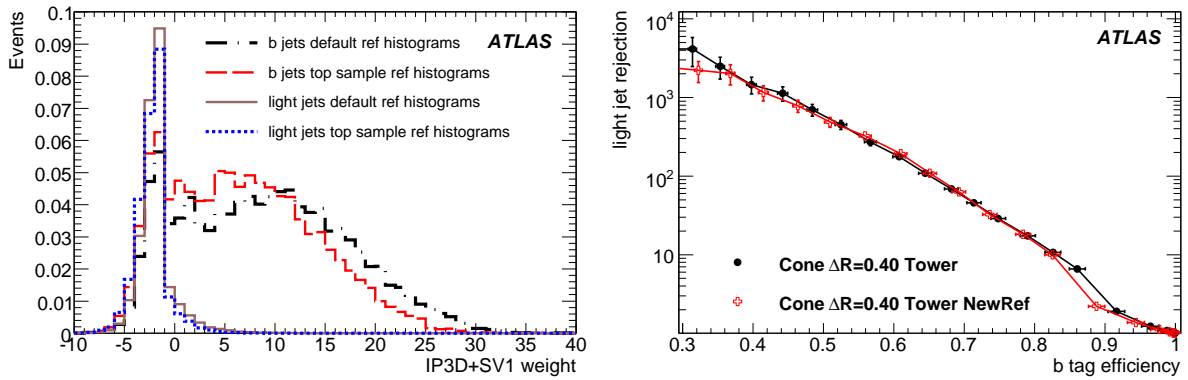

Figure 17: Comparison of  $b$  tagging weights and  $b$  tag performance using default and special top sample reference histograms.

## 6.1 Using $t\bar{t}$ specific reference histograms

For this study, reference histograms based only on  $t\bar{t}$  events (without the light jet purification procedure which discards light jets biased by nearby  $b$ -jets [6]) were created using a total of 250k events. By contrast, the default reference histograms were produced using a variety of physics processes, light jet purification, as well as different versions of the detector geometry, simulation, and reconstruction. The following comparison does not attempt to disentangle the various effects of those differences; for more details, see [6]. The resulting  $t\bar{t}$  event  $b$ -tagging weights are compared to those calculated using the default reference histograms, for the IP3D+SV1  $b$ -tagging algorithm with the default tower-based Cone jet algorithm with  $\Delta R = 0.4$ . The results are shown in Fig. 17. The left plots shows the  $b$ -tagging weights for  $b$ -jets and light jets calculated with both sets of reference histograms.

The weights for both  $b$ -jets and light quark jets calculated with the top sample reference histograms are on average smaller than those from the default reference histograms. However, because the  $b$ -tagging weights are smaller for both  $b$ -jets and light jets, the performance should not change significantly. This is confirmed by the right plot in Fig. 17, showing the  $b$ -tag efficiency vs the light jet rejection. Within the statistical uncertainty there is no difference in the performance. So there appears to be no significant advantage in using special dedicated  $t\bar{t}$  reference histograms when applying  $b$ -tagging to  $t\bar{t}$  events.

## 6.2 Calibrating $b$ -tagging using data

In principle, the  $b$ -jet selection methods discussed in Section 5 should allow the reference distributions for  $b$ -jets in  $t\bar{t}$  events to be determined directly from data, removing the need for Monte Carlo  $b$ -jets completely. However, none of the methods produce a pure  $b$ -jet sample without the need for background subtraction, and hence do not identify a pure sample of  $b$ -jets from which multiple variables (and their correlations) can be extracted simultaneously on a jet-by-jet basis. Instead, background-subtracted distributions are produced. These can be used directly as reference distributions only for one-dimensional likelihoods with a single input variable. For  $n$ -dimensional likelihoods (for example the standard tagging weight which is a two-dimensional combination of IP3D and SV1 taggers), an  $n$ -dimensional background-subtracted distribution would be needed in order to properly model both the two input distributions and their correlation. For higher-dimensional distributions, the required data statistics would quickly become prohibitive.

At least for initial data, a more feasible approach would be to use the background-subtracted  $b$ -jet samples to check each of the likelihood input variables individually, to determine how well the Monte Carlo simulation models the data. Monte Carlo would then be used to form the likelihood reference distributions as before (including correlations between input variables), with the comparison with data being used to assess systematic uncertainties, *e.g.* by reweighting Monte Carlo events to more precisely follow the data distributions if discrepancies are seen.

This technique is illustrated in Fig. 18, which shows background-subtracted distributions of five variables related to the  $b$ -tagging weight computation, derived from the  $b$ -jet sample selected using the topological technique of Section 5.1, compared to the true distributions from Monte Carlo. The integrated luminosity is  $948\text{ pb}^{-1}$ . The first two variables are IP3D, the weight derived from the 3D-impact parameters of all tracks in the jet; and SV1, the weight derived from the SV1 secondary vertex reconstruction algorithm. The others are all input variables used to form the SV1 secondary vertex weight: N2Track, the number of two-track vertices found; SVMass, the mass of the reconstructed secondary vertex, and SVEFrac, the energy fraction of the jets associated to the vertex. The spikes around zero for these last three variables correspond to jets where no secondary vertex was found. The variables have been transformed linearly onto the range  $[0,1]$  to simplify the subtraction procedure.

It can be seen that the background-subtracted distributions are consistent with the Monte-Carlo truth, demonstrating the validity of the method. It would be straightforward to construct reweighting factors from these distributions, to explore possible systematic variations. However, it should also be noted that the techniques discussed in Section 5.5 already allow the  $b$ -tagging efficiency to be measured with minimal dependency on the Monte Carlo—the main use of this technique would then be to understand how to improve the Monte Carlo simulation of  $b$ -jets, which could help to increase the  $b$ -tagging performance in  $t\bar{t}$  events by giving each variable its optimal weight in the likelihood.

## 7 Conclusions

The studies of jet reconstruction presented above show that the  $b$ -jet energy resolution in  $t\bar{t}$  events is not very sensitive to the jet algorithm and parameters chosen. The jet angular resolution is more sensitive, degrading in particular with large jet cone sizes.

With  $100\text{ pb}^{-1}$  of data, several methods are available to make useful measurements of the  $b$ -tagging efficiency in  $t\bar{t}$  events. The tag counting method can reach an overall relative precision of around 5 %, in both lepton+jets and dilepton channels. However, this method only gives an ‘integrated’ measurement, valid for the  $E_T$  and  $\eta$  distribution of  $b$ -jets selected by the  $t\bar{t}$  event selection. Monte Carlo techniques would have to be used to extrapolate this measurement for other jet  $E_T$  and  $\eta$  distributions, perhaps also incorporating information derived from studies of dijet samples [1].

Figure 18: Background-subtracted  $b$ -tagging variable distributions derived from the  $b$ -jet sample selected by the topological method, with 948 pb<sup>-1</sup> of simulated  $t\bar{t}$  plus background data. The derived distributions are shown by the points with error bars, and the Monte Carlo truth for an unbiased sample of  $b$ -jets is shown by the solid histograms.

Other techniques, based on the topology and kinematics of  $t\bar{t}$  events, can be used to select a sample of jets enriched in *b*-flavour, which can then be used to measure the *b*-tagging efficiency as a function of other variables. This requires that the remaining non-*b* background in the selected jet samples be estimated and removed, and a variety of techniques are available for doing that, based either on data or Monte Carlo. These techniques are less statistically powerful than the tag counting method, achieving overall *b*-tagging uncertainties of around 10 % with  $100 \text{ pb}^{-1}$ , but will become increasingly powerful as more data becomes available.

Calibrating the *b*-tagging likelihood reference distributions from Monte Carlo  $t\bar{t}$  events rather than the generic event mixture used by default does not significantly affect the performance of the standard algorithms, which demonstrates the robustness of the *b*-tagger. On the other hand, the *b*-jet selection methods discussed above also allow reference distributions from  $t\bar{t}$  data to be obtained; with moderate integrated luminosity these are likely to be more useful to cross-check the Monte Carlo description of likelihood input variables rather than as a direct input to *b*-tag calibration.

# ***b*-Tagging Calibration with Jet Events**

## **Abstract**

This note describes two strategies for data-based measurement of the semi-leptonic *b*-tagging efficiency of ATLAS lifetime *b*-tagging algorithms using jet data. The  $p_{T,rel}$  method uses templates of the muon  $p_T$  relative to the jet+muon axis for bottom, charm, and light jets to estimate the *b*-quark content of a jet sample. The *b*-tagging efficiency is obtained by measuring the *b*-quark content before and after tagging a sample. The second method, System 8, uses two samples of jets of differing *b*-quark content and two uncorrelated tagging algorithms to form a system of 8 equations and 8 unknowns, one of which is the *b*-tagging efficiency. Both methods use a Monte Carlo scale factor to convert the measured semi-leptonic efficiency to an inclusive efficiency. Both methods give results binned in  $p_T$  and  $\eta$ . Good agreement was found between the *b*-tagging efficiencies determined by both techniques and true Monte Carlo for  $15 < p_T < 80$  GeV, however above 80 GeV both methods have difficulty. Initial systematics studies have been performed which indicate that it should be possible to control the absolute error on *b*-tagging efficiency to 6% for both methods. This error does not include the error associated with converting the semi-leptonic efficiency to the inclusive efficiency.

## **1 Introduction**

Many analyses at the LHC will rely on the presence of *b*-quarks. Top production, Standard Model Higgs boson searches, and searches for physics beyond the Standard Model, for example, all have final states involving *b*-quarks. To estimate the backgrounds from well known Standard Model processes after applying *b*-tagging algorithms it is necessary to know the tagging efficiency for *b*-jets, for light-jets (fake rate or mistagging rate), and for *c*-jets (charm-tagging efficiency). All three efficiencies should be measured as accurately as possible: systematic errors in the *b*-tagging calibration can translate to large errors in an analysis. Although the fake rate and *c*-tagging rate are important, only the *b*-tagging efficiency is considered in this note.

In order to measure the *b*-tagging efficiency we must know the bottom quark content (*'b*-content') of a calibration sample well. Unfortunately, it is difficult to select a pure *b*-jet sample in the data. Two independent methods to calibrate the *b*-tagging algorithms are currently under study in ATLAS. The first method uses a high purity sample of top quark events. Full kinematic reconstruction enables the proper identification of the jet resulting from the fragmentation of the *b*-quark from the top quark decay. A tagging algorithm can be run on that sample of jets and the efficiency measured [1]. Similarly, one can count tags in a high purity sample of top events and estimate both the tag rate and the cross section [1].

This note describes the determination of the *b*-tagging efficiency in QCD jet data. Unfiltered QCD jet data have a very small fraction of *b*-jets at small jet energy and small effective  $\sqrt{s}$ , however. In order to increase the fraction of *b*-jets we require that jets in the sample contain a muon. Though muons come from other sources, a major source is the semi-leptonic decay of *b*-quarks or *c*-quarks resulting from the *b*-quark decays. A consequence is that only the lifetime tagging efficiency in semi-leptonic decays of *b*-jets is measured by the techniques described here. The semi-leptonic efficiency must be corrected to obtain an inclusive *b*-tagging efficiency. The scaling is determined from Monte Carlo; this note only briefly touches on the determination of this scale factor.

Two standard lifetime-based *b*-tagging algorithms, IP2D and IP3D+SV1 [2], are used to demonstrate the calibration methods and estimate systematic errors. Briefly, IP2D uses reconstructed tracks

and their transverse impact parameters to look for jets with displaced tracks inconsistent with light-jets. IP3D+SV1 is a combined tagger: IP3D is similar to IP2D, but also takes the longitudinal impact parameter into account; SV1 reconstructs a secondary vertex from tracks near a jet. SV1 uses a likelihood made up of the invariant mass of the tracks associated with the secondary vertex, the ratio of the energy of tracks in the secondary vertex to the energy of tracks associated to the jet, and the total number of two-track vertices reconstructed in a jet. Methods that measure the *b*-tagging efficiency that work for these particular taggers are expected to work for other lifetime taggers as well.

Two separate calibration techniques are described in this note:

- The  $p_{T,rel}$  method, described in Section 3, uses Monte Carlo-derived templates, for *b*-, *c*-, and light-jets, of the relative  $p_T$  of a muon with respect to the jet+muon axis. The *b*-content of a jet data sample can then be determined by fitting the  $p_{T,rel}$  distribution of the data with these templates before and after the lifetime tagging algorithms are applied. The *b*-tagging efficiency is derived from the changing *b*-fraction.
- The System 8 method, described in Section 4, employs two samples with different *b*-content and two uncorrelated tagging algorithms to construct a system of 8 nonlinear equations and 8 unknowns. One of the unknowns is the *b*-lifetime tagging efficiency.

Both of these techniques require a large sample of jets with muons. Section 2 describes a dedicated trigger that will be used to collect this sample along with the Monte Carlo samples and selection cuts used in this study.

The performance of the tagging algorithms varies with both jet  $p_T$  and  $\eta$  [2]. This is caused by both geometrical acceptance effects and variations in the track reconstruction efficiency. Both methods described in this note measure the efficiency as a function of  $p_T$  and  $\eta$ . The dependence on other variables could also be measured if required.

The efficiency measured from jet data is largely uncorrelated with that measured from the  $t\bar{t}$  data, since the data sets and the techniques are uncorrelated. Thus the results obtained with the two methods can be combined to further improve the understanding of *b*-tagging and reduce associated systematic errors. At low jet energies the  $t\bar{t}$  method is rather sensitive to background contamination, a region where the jet method will perform best. At higher jet energies the  $t\bar{t}$  method will have a better accuracy.

## 2 Samples and selection

Several sets of Monte Carlo QCD jet events were generated specially for this study. The jet samples were generated with the standard dijet process using the PYTHIA Monte Carlo generator and full ATLAS detector simulation and detector reconstruction software. ATLAS splits generation of its QCD samples by requiring the hard scatter parton  $p_T$  to be within a certain range: between 17 and 35 GeV, between 35 and 70 GeV, between 70 and 140 GeV, and between 140 and 280 GeV. Approximately 100,000 events were generated in each range. After generation the samples are combined for the analysis.

The *b*-jet statistics in the QCD sample are not sufficient to test the methods discussed here. To increase statistics we also generated *muon+jet samples*, which further required in each event a muon from any source with a true  $p_T > 3$  GeV and  $|\eta| < 2$ . The  $p_T$  cut was chosen as a representative lower limit for muons that can accurately be reconstructed and identified (we make a reconstructed muon  $p_T > 4$  GeV cut). The requirement of a muon has a dramatic effect on the flavor composition of the sample, increasing the *b*-jet content by about a factor of 10, and increasing the *c*-jet content by about a factor of 5.

Identification of electrons in jets is more challenging than that of muons, and so in the studies reported here we restrict ourselves to the muon channel.

Figure 1: The left plot shows the fraction of all muons with reconstructed  $p_T > 4$  GeV that are secondary muons vs muon  $p_T$  in the QCD samples (filled circles) and in the muon+jet samples (open circles). The difference is caused by the generator-level filtering of the  $\mu$  samples before ATLAS simulation has a chance to create the secondary muons. The right plot shows the fraction of muon-tagged jets that are due to a  $b$ -quark as identified by the default Monte Carlo labeling algorithm. In both plots, the black open circles represent muon-tagged jets found in the muon+jet sample and the red filled circles represent muon-tagged jets found in the QCD jet sample.

## 2.1 Selection cuts

This analysis depends, primarily, on two reconstructed objects: jets and muons. Jets are found as  $\Delta R < 0.4$  cone jets with a  $p_T > 15$  GeV [3]. Jets are calibrated with a standard jet energy scale calibration (and the jet  $p_T$  includes the muon  $p_T$ ) [4]. Muons are reconstructed from tracks in the outer muon detectors and must match an inner detector track with a fit  $\chi^2 < 10$ . The muons must have a reconstructed  $p_T > 4$  GeV [5]. A *muon-tagged jet* is a jet with a muon contained within a cone of  $\Delta R < 0.4$  of the jet axis.

The *flavor* of each jet must be determined ( $b$ -,  $c$ -, or light-jet) in Monte Carlo. The ATLAS flavor labeling algorithm [2] is used. A jet is labeled as a  $b$ -jet if a  $b$ -quark with  $p_T > 5$  GeV is found in a cone of size  $\Delta R = 0.3$  around the jet direction. If no  $b$ -quark is present, but instead a  $c$ -quark is found then the jet is labeled as a charm jet. Remaining jets are labeled as light-jets. Light-jets include jets that originate from a gluon as well as a  $u$ -,  $d$ -, or  $s$ -quark. A  $b$ - or  $c$ -quark that originates from gluon splitting will be classified as a  $b$ - or  $c$ -jet as long as the  $b$ - or  $c$ -quark is within  $\Delta R < 0.3$  of the jet axis.

## 2.2 Monte Carlo biases

Requiring that a true muon from  $b$  or  $c$  decay is present as imposed on the muon+jet Monte Carlo sample means that almost all muons from decays of  $\pi/K$ , or from material interactions, are missing. These latter sources are here denoted *secondary muons*. They are present in the inclusive jet sample, of course.

The QCD jet sample predicts the secondary muon rate shown by the filled circles in Fig. 1 (left). The muon+jet samples have a very different secondary muon average fraction, especially at low muon  $p_T$ , as seen by the open circles in Fig. 1 (left). Fig. 1 (right) shows the fraction of jets with selected muons which are  $b$ -jets in the two samples.

The adequacy of the modeling of the secondary muons was checked, firstly by checking that the secondary muon rates were consistent separately for  $b$ -jets,  $c$ -jets, and light-jets between the inclusive jet and muon+jet samples. Secondly, we compared the lifetime tagging rates of  $b$ -jets and light-jets in the

Figure 2: Tag rates (IP3D+SV1 weight  $> 4$ ) for jets containing a reconstructed muon. The left plot are jets labeled as *b*-jets and the right plot are jets labeled as light-jets. In both plots, the open circles represent muon-tagged jets found in the muon+jet sample and the filled circles represent muon-tagged jets found in the QCD jet sample.

two samples as a function of  $p_T$  after requiring a reconstructed muon. The results are shown in Fig. 2. The *b*-jet tag rates (a tag is defined as a jet having an IP3D+SV1 weight greater than 4) in the QCD jet and muon+jet samples are consistent within statistics. The light-jet lifetime-tag rate is a factor of about three higher in the muon+jet sample than in the muon-tagged inclusive jet sample. This arises from semi-leptonic heavy flavor decays in nearby jets which contaminate the light-jets with a muon and a displaced vertex. Muon-tagged jets in the QCD jet sample are less likely to suffer from this contamination because the muon is more likely to be a secondary, and thus not be associated with an event containing a *b*-quark. Real data is expected to look more like the QCD jet sample with the lower lifetime-tagger tag rate. We have checked that neither tagging calibration technique is affected by changes in the relative mix of light-jet muon sources as far as current Monte Carlo statistics allow.

### 2.3 Trigger

Dedicated trigger signatures are necessary to obtain the required number of muon+jet events. We consider the statistics obtainable as a function of jet  $p_T$ . We also discuss a more sophisticated trigger to increase statistics at high jet  $p_T$  compared to a single jet trigger. A full discussion of the operation of the ATLAS jet and muon trigger systems can be found elsewhere [6, 7].

The most obvious choice for a muon+jet trigger is a simple coincidence of lepton and jet triggers requiring no geometrical correlation. The rate for such a trigger is high, so that it must be prescaled, especially at low  $p_T$ . The flexible multi-level trigger system of ATLAS allows geometrical correlations to be used, explicitly requiring that the muon is close to the triggering jet direction.

In the current trigger menu foreseen for running at luminosities around  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  [8], various muon and jet trigger thresholds are available at Level-1 (L1). Example combinations of these thresholds which are promising for the studies reported here are the two triggers L1\_MU4\_J10 and L1\_MU6\_J10, which are L1 signatures with a muon with  $p_T > 4$  or 6 GeV and a jet with  $p_T > 10$  GeV.

At Level-2 (L2) the muon selection is refined [7]: the selection sequence is started by the *muFast* algorithm which confirms L1 muon candidates and makes a more precise muon momentum measurement using muon spectrometer hit information. A fast track combination algorithm, *muComb*, matches tracks found by *muFast* with tracks found in the inner detector. For the studies reported here, no further selection

is made at the third trigger level, the event filter (EF).

Since the trigger rate is likely to be limited by bandwidth considerations at low  $p_T$  rather than the physics rate, the key parameter in considering the trigger performance is the purity of the sample in terms of the final selected events which are desired: the offline muon-tagged jets. We define the purity of the triggered sample as the fraction of events passing the trigger that contain such an offline muon-tagged jet. For the purpose of this study, the offline muon-tagged jet candidate is as defined in Section 2 ( $p_T > 4$  GeV matching a reconstructed jet with  $p_T > 15$  GeV). The purities of jet samples selected by the different trigger requirements discussed above are shown in Table 1.

The second and subsequent rows of Table 1 show that a further refinement is possible by asking for angular matching between the trigger muon and jet directions (taken here to be within  $\Delta R = \sqrt{\Delta\phi^2 + \Delta\eta^2} < 0.4$ ). The choice between L1\_MU4\_J10 and L1\_MU6\_J10 will be driven essentially by the required muon  $p_T$  acceptance. Overall, purities relative to the offline selected sample of around 80% are attainable. This refined algorithm will be implemented for data-taking.

Table 1: Purities of muon-tagged jet events in the triggered sample for different trigger selections. The purity is shown for four triggers with two L1 muon trigger thresholds ( $X$ ). Errors are purely Monte Carlo statistics.

Signature	$X = 4$ GeV	$X = 6$ GeV
L1_MUX_J10	$20 \pm 1\%$	$40 \pm 3\%$
L1_MUX_J10 ( $\mu$ -jet matching)	$51 \pm 3\%$	$79 \pm 7\%$
L2_muX(muFast)_J10 ( $\mu$ -jet matching)	$70 \pm 5\%$	$82 \pm 8\%$
L2_muX(muComb: $\mu$ +ID)_J10 ( $\mu$ -jet matching)	$78 \pm 6\%$	$84 \pm 8\%$

A further concern is to provide a good coverage in jet  $p_T$  extending from low  $p_T$  as discussed above to much higher jet  $p_T$ , where the highest jet threshold will run unscaled. The strategy adopted, similar to the one used for the inclusive jet trigger, consists of building up a set of muon-jet triggers with different jet trigger thresholds with prescale factors that diminish as  $p_T$  rises. Figure 3 (left) shows the  $p_T$  distribution of the jet belonging to the muon-jet candidate selected using the signature L2\_mu4\_J10. Using the set of signatures L2\_mu4\_J10, L2\_mu4\_J18, L2\_mu4\_J23, L2\_mu4\_J35, L2\_mu4\_J42 with prescale factors 50/15/12/12/1 a more uniform jet  $p_T$  distribution is obtained as shown in Fig. 3 (right).

Under the assumption that the rate budget for the muon+jet trigger is 1 Hz, 100 000 muon+jet events are expected for around 30 hours of running time, corresponding to  $1 \text{ pb}^{-1}$  of data at a luminosity of  $10^{31} \text{ cm}^{-2}\text{s}^{-1}$ . The combined muon-jet sample used in this study is therefore equivalent to roughly  $5 \text{ pb}^{-1}$  of data, assuming that the  $p_T$  acceptance of the trigger is comparable to that generated in the Monte Carlo samples.

### 3 The $p_{T,rel}$ method

The  $p_{T,rel}$  method is based on the different relative transverse momentum distributions of muons in *b*-jets, *c*-jets, and light-jets. This arises because the muon typically originates from the semi-leptonic decay of a heavy hadron in heavy-flavor jets. The variable  $p_{T,rel}$  is defined as the  $p_T$  of the muon with respect to the jet+muon axis. As can be seen Fig. 4,  $p_{T,rel}$  has good discrimination between *b*-jets and *c*-jets and light-jets.

The fraction of *b*-jets in the muon-tagged jet sample is estimated by performing a fit to the  $p_{T,rel}$  distribution of muons using templates describing the  $p_{T,rel}$  shape from *b*-jets, *c*-jets and light-jets. The first two templates are determined from Monte Carlo using muons originating either from *b*- or *c*-hadron

Figure 3: Jet  $p_T$  distribution for trigger L2\_mu4\_J10 (left plot) and the jet  $p_T$  distribution for the sum of triggers L2\_mu4\_J10, L2\_mu4\_J18, L2\_mu4\_J23, L2\_mu4\_J35, L2\_mu4\_J42 (right plot). In the case of the sum of triggers, the triggers were relatively prescaled by factors 50/15/12/12/1. In both plots the muon is confirmed at L2 by the muComb algorithm.

decays. The template for light-jets is obtained by picking random tracks from jets with no heavy flavor in close proximity, assuming a uniform probability that such tracks fake a muon. We plan on using the same procedure to determine the light-jet templates from data once data is available, although we will still use Monte Carlo for the *b*- and *c*-templates. A systematic uncertainty will arise from the presence of non *b*- and *c*-jets in the real data sample, as discussed in Section 3.3.

The  $p_{T,rel}$  templates are determined in bins of jet  $p_T$  and  $\eta$  to allow the *b*-tagging efficiency to be measured as a function of these variables. The  $p_{T,rel}$  distribution is fitted by allowing the normalization of the three templates to vary and minimizing a likelihood that also accounts for the template statistics [9]. The fit results are expressed in terms of fit fractions of the *b*-, *c*-, and light-jet  $p_{T,rel}$  templates,  $F_b$ ,  $F_c$  and  $F_{light}$ . The *b*-tagging efficiency is obtained from the fit results by:

$$\epsilon_b^{data,i} = \frac{N_{\mu-jet}^{tag,i} F_b^{tag,i}}{N_{\mu-jet}^i F_b^i} \quad (1)$$

where  $N_{\mu-jet}^i$  and  $N_{\mu-jet}^{tag,i}$  are, respectively, the number of  $\mu$ -jets in the  $i$ 'th jet  $p_T$  and  $\eta$  bin before and after tagging.

As described in Section 5, a Monte Carlo-based correction is needed to correct the efficiency for *b*-jets with a muon to inclusive *b*-jets. In this section we discuss only the lifetime-tagging efficiency measurement for *b*-jets with muons.

### 3.1 Measuring the *b*-tagging efficiency using $p_{T,rel}$

The full muon+jet sample was split into two equal parts. The first half was used to obtain the  $p_{T,rel}$  templates for light-, *c*- and *b*-jets, while the second half was used to measure the tagging performance.

As mentioned above, the light-jet  $p_{T,rel}$  templates were built from the  $p_{T,rel}$  of all tracks within a cone of  $\Delta R < 0.4$  and  $p_T > 4$  GeV of any reconstructed jet labeled as ‘light’. The candidate jet was further required to be at least  $\Delta R$  away from any other non-light-labeled jet.

Representative templates are shown in Fig. 4. The  $p_{T,rel}$  distributions depend on jet  $p_T$ , especially for *b*-jets, and the templates are therefore derived in several bins of jet  $p_T$ . For high- $p_T$  jets, the separation power of the  $p_{T,rel}$  variable significantly decreases: both the shape and peak value of the  $p_{T,rel}$  distribution for *b*-jets approaches that of *c*- and light-jets. This can be seen in the right plot of Fig. 4.

The ROOT TFractionFitter [9] algorithm is used to fit the templates to the data (the second half of the Monte Carlo sample for this study). TFractionFitter uses a standard likelihood fit that takes into account both the template and data statistics. It includes the constraint that the templates must sum to the data distribution. The histograms in Fig. 5 show the results of the fit applied to muon-tagged jet samples before applying the IP3D+SV1 tagger (left) and after (right). Since the shape of the templates for *c*- and light-jets do not differ greatly, the relative rate of *c*- and light-jets is not so well determined. The shape of the template for *b*-jets does differ significantly, and so the fraction of *b*-jets can be reliably determined. The *b*-tagging efficiency is then determined directly using Equation (1).

As a first step, an inclusive *b*-tagging efficiency was measured, averaged over the  $p_T$  and  $\eta$  spectra of the jets. The results for the inclusive *b*-tagging efficiency, for various cuts on the tagger weight  $w$ , are presented in Table 2. Good agreement is observed between the true Monte Carlo *b*-tagging efficiency and that measured with the  $p_{T,rel}$  method, within 1-2% statistical precision.

Table 2: True Monte Carlo efficiencies and efficiencies obtained with the  $p_{T,rel}$  method for 2 taggers using the combined muon+jet samples. The errors are statistical only.

Tagger	Weight cut	$\epsilon_{true}$	$\epsilon_{meas}$
IP3D+SV1	$w > 4$	0.748	$0.758 \pm 0.018$
	$w > 7$	0.627	$0.630 \pm 0.013$
	$w > 10$	0.489	$0.475 \pm 0.010$
IP2D	$w > 2$	0.731	$0.715 \pm 0.017$
	$w > 3$	0.640	$0.631 \pm 0.013$
	$w > 4$	0.550	$0.541 \pm 0.009$

Figure 4:  $p_{T,rel}$  templates obtained at low  $p_T^{\text{jet}}$  ( $15 < p_T^{\text{jet}} < 28$  GeV) (left) and high  $p_T^{\text{jet}}$  ( $163 < p_T^{\text{jet}} < 300$  GeV) region. Intermediate  $p_T^{\text{jet}}$  ranges have distributions lying between these extremes.

The stability and sensitivity of the algorithm was tested by varying the fraction of *b*-jets in the Monte Carlo data-like test sample. This can be done in two ways: by decreasing the number of *b*-jets or by adding more light-jets to the initial sample. We have chosen the second approach.

We varied the input fraction of light-jets in the Monte Carlo test sample (and thus the fraction of *b*-jets) and re-measured the efficiency. The true input fractions and those obtained from fits to templates are shown in Table 3. We find agreement within statistical errors.

Figure 5: A fit of the  $p_{T,rel}$  templates to the test sample. The test sample (black error bars) was fit with the  $p_{T,rel}$  templates obtained from QCD jet Monte Carlo samples (green triangle: light-jet, blue square:  $c$ -jet, and red dot:  $b$ -jet). The red histogram is the result of the fit. The left plot shows the fit results for all muon-tagged jets, and the right shows that obtained after tagging.

Table 3: The stability of the  $p_{T,rel}$  method as a function of changing  $b$ -,  $c$ -, and light-jet fractions. The fraction of  $b$ -jets was varied by altering the number of light-jets as described in the text. The first two columns show the true and fitted fractions of  $b$ -jets in the muon-tagged jet sample ( $f_B$  - true and  $f_B$  - result of fit). The remaining columns show the efficiency for two taggers (IP3D+SV1 with  $w > 7$  and IP2D with  $w > 3$ ) as measured directly in Monte Carlo ( $\epsilon_{true}$ , and as determined by the  $p_{T,rel}$  method ( $\epsilon_{meas}$ ).

$f_B$ - true	$f_B$ - result of fit	$\epsilon_{true}^{w_{IP3D+SV1}>7}$	$\epsilon_{meas}^{w_{IP3D+SV1}>7}$	$\epsilon_{true}^{w_{IP2D}>3}$	$\epsilon_{meas}^{w_{IP2D}>3}$
0.259	$0.260 \pm 0.005$	0.627	$0.630 \pm 0.024$	0.640	$0.632 \pm 0.014$
0.298	$0.298 \pm 0.005$	0.627	$0.632 \pm 0.013$	0.640	$0.633 \pm 0.013$
0.347	$0.349 \pm 0.006$	0.627	$0.630 \pm 0.015$	0.640	$0.631 \pm 0.014$
0.398	$0.397 \pm 0.006$	0.627	$0.634 \pm 0.015$	0.640	$0.635 \pm 0.012$
0.457	$0.463 \pm 0.010$	0.627	$0.625 \pm 0.016$	0.640	$0.625 \pm 0.016$

### 3.2 $b$ -tagging efficiency as a function of jet $p_T$ and $\eta$

The  $b$ -tagging efficiency is strongly dependent on jet  $p_T$  and  $\eta$  [2]. The above Monte Carlo test is an average and is only applicable for physics analysis that have the same kinematic properties as the muon+jet sample. In order to properly account for such effects the  $b$ -tagging efficiency should be parameterized and measured as a function of at least these two variables. Since the Monte Carlo statistics are limited, the method is tested by binning separately in  $p_T$  and  $\eta$ . With more statistics a two-dimensional ( $p_T, \eta$ )-binning will be used. For the first case, the  $p_{T,rel}$  templates are derived in several jet  $p_T$  bins. Event samples in each  $p_T$  bin are split in half as before: the first half was used to determine the  $b$ ,  $c$ , and light jet  $p_{T,rel}$  templates, while the second half was used as a data-like test sample to measure the  $b$ -tagging efficiency. The efficiency obtained in this way is integrated over the whole jet  $\eta$  spectrum. The procedure was repeated to measure the efficiency dependence on jet  $|\eta|$ . In this case, the efficiency was integrated over the  $p_T$  spectrum of jets.

The measured  $p_T$  dependence of the  $b$ -tagging efficiency is shown in Fig. 6 (left) for the tagger IP3D+SV1. We observe a good agreement between measured and true efficiencies in this low jet  $p_T$  region. For jets with  $p_T > 80$  GeV, not shown, the statistical error from the fit becomes large and

the results become unreliable. At present, therefore, we conclude that the efficiency can be reliably determined only in the low jet  $p_T$  region ( $p_T < 80$  GeV). This is related to the poor separation of *b*-jet templates from *c*- and light-jet templates in the high jet  $p_T$  region (compare the plots in Fig. 4 for an example). In view of this, the  $|\eta|$ -dependence of the *b*-tagging efficiency was studied only for jets with  $p_T < 80$  GeV (Fig. 6 right). Good agreement over the whole  $|\eta|$  range is observed.

Figure 6: Efficiency as a function of jet  $p_T$  (left) and jet  $|\eta|$  (right) for the tagger IP3D+SV1 as measured using the  $p_{T,rel}$  method. The dots are the true value as measured in the Monte Carlo, and the squares (with error bars) are determined from the  $p_{T,rel}$  method. The lines are parameterizations to the measured  $p_{T,rel}$  points. At high jet  $p_T$  the  $p_{T,rel}$  measurement technique fails and so we do not attempt to measure *b*-tagging performance above 80 GeV. The  $|\eta|$  plot (right) includes only jets with  $p_T < 80$  GeV.

### 3.3 Expected Errors

The high yield of muon-tagged jets from the muon-jet trigger means that the statistical error for determining efficiencies with the  $p_{T,rel}$  method should rapidly become small: for  $100 \text{ pb}^{-1}$  of data, for example, the overall statistical error would already be well below 1%.

The study of the systematic errors in the  $p_{T,rel}$  method is in progress, and will require real data for detailed evaluation. Sources of systematic error being considered include:

- The major uncertainty of this method is the use of Monte Carlo to model the  $p_{T,rel}$  templates for *b*- and *c*-jets. A change in the fragmentation function, for example, will likely change the muon  $p_{T,rel}$  spectrum. We estimated the contribution of these effects by scaling the  $p_{T,rel}$  shape of the *b* and *c* templates, resulting in an change in  $\epsilon_{meas}$  of 5%.
- The light-jet templates will be drawn from data and thus will have some heavy flavor contamination. QCD Monte Carlo predicts a jet sample will contain 2.5% *b*-jets and 5% *c*-jets. We expect little error to be introduced by *c*-jets as their  $p_{T,rel}$  distribution is so similar to light-jets. We tested the effect of 2.8% *b*-jets in the pool of jets that was used to determine the light-jet template and re-ran the  $p_{T,rel}$  fit. We observed a systematic shift to smaller *b*-jet efficiencies by 3%. We add  $\pm 3\%$  as a systematic error due to heavy flavor contamination of the light jet templates. There is evidence we can mitigate the size of this error by rejecting jets from the light-jet template that satisfy a loose lifetime tagging requirement.
- Detector modeling has also been examined as a source of further systematic error. Jet  $p_T$  resolution, the muon  $p_T$  resolution, and the jet and muon direction resolution are all potential contributors. Studies indicate the error due to this are of order a few percent. Detector modeling of muon

systematics have not been studied as it is assumed that the Monte Carlo modeling errors will be larger.

- We have an implicit assumption that all tracks in jets correctly model the  $p_{T,rel}$  distribution for light jets. A further systematic will exist because  $p_{T,rel}$  distribution for fake muons in light jets is not the same as the tracks associated with light jets.

These preliminary studies to date indicate that the systematic error sources should be controllable at the level of 6% or better on the lifetime tagging efficiency.

## 4 The System 8 method

The System 8 technique is designed to measure the *b*-tagging efficiency with reduced dependence on Monte Carlo [10], [11]. This method uses two data samples with different *b*-fractions and two uncorrelated tagging algorithms. A system of 8 nonlinear equations involving known quantities - like the total number of jets tagged in each sample - and 8 unknown quantities - like the *b*-tagging efficiency - can be written down and solved.

Before writing down the system of 8 equations we define the taggers and two samples more fully. The two taggers used must be as uncorrelated as possible. For this study we use the muon-in-jet tagger algorithm (SMT) [5] as one tagger. The SMT algorithm forms a 1-dimensional likelihood using the  $p_{T,rel}$  of the muon. In the present analysis an event is said to be tagged by the SMT tagger if the likelihood value is greater than 1.4. The second tagger, the one whose efficiency we want to measure is either the IP3D+SV1 or the IP2D algorithm. We abbreviate this second algorithm as “LT”, short for “lifetime tagger”.

The two samples are denoted the “n-sample” and the “p-sample.” The n-sample is the full sample of jets containing a muon described in Section 2. The p-sample is a subset of the n-sample selected to have an enhanced *b*-content. A muon-tagged jet in the p-sample is required to have at least one back-to-back ( $\Delta\phi > 2.5$ ) lifetime-tagged (IP3D+SV1 weight  $> 3$ ) jet. This selection criterion increases the *b*-fraction of the p-sample relative to the n-sample by about a factor of two. The cuts for the p-sample were chosen to keep the statistics of the p-sample as large as possible and also to ensure the stability of the method.

### 4.1 The 8 equations

Four numbers are measured in each sample: the number of jets before tagging ( $n$  in the n-sample,  $p$  in the p-sample), the number of jets tagged by the LT algorithm ( $n^{LT}$ ,  $p^{LT}$ ), the number of jets tagged by the SMT algorithm ( $n^{SMT}$ ,  $p^{SMT}$ ), and the number of jets tagged by both algorithms ( $n^{both}$ ,  $p^{both}$ ).

While the total number of muon-tagged jets in each sample is an experimental observable, their flavor composition is not. We denote the number of *b*-jets in each sample as ( $n_b$ ,  $p_b$ ) and *c*- and light-jets as ( $n_{cl}$ ,  $p_{cl}$ ). The tagging efficiencies of the algorithms on the selected *b*-jets are ( $\epsilon_b^{LT}$ ,  $\epsilon_b^{SMT}$ ) and non-*b*-jets tagging efficiencies are ( $\epsilon_{cl}^{LT}$ ,  $\epsilon_{cl}^{SMT}$ ) — which are also unknown. Unless otherwise stated, each efficiency is that which would apply to tagging of the n-sample.

These 8 quantities can be related by 8 equations. These equations also contain parameters encoding the extent to which the following assumptions are valid: that the efficiency of each tagger is the same on the n- and p-sample, and that the two tagging algorithms are uncorrelated. The parameters introduced are  $\alpha_i$  as follows:

$$\epsilon_b^{both} = \alpha_1 \epsilon_b^{LT} \epsilon_b^{SMT} \quad (2)$$

$$\epsilon_{cl}^{both} = \alpha_2 \epsilon_{cl}^{LT} \epsilon_{cl}^{SMT} \quad (3)$$

$$\epsilon_{cl}^{SMT} \text{ (on p-sample)} = \alpha_3 \epsilon_{cl}^{SMT} \text{ (on n-sample)} \quad (4)$$

$$\epsilon_{cl}^{LT} \text{ (on p-sample)} = \alpha_4 \epsilon_{cl}^{LT} \text{ (on n-sample)} \quad (5)$$

$$\epsilon_b^{SMT} \text{ (on p-sample)} = \alpha_5 \epsilon_b^{SMT} \text{ (on n-sample)} \quad (6)$$

$$\epsilon_b^{LT} \text{ (on p-sample)} = \alpha_6 \epsilon_b^{LT} \text{ (on n-sample)} \quad (7)$$

The  $\alpha_1$  and  $\alpha_2$  coefficients measure how correlated the two taggers are on *b*-jets and non-*b*-jets. The  $\alpha_3$ ,  $\alpha_4$ ,  $\alpha_5$ , and  $\alpha_6$  are sensitive to any tag rate differences caused by the selection of the p-sample. The method is constructed in such a way that the  $\alpha_i$  should each be approximately unity. The values of the  $\alpha_i$  must be determined from Monte Carlo and possible differences of each  $\alpha_i$  from that in data must be included in the systematic error. The current method used to evaluate this systematic is described in Section 4.3.

The eight jet counts enumerated above can be related by the following eight equations, including the  $\alpha_i$ :

$$n = n_b + n_{cl} \quad (8)$$

$$p = p_b + p_{cl} \quad (9)$$

$$n^{LT} = \epsilon_b^{LT} n_b + \epsilon_{cl}^{LT} n_{cl} \quad (10)$$

$$p^{LT} = \alpha_6 \epsilon_b^{LT} p_b + \alpha_4 \epsilon_{cl}^{LT} p_{cl} \quad (11)$$

$$n^{SMT} = \epsilon_b^{SMT} n_b + \epsilon_{cl}^{SMT} n_{cl} \quad (12)$$

$$p^{SMT} = \alpha_5 \epsilon_b^{SMT} p_b + \alpha_3 \epsilon_{cl}^{SMT} p_{cl} \quad (13)$$

$$n^{both} = \alpha_1 \epsilon_b^{LT} \epsilon_b^{SMT} n_b + \alpha_2 \epsilon_{cl}^{LT} \epsilon_{cl}^{SMT} n_{cl} \quad (14)$$

$$p^{both} = \alpha_1 \alpha_5 \alpha_6 \epsilon_b^{LT} \epsilon_b^{SMT} p_b + \alpha_2 \alpha_3 \alpha_4 \epsilon_{cl}^{LT} \epsilon_{cl}^{SMT} p_{cl} \quad (15)$$

This system of eight equations (giving the method its name) is well specified if the value of each  $\alpha_i$  is known. The  $\epsilon_b^{LT}$  is the unknown that is of most interest — most of the others are not directly usable for other analysis. The System 8 method is based on a technique used by the D0 experiment at the Tevatron [10]. The CDF experiment has also used jet events to calibrate their lifetime *b*-tagging efficiency [12] using a different technique.

## 4.2 Solving System 8, statistical error, and stability

Solving the system of 8 equations is in general straightforward with tools like Mathematica (analytical solution) or MINUIT (numerical solution). However, the nonlinearity of the 8 equations makes evaluating the statistical errors nontrivial. As a result Monte Carlo methods are employed. The System 8 observables, the jet counts  $\{n, p, n^{LT}, p^{LT}, n^{SMT}, p^{SMT}, n^{both}, p^{both}\}$  are correlated; from them 8 uncorrelated jet counts  $\{x_1, \dots, x_8\}$  are defined by dividing the n-sample into non-overlapping subsets. These parameters are varied according to Gaussian distributions with standard deviation  $\sqrt{x_i}$ . The variation of all  $x_i$  was performed simultaneously assuming no correlations between them. The counts were varied in this way 100,000 times and the 8 equations were solved each time. The resulting distribution of  $\epsilon_b^{LT}$  was used to determine the one-sigma statistical error. Statistical errors are shown for current Monte Carlo statistics in Table 5.

The System 8 solution is not well constrained when the equations are close to being linearly-dependent. As the equations near linear dependence, the System 8 solution becomes increasingly sensitive to statistical fluctuations, resulting in unreliable values of  $\epsilon_b^{LT}$ . The term ‘stability’ will be used to describe the sensitivity of System 8 to statistical variations in the data.

The 8 equations are linearly independent as long as the *b*-content of the n- and p-samples differ, and as long as  $\epsilon_b \neq \epsilon_{cl}$  for both the SMT and LT tagging algorithms. In practice the first condition is easily met by construction of the p-sample (which requires a back-to-back *b*-tagged jet), but in the case of the

SMT the second stability requirement ( $\epsilon_b^{SMT} \neq \epsilon_{cl}^{SMT}$ ) becomes increasingly difficult to satisfy at high jet  $p_T$ .

The SMT algorithm is highly correlated with the  $p_{T,rel}$  distribution of muons to distinguish between *b*-, *c*- and light-jets. These distributions become very similar at high jet  $p_T$  (see Fig. 4), leading to the poor ability of the SMT to separate *b* and non-*b*-jets at high momentum. It is for this reason we restrict the analysis to  $p_T < 80$  GeV.

### 4.3 Correlation systematic error

It is important to determine how well the Monte Carlo describes the  $\alpha_i$  in the data. Possible deviations should be reflected in the systematic error. We evaluate this contribution as the change in  $\epsilon_b^{LT}$  obtained by shifting each  $\alpha_i$  from its value in Monte Carlo to unity. The total contribution to the systematic error, formed by adding the individual shifts in quadrature, is abbreviated as the correlation error.

Each  $\alpha_i$  is measured from Monte Carlo and the results are shown for the IP3D+SV1 tagger ( $w > 4$ ) in Table 4. The errors on each  $\alpha_i$  come only from Monte Carlo statistics. We have checked other tagging algorithms and weight cuts and the results are similar. It can be seen that only  $\alpha_3$  differs by much more than one sigma from unity, and the others lie within 3% of unity.

Table 4: The  $\alpha$  coefficients measured on Monte Carlo for jet  $15 < p_T < 80$  GeV, for the IP3D+SV1 tagger weight  $w > 4$  and SMT cut of 1.4 ( $\alpha_i^{meas}$ ). The last two columns show how the *b*-tagging efficiency ( $\epsilon_b$ ) is affected by different variations in  $\alpha_i$ : a 1% variation ( $\alpha_i = 1 \pm 0.01$ ) and the measured offset of each  $\alpha_i$  from unity ( $\alpha_i = 1 \pm (\alpha_i^{meas} - 1)$ ). The change in  $\epsilon_b$  is labeled  $\Delta_{\epsilon_b}$ . The latter column is added in quadrature to determine the total systematic error for the correlation error (see text).

Assumption	Value ( $\alpha_i^{meas}$ )	$\Delta_{\epsilon_b}$ for $\alpha_i = 1 \pm 0.01$	$\Delta_{\epsilon_b}$ for $\alpha_i = 1 \pm (\alpha_i^{meas} - 1)$
$\alpha_1$	$1.016 \pm 0.012$	0.027	0.043
$\alpha_2$	$1.018 \pm 0.024$	0.002	0.004
$\alpha_3$	$1.052 \pm 0.019$	0.006	0.031
$\alpha_4$	$1.028 \pm 0.020$	$< 0.001$	$< 0.001$
$\alpha_5$	$1.011 \pm 0.011$	$< 0.001$	$< 0.001$
$\alpha_6$	$1.005 \pm 0.010$	0.016	0.008

We vary each  $\alpha_i$  by  $\pm 0.01$  to give an idea of how each  $\alpha_i$  contributes to the error in  $\epsilon_b^{LT}$ . Table 4 shows that variations in  $\alpha_2$ ,  $\alpha_4$  and  $\alpha_5$  should have rather less impact on the *b*-tagging efficiency measurement than  $\alpha_1$ ,  $\alpha_3$  and  $\alpha_6$ . The measured values of the coefficients  $\alpha_1$  and  $\alpha_6$  are statistically consistent with unity and show little statistically-significant dependence on jet  $p_T$  or SMT cut. The coefficient  $\alpha_3$ , on the other hand, is not consistent with unity and shows a  $p_T$  dependence, and has a pronounced effect on the measured efficiency at high jet  $p_T$ . The non-unity  $\alpha_3$  is understood to be primarily due to the different relative fractions of charm and light in the n- and p-samples.

In order to work out the correlation error we evaluate the shift in  $\Delta_{\epsilon_b^{LT}}$  for a variation in  $\alpha_i$  of  $\pm(\alpha_i - 1)$ , as shown in Table 4. Adding the errors in quadrature gives an estimate of the correlation error of 6%. Larger Monte Carlo samples will help improve our understanding of this error and help better understand which  $\alpha_i$  really aren't unity.

### 4.4 Tests on Monte Carlo

We evaluated the System 8 method on the muon+jet Monte Carlo sample, for the following standard ATLAS taggers: IP2D, and the default combination of IP3D+SV1 for jets with  $p_T < 80$  GeV.

To derive  $p_T$  and  $\eta$  dependent efficiency curves, the System 8 method was applied in bins of  $p_T$  and  $\eta$ . Due to lack of Monte Carlo statistics it is not currently possible to bin in both  $p_T$  and  $\eta$  simultaneously; instead, System 8 was tested in  $p_T$  bins for  $|\eta| < 2.5$ , and separately in  $\eta$  bins for  $15 < p_T < 80$  GeV. With larger Monte Carlo statistics and much larger data statistics (such as with  $50 \text{ pb}^{-1}$ ) we should have enough for four bins in  $p_T$  and four in  $|\eta|$  simultaneously for jet  $p_T < 80$  GeV. The exact binning configuration will be optimized to give the best possible resolution at low jet  $p_T$  where the *b*-tagging efficiency is changing most rapidly. For this study, three bins in  $p_T$  (15-30 GeV, 30-50 GeV, 50-80 GeV), and four bins in  $|\eta|$  (0.0-0.5, 0.5-1.0, 1.0-1.5, 1.5-2.5) were considered.

Table 5 shows the results of calibrating the IP3D+SV1 tagger ( $w > 4$ ) and IP2D tagger ( $w > 3$ ) in bins of  $p_T$  and  $\eta$ . The statistical error is shown. Recall the correlation error is an additional 6% which should be added in quadrature.

Table 5: Measured efficiencies, the statistical error, and their deviation from the true efficiencies in bins of  $p_T$  and  $\eta$ , as described in the text. The statistical error is for the muon+jet Monte Carlo statistics. The correlation error, estimated to be  $\pm 0.06$ , must be added as well.

Tagger	Bin	Measured $\epsilon_b$	$ \Delta_{meas.,true} $
IP3D+SV1	$p_T$ : 15-30	$0.672 \pm 0.036$	0.040
	$p_T$ : 30-50	$0.723 \pm 0.026$	0.004
	$p_T$ : 50-80	$0.755 \pm 0.029$	0.017
	$ \eta $ : 0.0-0.5	$0.748 \pm 0.041$	0.008
	$ \eta $ : 0.5-1.0	$0.734 \pm 0.045$	0.029
	$ \eta $ : 1.0-1.5	$0.736 \pm 0.038$	0.017
	$ \eta $ : 1.5-2.5	$0.707 \pm 0.043$	0.001
IP2D	$p_T$ : 15-30	$0.520 \pm 0.030$	0.002
	$p_T$ : 30-50	$0.619 \pm 0.027$	0.003
	$p_T$ : 50-80	$0.671 \pm 0.033$	0.011
	$ \eta $ : 0.0-0.5	$0.663 \pm 0.043$	0.003
	$ \eta $ : 0.5-1.0	$0.656 \pm 0.052$	0.016
	$ \eta $ : 1.0-1.5	$0.606 \pm 0.036$	0.034
	$ \eta $ : 1.5-2.5	$0.587 \pm 0.046$	0.018

To conclude, System 8 works well for different types of lifetime tagging algorithms for jet  $p_T < 80$  GeV. It demonstrates stable results for different cuts on *b*-tagging weights.

## 5 The inclusive *b*-tagging efficiency

This note describes two methods which measure the lifetime-tagging efficiency for *b*-jets containing muons. In this section we briefly discuss how to convert from the measured tag efficiency to a lifetime tagging efficiency relevant to inclusive jet samples.

Fig. 7 shows the ratio of the muon-jet lifetime tag rate to the inclusive-jet tag rate for the default IP3D+SV1 tagger ( $w > 4$ ) as a function of  $p_T$ . The difference between the tag rates in the two samples is primarily due to about a 50% difference in the  $p_T$  of the highest  $p_T$  track and in the average number of tracks per jet.

We define a scale factor,  $S_b$ , to describe the difference in tag rates. The scale factor is defined in

Figure 7: The right hand plot shows the ratio of efficiencies for semi-leptonic jet tagging and hadronic jet tagging in the QCD jet sample.

Monte Carlo:

$$\epsilon_{b \rightarrow \text{had}}^{MC}(p_T, \eta) = S_b(p_T, \eta) \epsilon_{b \rightarrow \ell \nu X}^{MC}(p_T, \eta) \quad (16)$$

and thus, given a hadronic Monte Carlo *b*-jet, one calculates its calibrated lifetime tagging efficiency as follows:

$$\epsilon_{b \rightarrow \text{had}}(p_T, \eta) = \epsilon_b(p_T, \eta) S_{b \rightarrow \text{had}}(p_T, \eta) \quad (17)$$

where  $\epsilon_b$  is the tagging efficiency measured with System 8 or  $p_{T,rel}$  in muon-tagged jets.

To understand the systematic error on the scale factor we need a better understanding of the causes of the differences in tag rate. This work is in progress.

## 6 Conclusions

We have presented two methods to calibrate lifetime *b*-tagging algorithms using dijet data. Trigger studies were performed in order to assure that there will be enough data for the *b*-tagging calibration. Detailed *b*-tagging performance can be obtained with data corresponding to  $50 \text{ pb}^{-1}$  of integrated luminosity.

The suggested methods,  $p_{T,rel}$  and System 8, were studied using Monte Carlo jet events, at least one of which has an associated muon. Good agreement is observed between true semi-leptonic *b*-tagging efficiency and that measured by  $p_{T,rel}$  and System 8. Both methods were verified in different jet  $\eta$  and  $p_T$  regions. We found that the current version of the  $p_{T,rel}$  method can be used for jets below 80 GeV in entire  $\eta$  region. System 8 was also proved to work well up to 80 GeV in the entire  $\eta$  region.

The total error of both methods is expected to be rapidly dominated by systematic uncertainties. The systematic errors studied so far indicate that both methods should be able to control the absolute error on  $\epsilon_b$  to 6%. The additional systematic uncertainties associated with converting the semi-leptonic efficiency to the inclusive efficiency have not yet been determined. The two methods are complementary to those discussed in [1], in that they are most useful in measuring the turn-on of the *b*-tagging efficiency at low jet  $p_T$ .

# Trigger

# The Trigger for Early Running

## Abstract

The ATLAS trigger and data acquisition system is based on three levels of event selection designed to capture the physics of interest with high efficiency from an initial bunch crossing rate of 40 MHz. The selections in the three trigger levels must provide sufficient rejection to reduce the rate to 200 Hz, compatible with offline computing power and storage capacity. The LHC is expected to begin its operation with a peak luminosity of  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  with a relatively small number of bunches, but quickly ramp up to higher luminosities by increasing the number of bunches, and thus the overall interaction rate. Decisions must be taken every 25 ns during normal LHC operations at the design luminosity of  $10^{34} \text{ cm}^{-2} \text{ s}^{-1}$ , where the average bunch crossing will contain more than 20 interactions. Hence, trigger selections must be deployed that can adapt to the changing beam conditions while preserving the interesting physics and satisfying varying detector requirements. In this paper, we provide a menu of trigger selections that can be deployed during the startup phase at each trigger level and show its evolution to higher luminosities. The studies presented in this paper are based on simulated data.

## 1 Introduction

The ATLAS trigger [1, 2] is composed of three levels of event selection: Level 1 (L1) [3] which is hardware-based using ASICs and FPGAs, the Level 2 (L2) and Event Filter (EF) (collectively referred to as the High Level Trigger or HLT [4]) based on software algorithms analyzing the data on large computing farms. The three levels of the ATLAS trigger system must reduce the output event storage rate to  $\sim 200$  Hz (about 300 MB/s) from an initial LHC bunch crossing rate of 40 MHz. It is evident from Fig. 1 that large rejection against QCD processes is needed while maintaining high efficiency for low cross section physics processes that include searches for new physics.

During the ATLAS startup phase, where low luminosity conditions ( $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ ) are expected to prevail, the focus of the trigger selection strategy will be to commission the trigger and the detector and to ensure that established Standard Model processes are observed. It is therefore important to deploy loose selection criteria at each stage. In early operations many triggers will operate in pass-through mode, which entails executing the trigger algorithms but accepting the event independent of the algorithmic decision. This allows the trigger selections and algorithms to be validated to ensure that they are robust against the varying beam and detector conditions that are hard to predict before data-taking. As the luminosity increases, the use of higher thresholds, isolation criteria and tighter selections at HLT become necessary to reduce the background rates while achieving selection of interesting physics with high efficiency.

This note describes the possible triggers that can be deployed during the initial low luminosity running and discusses the strategy for triggering as the LHC ramps up to its design luminosity of  $10^{34} \text{ cm}^{-2} \text{ s}^{-1}$ . The performance of the various trigger algorithms at each of the three trigger levels is described in a set of additional accompanying notes. It should be emphasized that the rate estimates discussed in this note are based on simulations and are subject to several sources of uncertainty which include lack of knowledge of the exact cross-sections, detector performance, and beam related background conditions. Observations with early data will allow validation of these estimated rates and extrapolations to higher luminosities.

Figure 1: Expected event rates for several physics processes at the LHC design luminosity.

## 2 Level 1 trigger

The Level 1 trigger system receives data at the full LHC bunch crossing rate of 40 MHz and must make its decision within  $2.5 \mu\text{s}$  to reduce the output rate to 75 kHz ( $\sim 40$  kHz during ATLAS start-up). The L1 trigger has dedicated access to data from the calorimeter and muon detectors. The L1 calorimeter trigger [5] decision is based on the multiplicities and energy thresholds of the following objects observed in the ATLAS Liquid Argon [6] and Tile [7] calorimeter sub-system: Electromagnetic (EM) clusters, taus, jets, missing transverse energy ( $\cancel{E}_T$ ), scalar sum  $E_T$  ( $\sum E_T$ ) in calorimeter, and total transverse energy of observed L1 jets ( $\sum E_T(\text{jets})$ ). These objects are computed by the L1 algorithms using the measured  $E_T$  values in trigger towers of  $0.1 \times 0.1$  granularity in  $\Delta\eta \times \Delta\phi$ . The L1 muon trigger [8] uses measurement of trajectories in the different stations of the muon trigger detectors: the Resistive Plate Chambers [9] (RPC) in the barrel region and the Thin Gap Chambers [8] (TGC) in the endcap region. The input to the trigger decision is the multiplicity for various muon  $p_T$  thresholds.

There are a limited number of configuration choices that are available at L1. The most common

difference between configuration choices is the amount of transverse energy or momentum required, so we refer to these configurations as “thresholds,” but note that in addition to the  $E_T$  threshold condition, three different isolation criteria can be applied for L1 EM and tau objects, and three different window sizes can be specified for L1 jet objects. Table 1 gives the number of these so-called thresholds that can be set for each object type. The total number of thresholds allowed for EM and tau objects is 16, where 8 are dedicated to be EM objects and 8 can be configured to be either EM or tau objects. The forward jets have four thresholds that can be set independently in each of the detector arms.

Object	EM	Taus	Jets	For. Jets	$\cancel{E}_T$	$\sum E_T$	$\sum E_T(jets)$	$\mu_{\leq 10 \text{ GeV}}$	$\mu_{> 10 \text{ GeV}}$
# of thresholds	8 - 16	0 - 8	8	4+4	8	4	4	3	3

Table 1: Number of L1 thresholds that can be set for each L1 object type at any given time (see text for details).

The total number of allowed L1 configurations (also called L1 items) that can be deployed at any time is 256. Each of these L1 items, programmed in the Central Trigger Processor (CTP) [10], is a logical combination of the specified multiplicities of one or more of the configured L1 thresholds. As an example L1\_EM25i and L1\_EM25 (A single L1 EM object with  $E_T > 25 \text{ GeV}$  with and without isolation respectively) uses two L1 EM thresholds while L1\_2EM25i (Two L1 isolated EM object with  $E_T > 25 \text{ GeV}$ ) uses the same L1 threshold as the L1\_EM25i item. Furthermore, for each of the 256 L1 items, a prescale factor N can be specified (where only 1 in N events is selected and passed to the HLT for further consideration). As the peak luminosity drops during a fill, the L1 prescale value can be adjusted to keep the output bandwidth saturated without stopping and restarting a data-taking run, if desired. A given data-taking run is sub-divided into time intervals of the order of one minute. These sub-divisions, called luminosity blocks [11], provide the smallest granularity at which various data will be monitored and available for physics analysis. The trigger configuration, including the L1 prescale settings, remains unchanged within this luminosity block and adjustments to L1 prescale factors will be made on luminosity block boundaries.

### 3 Level 2

The L2 trigger is software-based, with the selection algorithms running on a farm of commodity PCs. The selection is largely based on regions-of-interest (RoI) identified at L1 and uses fine-grained data from the detector for a local analysis of the L1 candidate. A seed is constructed for each trigger accepted by L1 that consists of a  $p_T$  threshold and an  $\eta$ - $\phi$  position. The L2 algorithms use this seed to construct an RoI window around the seed position. The size of the RoI window is determined by the L2 algorithms depending on the type of triggered object (for example, a smaller RoI is used for electron triggers than for jet triggers). The L2 algorithms then use the RoI to selectively access, unpack and analyze the associated detector data for that  $\eta$ - $\phi$  position. The ability to move, unpack, and analyse the local data only around the seed position greatly reduces both the processing times and the required data bandwidth.

The L2 algorithms provide a refined analysis of the L1 features based on fine-grained detector data and more optimal calibrations to provide results with improved resolution. They provide the ability to use detector information that is not available at L1, most notably reconstructed tracks from the Inner Detector. The information from individual sub-systems can then be matched to provide additional rejection and higher purity at L2. For each L1 RoI, a sequence of L2 algorithms is executed which compute event feature quantities associated with the RoI. Subsequently, a coherent set of selection criteria is applied on the derived features to determine if the candidate object should be retained.

The L2 farm will consist of around 500 quad-core CPUs. On average, the L2 can initiate the processing of a new event every  $10\ \mu\text{s}$ . The average processing time available for L2 algorithms is 40 ms, which includes the time for data transfers. The L2 system must provide an additional rejection compared to L1 of about 40 to reduce the output rate down from  $\sim 75$  (40) kHz to  $\sim 2$  (1) kHz during nominal (startup) operations.

## 4 Event Filter

The final online selection is performed by software algorithms running on the Event Filter (EF), a farm of processors that will consist of 1800 dual quad-core CPUs. The EF receives events accepted by L2 at a rate of 2 kHz (1 kHz) during nominal (startup) operations and must provide the additional rejection to reduce the output rate to  $\sim 200$  Hz, corresponding to about 300 MB/s. An average processing time of 4 s per event is available to achieve this rejection. The output rate from the Event Filter is limited by the offline computing budget and storage capacity.

As in L2, the EF works in a seeded mode, although it has direct access to the complete data for a given event as the EF selection is performed after the event building step. Each L2 trigger that has been accepted can be used to seed a sequence of EF algorithms that provide a more refined and complete analysis. Unlike L2, which uses specialized algorithms optimized for timing performance, the EF typically uses the same algorithms as the offline reconstruction. The use of the more complex pattern recognition algorithms and calibration developed for offline helps in providing the additional rejection needed at the EF.

## 5 Trigger rate estimation

Trigger rates have been estimated using a sample of simulated events. The design of a specific trigger menu often requires several iterations of selection optimization to ensure that the output rate is within allowed bandwidths and that interesting physics is triggered with high efficiency.

The first step in approximating trigger rates is to choose an appropriate input simulation sample. Most trigger selections are dominated by backgrounds from common processes, so samples with large physics cross-sections are generally used. However, these typically contain very few events that satisfy the trigger criteria and hence a very large number of events are required to obtain adequate statistical uncertainties on the estimated rates. In order to design the trigger menu for a luminosity of  $10^{31}\ \text{cm}^{-2}\ \text{s}^{-1}$ , a minimum-bias dataset containing seven million non-diffractive events with a cross-section of approximately 70 mb was used. To estimate the trigger rates with comparable statistical uncertainties for higher luminosities would require prohibitively large generated samples, hence other approaches are being pursued. These include using a combination of QCD and minimum bias event samples or alternatively using the so-called enhanced bias sample. The enhanced bias sample is a loosely filtered minimum bias sample requiring the lowest L1  $p_T$  thresholds for muon, EM, or jet to have been fulfilled. Only events that pass the filtering process are reconstructed, resulting in a much more effective use of the computing resources. In addition to QCD processes, other high cross-section physics processes, such as  $W$  and  $Z$  boson production, need to be considered for estimating trigger rates at very high luminosities. Although such simulated samples provide a reasonable starting point to establish a data taking menu, these trigger menus will evolve as our understanding of the detector and trigger evolve, and as the physics requirements mature. Once data taking operations begin, dedicated data samples for further menu optimization and rate estimations will be collected.

In order to compute the initial trigger rates, the full trigger simulation (L1, L2, and EF) is executed on a minimum bias data sample generated with PYTHIA [12] and simulated with realistic detector effects

in Geant4 [13]. The rate estimates presented in this paper are based on an analysis of seven million minimum-bias events. At a luminosity of  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  each unscaled event corresponds to a rate of about 0.1 Hz. These raw rates are subsequently weighted for any applied prescale factors, which allows more accurate rate measurements as it makes use of all the events in the data sample. For each level, the individual trigger rates are computed using the equation

$$R = \mathcal{L} \times \frac{n_{\text{accepted}}}{n_{\text{total}}} \times \frac{1}{\prod_{l=\text{lowest level}}^{\text{current level}} P_l} \times \sigma \quad (1)$$

where  $R$  is the rate at the current level,  $\mathcal{L}$  is the instantaneous luminosity,  $P_l$  is the prescale factor applied at a specific level,  $n_{\text{accepted}}$  is the number of events accepted after the specific trigger level studied (and hence all the previous lower levels as well), and  $n_{\text{total}}$  is the total number of events in the dataset and  $\sigma$  is the cross section.

Trigger rates are estimated by assigning a probability for an event to have been accepted. The computation of rates based on probabilities makes maximal use of the available set of simulated events from a statistical point of view. The probability  $Pr_i$  of an event being accepted by a trigger item  $i$  is given by:

$$Pr_i(\text{event}) = D_i(\text{event})/P_i, \quad (2)$$

where  $D_i$  is the decision probability accepting an event when no prescale factor is applied, and  $P_i$  is the overall prescale associated with the trigger item.

In order to compute the overall acceptance rate of a specific menu, the overlap in acceptance from different trigger items needs to be correctly taken into account. The probability that two triggers accept an event simultaneously is then given by:

$$Pr_{12}(\text{evt}) = Pr_1(\text{evt}) \times Pr_2(\text{evt}). \quad (3)$$

The overall probability of accepting an event in a menu of two triggers, including their correlations, is thus given by

$$Pr_{\text{menu}}(\text{evt}) = Pr_1(\text{evt}) + Pr_2(\text{evt}) - Pr_1(\text{evt}) \times Pr_2(\text{evt}) \quad (4)$$

This computation, although simple in the case of two triggers, becomes increasingly complex as the number of items in the menu increases. Fortunately, this problem can be solved recursively. Dedicated tools employing these methods have been developed to compute trigger acceptance rates and overlaps for various trigger menus.

## 6 Trigger menu for a luminosity of $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$

The initial LHC startup luminosity is expected to be approximately  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  with a low number of bunches in the machine. These conditions will be ideal for commissioning the trigger and detector systems, as well as for the initial data taking, which will be dedicated to high cross section Standard Model signatures. Hence, the trigger selections deployed during this early running phase will primarily be a combination of low  $p_T$  thresholds and loose selection criteria. Triggers at higher selection stages will be operated in pass-through mode wherever possible.

Trigger menus are tables of triggers that incorporate the signatures for various physics objects at each of the three trigger levels. These signatures fully specify the thresholds and selection criteria at each level, providing a recipe for triggering on various physics processes. Each signature is considered carefully addressing its physics goals, the efficiency and background rejection it provides for meeting these goals and the trigger bandwidth it consumes. Trigger menus also must include additional triggers

for trigger validation, monitoring, calibration and measuring the performance of the physics triggers. With these considerations, a trigger menu for the startup phase has been developed. The rates have been estimated using the previously described simulated minimum-bias events.

The following notation is used to label the different trigger items: e (electron), g (photon), EM (electromagnetic), J (jets), FJ (forward jets), XE (Missing  $E_T$ ), TE (Total scalar sum  $E_T$ ), JE (Scalar sum of jet  $E_T$ ), MU (muons), and tau (tau leptons). A typical example of a trigger item is 2e15i (two isolated electrons with a  $p_T$  greater than 15 GeV) or tau20i\_XE30 (an isolated tau decaying hadronically with visible  $p_T$  above 20 GeV and  $\cancel{E}_T$  above 30 GeV). A prefix to the item name is used to specify the trigger level at which the item is deployed. If the presence of several trigger object types are required, the AND of these multiple object types is shown using an “-”, for example, tau25i\_XE30 requires an isolated tau lepton with a  $p_T$  above 25 GeV AND a Missing ET above 30 GeV (when objects are combined with no qualifier a simpler notation can be used, for example,  $e + \mu$  for a trigger with an electron and a muon).

### 6.1 L1 items foreseen for a luminosity of $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$

All rates given in this section are measured using simulated events with a luminosity of  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ . Table 2 shows a potential set of EM L1 signatures, their prescale factors and estimated rates that could be deployed during start-up for an assumed luminosity of  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ . It shows the eight L1 EM thresholds and the multi-EM object thresholds that are direct combinations of the single EM thresholds. At low luminosities, a single non-isolated trigger of 7 GeV can be used without the application of prescale factors at the first trigger level with a rate of about 5 kHz. All multi-object EM triggers at L1 have sufficiently low trigger rates and can be deployed without the application of any prescale factors. The total L1 output rate out for the EM objects defined in Table 2 is about 10 kHz after correctly accounting for events that have passed multiple L1 EM object signatures. The L1 EM object triggers are then used to seed both electron and photon signatures at the HLT.

Trigger Item	EM3	EM7	EM13	EM13I	EM18	EM18I	EM23I	EM100
Prescale	60	1	1	1	1	1	1	1
Rate (Hz)	674	4900	950	480	369	143	53	1.5
Trigger Item	2EM3	2EM7	2EM13	2EM13I	2EM18	2EM18I	2EM23I	3EM7
Prescale	1	1	1	1	1	1	1	1
Rate (Hz)	6500	534	108	8	47	2	0.6	53

Table 2: L1 trigger items and estimated rates at  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  for electromagnetic objects.

Several higher threshold signatures are deployed with and without isolation, even though lower thresholds can be deployed without the application of prescale factors at low luminosities. This allows the validation of the higher thresholds and trigger items that will be needed at high luminosities when the lower threshold triggers can only be deployed with prescale factors due to rate considerations.

The inclusive L1 jet trigger items and corresponding prescale factors, as shown in Table 3, are chosen to given an approximately flat trigger rate across the steeply falling jet  $E_T$  spectrum. At a luminosity of  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ , a single jet trigger with a threshold  $E_T$  of 120 GeV can be deployed without prescale factors and has a L1 output rate of about 8 Hz. Figure 2 shows that triggered jet  $E_T$  spectrum is fairly flat up to the threshold value of 120 GeV and then falls with the jet cross section. This strategy provides sufficient statistics across the  $E_T$  spectrum for the measurement of the differential cross sections and for measuring the efficiencies and performance of different algorithms.

At a luminosity of  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ , the HLT algorithms for the inclusive jet triggers are run in pass-through mode with the rate controlled only by using L1 prescale factors. This allows validation of the

Trigger Item	J10	J18	J23	J35	J42	J70	J120	3J10	3J18	4J10	4J18	4J23
Prescale	42000	6000	2000	500	100	15	1	150	1	30	1	1
Rate (Hz)	4	1	1	1	4	4	9	40	140	40	20	7

Table 3: L1 trigger items and estimated rates at  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  for jet objects.

Figure 2: Jet  $E_T$  spectrum at  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  before (dashed) and after (solid) pre-scaling at L1.

HLT algorithms for jet triggers that can then be deployed at higher luminosities.

Unlike single jet triggers, where the output rates are controlled by applying prescale factors at L1, jet triggers with higher multiplicities (multi-jets) have a larger allocated L1 output bandwidth to allow the use of additional selection algorithms only applicable at the HLT (e.g. b-tagging). Their total output rate to disk storage is subsequently controlled at the HLT with either a combination of jet algorithms and additional prescale factors (leading to normal jet signatures) or additional highly rejective selections, (e.g. b-tagging algorithms leading to b-jet signatures).

The prescale factors and rates for forward jet triggers are shown in Table 4. The HLT algorithms at low luminosity are executed in pass-through mode with rates controlled using L1 thresholds and prescale factors.

Trigger Item	FJ18	FJ35	FJ70	FJ120	2FJ18	2FJ35
Prescale	7000	700	20	1	100	1
Rate (Hz)	1	1	1	1	1	2

Table 4: L1 trigger items and estimated rates at  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  for forward jet objects.

Table 5 shows the rates for the suite of single muon and dimuon signatures; these triggers can all be deployed at  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  without L1 prescale factors with further selection at HLT to control the output rates. Three of the six available muon thresholds must be established below  $p_T$  of 10 GeV and are based on a coincidence of only two of the inner three stations. The lowest possible muon threshold of 4 GeV is set by opening the coincidence window in the two stations to the maximum allowed size. The remaining three high  $p_T$  threshold L1 muon triggers ( $p_T > 10 \text{ GeV}$ ) require a coincidence in all three muon trigger stations. The largest contribution to the rates shown in Figure 3 come from b, c quark decays and in-flight decays of pions and kaons. The L1 muon trigger is highly efficient (99%) for  $p_T$  above the threshold values within the fiducial acceptance of the detector.

Table 5: L1 trigger items and estimated rates at  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  for muon objects.

Some of the signatures and estimated rates for single and double tau triggers at  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  are shown in Table 6. The triggers at low luminosity are chosen to collect large statistics of  $W$  and  $Z$  boson decays to tau leptons. For  $W$  boson decays, additional cuts on  $\cancel{E}_T$  help reduce the rates. However, reliance on  $\cancel{E}_T$  is limited during startup as it is very sensitive to several detector and acceptance effects, and will take time to validate. Alternative approaches that use  $\cancel{E}_T$  only in the Event Filter seeded with a single tau signature at L1 are being studied. In addition to the  $2\tau$  triggers at L1,  $\tau + e$  and  $\tau + \mu$  triggers have been implemented at L1 to trigger on  $Z \rightarrow \tau\tau$  decays with one of the taus decaying leptonically.

The eight  $\cancel{E}_T$  thresholds likely to be deployed at the L1 stage are shown in Table 7. The strategy here is similar in nature to that of the jet triggers, with L1 prescale factors tuned to provide a flat rate across the  $\cancel{E}_T$  spectrum. The reliance on inclusive  $\cancel{E}_T$  trigger will be small especially during the early running period as it is sensitive to various detector effects that will require time to understand. Most of the  $\cancel{E}_T$  thresholds are expected to be used in combination with other signatures.

In addition to the  $\cancel{E}_T$  trigger thresholds, there are four thresholds available for the scalar sum  $E_T$  (TE) and the scalar sum  $E_T$  of observed L1 jets (JE). As for the  $\cancel{E}_T$  triggers, reliance on such triggers will be

limited in the early running period, but could prove to be valuable to ensure that very high  $E_T$  events are recorded. Table 8 shows the selections, the pre-scale factors necessary to achieve the desired rate reduction, and estimated L1 output rates for the TE and JE triggers that could be deployed at startup.

In addition to L1 triggers that rely on thresholds and multiplicities of a single object type (EM, Jet, muon etc.), several triggers are formed by combining multiple L1 object types (e.g: EM + muon, Jet + missing  $E_T$  etc.). Table 9 shows some of the typical combined signatures and their estimated rates. The rates for these triggers are generally small because they combine objects of different types at L1 and can thus be executed without prescale factors. Combining object types at L1 provides a mechanism to control the rates while maintaining low enough thresholds to meet the physics goals of the trigger. Even though single object triggers may suffice for low luminosity running, it is necessary to deploy the multi-object triggers at low luminosity to validate them and ensure their reliability as the LHC moves to high luminosity operations.

## 6.2 HLT signatures foreseen for a luminosity of $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$

During low luminosity running, most of the triggers at Level 2 and Event Filter are either executed in pass-through mode or with loose selections. Table 10 shows some of the lowest threshold trigger items that can be executed without applying prescale factors and their estimated rates for  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ . Higher threshold triggers, which will become important during high luminosity running are also deployed so that they can be validated with early data.

Trigger Item	e12	2e5	g20	tau60	tau25i_XE30	MU10	2MU4	e10_MU6	J120	4J23	2b23
Rate (Hz)	19	7	7	10	3.5	18	2.3	0.5	9	7	3

Table 10: Examples of low threshold trigger terms executed without prescale factors and estimated rates that can be deployed at  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ .

Figure 4 shows a graphical summary of the EF output rates for each trigger group and the cumulative rates, which provide a running total of the rates. The sum of the rates for all the trigger groups is more than the cumulative rates due to overlaps between the groups. The grouping is done as follows: single and multi-object triggers of the same object type are grouped together, hence “Electrons” refers to the

total rates estimated for all single and multi-electron triggers including triggers executed with prescale factors and in pass-through mode. “*B*-Physics and Topological” refers primarily to *B*-physics triggers and other triggers where invariant mass cuts have been applied during the selection process, such as in selection of  $J/\psi$ ,  $\Upsilon$ , and  $Z$  decays. The “Other Topological” triggers require two or more object types, such as  $e + jets$ ,  $\tau + \cancel{E}_T$  etc.

The trigger grouping and associated rates are shown in finer detail in Table 11 for each of the trigger levels. The rates for each trigger grouping accounts for overlaps between signatures in that group, but not across groups. The “Total” row gives the cumulative rates for this trigger menu, accounting for overlaps between the trigger groups as well. The total output rates for each trigger level, for the proposed trigger menu at a luminosity of  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ , is estimated to be within the available bandwidth, although there are large uncertainties inherent in the simulation. The estimated rate out of L1/L2 is 12 kHz/620 Hz well below their respective targets of 40 kHz and 1 kHz available during the LHC startup phase. The selections have been tuned to yield the targeted EF output rate of 200 Hz, but it is evident that this preliminary trigger list will need to be optimized based on early experience with real data.

## 7 Data streams

ATLAS has adopted an inclusive streaming model whereby raw data events can be streamed to one or more files based on the trigger decision. A proposed initial streaming configuration consists of four raw data streams called egamma, jetTauEtmiss, muons, and minbias. Each stream consists of events that pass one or more trigger signatures. The stream names indicate the type of trigger signatures they will contain,

Figure 4: HLT unique (black) and cumulative (gray) estimated rates at  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  for different trigger groups as described in the text.

Object	L1 (Hz)	L2 (Hz)	EF (Hz)

<b>Total</b>	<b>12000</b>	<b>620</b>	<b>197</b>

Table 11: L1, L2, and EF estimated rates for several groups of trigger items at a luminosity of  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ . The total rate accounts for overlaps between the groups. The L1 objects labeled “common” have the same L1 triggers as other object types and hence do not require any additional L1 bandwidth.

for example, events passing electron or photon triggers will be written to the egamma stream. Events passing certain topological triggers could be written to more than one stream. Two examples,  $e + \cancel{E}_T$  and  $e + \mu$ , can be used to demonstrate the two possible modes for streaming events that pass a topological trigger. For the  $e + \cancel{E}_T$  signature, events are only written to the egamma stream unless they also pass an inclusive  $\cancel{E}_T$  signature after pre-scaling, in which case they are also written to the jetTauEtmisss stream. For the  $e + \mu$  signature, events are written to both egamma and muon stream regardless of whether they pass the inclusive single electron or single muon trigger.

Streams are chosen to have approximately the same proportion of events and to keep the total overlap (event duplication across streams) to less than 10%. The final optimization of these streams can only be achieved with an understanding of the overlaps observed with real data. Furthermore, the number and type of raw data streams may be optimized for use at different luminosity settings.

Table 12 shows the total and the unique rates of the proposed early stream configuration. The unique rate reflects the number of events written solely to the specified stream, hence the difference between the total rate and the unique rate is the rate of replicated events in each stream.

As shown in the Table, in addition to the raw data streams, an express stream and a calibration stream have also been defined. An express stream containing a subset of triggers can be used to provide rapid feedback on the quality of the data. It is therefore reconstructed first and any relevant knowledge of the quality of data is incorporated into the reconstruction of the remaining streams. Events in express stream are primarily intended for monitoring and not for physics analysis. Hence, by definition, events

appearing in express stream would also appear in one of the primary raw data streams.

Additional triggers required for detector calibration can be run in a parasitic mode during data taking operations. These include triggers that provide data needed for detector alignment and energy scale determination. Such data can be written to their own raw data stream with the advantage of being processed early and the extracted calibration constants used as part of the bulk reconstruction of the primary raw data streams.

## 8 Evolution to higher luminosities

Experience with early running will allow further optimization of the trigger algorithms and menus and improve the ability to estimate rates in the high luminosity regime. As the LHC ramps up to its design luminosity, complex trigger signatures with multiple observables, higher  $p_T$  thresholds and tighter selections will be deployed to maintain the output Event Filter rates at about 200 Hz.

As noted in Section 2, there are a limited number of L1 thresholds available for each object type. The intent is to keep the L1 thresholds as stable as possible. With increasing luminosity, higher L1 thresholds need to be introduced at the expense of some of the lower thresholds. However, many of the thresholds will be retained providing common points of comparison across luminosity regimes. At high luminosity, the luxury of running in pass-through mode or with loose selections will not be possible, and tighter HLT selections will be implemented to achieve the required rejection. For example, jet triggers that used only the L1 prescale to control the rates at low luminosity, will enable the HLT at high luminosity to obtain the additional rejection needed to control the EF output rates. In addition, topological triggers that include jets at lower thresholds than the inclusive jet triggers but in combination with other objects or requirements to achieve reduction in output rate, are deployed to increase the physics acceptance.

At high luminosities, the trigger software and selection must be robust against high detector occupancies, pile-up effects and cavern backgrounds. Pile-up effects becomes significant with increasing luminosities with an average of more than 20 interactions per crossing expected at a luminosity of  $10^{34} \text{ cm}^{-2} \text{ s}^{-1}$ . The trigger should ensure coverage of the full physics programme, including searches for new physics and precision measurements of Standard Model parameters. The signatures include lepton, photon, and jet triggers, but with higher thresholds and tighter selection criteria employed to control the rates. Additional requirements that operate in pass-through mode at low luminosities, such as isolation, large  $\cancel{E}_T$  and other complex criteria such as flavour tagging, must also be deployed to achieve the necessary rate reduction.

Table 13 shows a representative sample of L1 and HLT trigger items that can be expected to be deployed without prescale factors at a luminosity of  $2 \times 10^{33} \text{ cm}^{-2} \text{ s}^{-1}$ . A comparison of this menu to the one at a luminosity of  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  illustrates the evolution of the rates and thresholds as a function of luminosity. The evolution is not linear as some of the triggers also have employed tighter selection conditions at higher luminosity. While Table 13 gives a flavour of some of the primary triggers and

Stream	Total Rate (Hz)	Unique Rate (Hz)
egamma	55	48
muon	35	29
jetTauEtmiss	104	89

expected rates, the full physics trigger menu will consist of many additional signatures for precision measurements and the discovery program, as well as triggers required for calibration and background studies.

Preliminary rate studies suggest that about 30% of the 200 Hz bandwidth will be available for electron and photon triggers, 25% for muon triggers, 15% for jet triggers, and 15% for triggers involving taus and  $\cancel{E}_T$ . About 5% of the bandwidth is allocated to *B*-physics related triggers which will involve low  $p_T$  di-muon signatures with additional mass cuts to select  $J/\psi$  and other rate *B*-meson decays, with the balance of the bandwidth used for calibration and background triggers. This proposed distribution, will of course evolve with experience, and will be tuned to ensure full coverage for discovery and precision physics at all luminosities.

## 9 Summary

The LHC is expected to begin its operation at a low luminosity of about  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  and ramp up to the design luminosity of  $10^{34} \text{ cm}^{-2} \text{ s}^{-1}$  over the first few years of operation. The three levels of the ATLAS trigger have been designed to handle the high rates and occupancies at high luminosity. The trigger items and their performance have been studied in detail in both the low and high luminosity regimes and a comprehensive trigger menu has been developed for the LHC startup phase. Details of the triggers comprising this menu have been discussed in this note and primarily consist of low  $p_T$  thresholds and loose selections that would allow for rapid commissioning and preparation for the high luminosity regime. The rates estimated for a trigger menu that will likely be deployed during the initial phase of the LHC run are within the limits of the TDAQ bandwidths, but are subject to fairly large uncertainties due to the use of simulations that extrapolate from the 2 TeV center-of-mass energy of the Tevatron to the 14 TeV expected for the LHC. The trigger menu in the high luminosity regime will use high  $p_T$  thresholds and complex triggers involving multiple objects to provide efficient selection of physics processes and high background rejection. A flavour of such signatures has been discussed in this note. The initial running will allow further optimization of the trigger menus, which will evolve as the luminosity increases over three orders of magnitude to the design luminosity.

# HLT Track Reconstruction Performance

## Abstract

This note reviews the tracking algorithms used at the L2 and Event Filter stages of the High Level Trigger of ATLAS. The tracking performance (efficiency, resolution) is studied for different topologies (single tracks, high and low  $p_T$  jets) using simulated data. Detailed information on the execution time of the algorithms is also given.

## 1 Introduction

The aim of this note is to describe the tracking algorithms used at the L2 and Event Filter stages of the High Level Trigger of ATLAS and to study their performance.

The definitions of the relevant quantities (efficiency, fake rate, and resolution) given in this note can differ with the ones used in the different selection algorithms of specific trigger objects ( $e/\gamma$ , muon, taus,  $b$ -jet and  $B$ -physics): here the purpose is to define a common language to study and compare the different tracking algorithms.

A detailed description of the complete ATLAS detector and its performance can be found in [1]. In addition to a description of the trigger system, it also contains relevant information on the ATLAS tracking detectors, the Inner Detector (ID) and its subsystems (Pixel, SCT and TRT).

## 2 Track reconstruction at L2

### 2.1 Data preparation

Detector data should be converted before it can be used by tracking algorithms. The conversion process includes the bytestream decoding, the cluster formation in the Pixel and SCT detectors [1], and their conversion in spatial coordinates (space points).

### 2.2 IDScan

IDScan is a set of algorithms for fast pattern recognition and track reconstruction at the second level trigger, using space points provided by the tools described in Section 2.1. These algorithms first determine the  $z$ -position of the interaction point along the beam axis and then perform combinatorial tracking only inside groups of space points that point back to that determined position.

The first algorithm, aiming to determine the  $z$ -position of the primary vertex, divides the region-of-interest (RoI) into many equally-sized  $\phi$  slices, whose width is tuned according to the individual RoI type, based on the lowest track momenta desired and the level of background hits in the detector. While tracks of high momenta produce most of their hits in a small number of neighbouring slices, hits from lower-momentum, curved tracks populate several different slices. Every space point is paired (or optionally every space point from the innermost three silicon layers) in each slice to the other space points in that slice and in a few neighboring slices, and each pair is used to calculate a  $z$ -position by linear extrapolation to the beam line. (This exploits the fact that helical trajectories of charged particles in a solenoidal magnetic field are straight lines in the  $\rho$ - $z$  projection.) A one-dimensional histogram accumulates all the calculated  $z$  values, and the peak(s) in this histogram provide the rest of the IDScan algorithms with the  $z$ -coordinate of the  $pp$  interaction point. The correct position is identified in more than 98% of the RoIs, with a resolution between 150 and 200  $\mu\text{m}$  (depending on the type of RoI) for the central RoIs.

Using the  $z$ -position previously reconstructed, the second algorithm computes the pseudorapidity for all the space points in the RoI and fills a two-dimensional histogram in  $(\eta, \phi)$ . Since all hits from a given (sufficiently) high- $P_T$  track tend to be contained in a small solid angle (with its apex at the origin for the track), the space points from each track that originates from the computed  $z$ -position on the beam axis form a cluster of neighbouring bins in this histogram. When the bin size is small enough, the occupancy for each bin is low and each cluster, called a group, often contains the space points of a single track. Fake candidates are reduced by keeping track of which detector layers contribute space points to each bin and requiring that at least four out of an expected seven layers to have contributed to a given bin or its immediate neighbours, before that bin is included in a group.

After the groups have been identified random space points and/or space points from multiple tracks in each group are separated. This is achieved by considering all possible triplets of space points within a group and making use of the fact that any three hits from a track can be used to extract the same track parameters  $\phi_0$  and  $1/P_T$  in the transverse plane. The algorithm fills a two-dimensional histogram with extracted  $(\phi_0, 1/P_T)$  values and considering combinations containing space points from at least four different silicon layers.

Finally the cleaned groups are subjected to the clone removal algorithm, which identifies groups sharing at least a certain number of space points (currently 2 or 3 depending on the RoI type) and removes all but the one with the highest number of space points. Furthermore, a group is removed if it shares more than 45% of its space points with others. This step significantly reduces the number of fake groups that contain a few random space points in addition to a small number of space points from an actual track.

After all these steps, the remaining groups are passed on to a track fitter. The default fitter used by IDScan is described in Section 2.5.

### 2.3 SiTrack

The SiTrack L2 algorithm adopts a combinatorial pattern recognition approach to reconstruct tracks starting from space points formed in the ID silicon detectors.

In order to perform space point combinations, these are first of all grouped into sets from which the entries of each combination will then be extracted; the grouping is implemented in SiTrack, using the idea of “logical layers”. These correspond to a list of physical detector layers, i.e. barrel layers and end-cap disks, and are labeled with increasing numbers moving away from the beam line. The same physical layer can be included in more logical layers, to increase the robustness of the track finding process. To provide a tangible example, the first logical layer adopted for the reconstruction of high- $p_T$  isolated leptons includes the innermost two pixel barrel layers and the innermost pixel end-cap disk.

Once the space points have been associated to the logical layers they belong to, the track reconstruction algorithm proceeds through the following five steps:

- formation of track seeds;
- optional primary vertex reconstruction along the beam line;
- extension of track seeds;
- merging of extended seeds;
- clone removal.

The formation of track seeds corresponds to a combinatorial pairing of space points coming from the innermost two logical layers. For each seed, the extrapolation to the beam line is evaluated, using a straight line approximation; this process is depicted in Fig. 1. At this point a cut on the transverse

Figure 1: Pictorial scheme of the SiTrack combinatorial strategy for track seeds formation (left) and track seeds extension (right).

impact parameter is applied. This cut, meant to reduce the number of seeds to be further processed, is particularly important, as it fixes the lowest reconstructible track  $p_T$  value.

The subsequent step is the reconstruction of the position of the primary interaction vertex along the beam line, used to reject tracks not coming from the primary interaction. The vertex reconstruction is performed filling a histogram with the longitudinal impact parameter of the seeds and searching for histogram maxima; more vertex candidates can be retained and seeds not pointing to any of the reconstructed vertexes are discarded. This optional step is useful for high track multiplicity topologies like jets, but is typically skipped in the case of low multiplicity event topologies, e.g. for the reconstruction of single isolated leptons. Each retained seed is extended, as depicted in Fig. 1, extrapolating it to the outer logical layers and forming one or more space point triplets for each seed; extensions are selected applying a cut on the distance between the outer space point and the extrapolated seed. Each extended seed is then fitted by a straight line in the longitudinal plane and parametrized as a circle in the transverse plane.

All the extensions found for each seed must then be merged into a single full track, grouping the triplets having similar track parameters after the fit. The full track is thus formed by the union of the space points from all the merged extensions. All the triplets not involved in the merging process are discarded, while track parameters are re-evaluated for the full track, fitting it with a straight line in the longitudinal plane and a circle in the transverse one.

Two full tracks obtained from different track seeds may still share most of their space point; these tracks are defined as clones. To eliminate these ambiguous cases, only the clone track containing the largest number of space points is retained; in case more clone tracks contain the same number of space points, the one with the lowest  $\chi^2$  value prevails. The retained full tracks are finally refit using one of the available common fit tools.

## 2.4 TRT tracking

Information from the TRT part of Inner Detector can be used as the basis of a L2 tracking algorithm. The core of the algorithm is a set of utilities from the offline reconstruction package xKalman [2] for the reconstruction of tracks in the TRT detector. It is based on the Hough-transform (histogramming) method. At the initialization step of the algorithm, a set of trajectories in the  $\phi - R(Z)$  space is calculated for the barrel and endcap parts of the TRT. The value of the local magnetic field is taken into account

at each straw position and coordinate along it when calculating the trajectories. After initialization, a histogram (with a size of 500 bins in  $\phi$  and 70 bins in curvature) is filled for each event with the TRT hit positions. The track candidates can be identified from peaks in the histogram. Bins with at least eight hits are considered as track candidates. These track candidates should satisfy some quality parameters like the number of unique hits and the ratio of hits to number of straws crossed by the trajectory. For each track candidate, the parameters are tuned so that the track lies on the maximum number of drift circle positions. It is at this stage that drift information is taken into account to further improve the resolution of the track parameters.

## 2.5 Track fitting tools

The track fitting procedure used by the L2 ID algorithms in Pixel and SCT detectors is based on a Kalman filtering technique.

At first, space points are dissolved into clusters and a filtering node is created for each cluster. The filtering nodes encapsulate implementations of the Kalman filter algorithm for various measurement models. The fitter object uses the filtering nodes to update a track state described as a 5-dim vector of track parameters (local  $x$ , local  $y$ , angles  $\phi$  and  $\theta$  given in the global coordinate system, and track inverse momentum  $Q$ ) and corresponding covariance matrix.

The track state update consists of three steps. First, the track state is extrapolated using a simple parabolic approximation of a trajectory in uniform magnetic field. The material-related corrections (multiple scattering, energy losses) are added to the covariance matrix during this step. The extrapolated track state is used to *validate* the next hit: if the  $\chi^2$  distance between the hit and state is less than a predefined cut for this filtering node the track state is updated. These “extrapolate-validate-update” steps are repeated for every node. After that, a standard backward smoother is applied.

There exists another tool which performs track fit and simultaneous pattern recognition in the TRT. The implementation of this tool is based on a distributed approach. More details on the L2 TRT track extension tool can be found in Ref. [3].

## 2.6 Vertex Fitting tools

An essential part of the L2 event selection (e.g.  $B$ -physics event selection) is vertex finding and fitting using tracks reconstructed by the L2 tracking algorithms as input. Due to the L2 timing constraints a vertex fitting algorithm for the L2 application has to be fast. An additional requirement stems from the L2 track reconstruction which provides input track parameter errors in form of a covariance matrix. In contrast, vertex fitting algorithms proposed in literature assume uncertainties of the input track parameters to be described by weight (inverse covariance) matrices. However, if only track covariance matrices are available, these algorithms require them to be inverted beforehand thus resulting in substantial computing time overhead.

To alleviate this drawback a fast vertex fitting algorithm capable of using track covariance matrices directly (i.e. without time-consuming inversion) has been developed. The specific feature of the algorithm is that track momenta at perigee points rather than “at-vertex” momenta are selected as the fit parameters. Such a choice of fit parameters makes it possible to apply a decorrelating measurement transformation so that the transformed measurement can be partitioned into two uncorrelated vectors – measured momenta and its linear combination with measured track coordinates at the perigee. This linear combination comprises a new 2-dim measurement model while the measured momenta and the corresponding blocks of the input track covariance matrices are used to initialise a vertex fit parameter vector and covariance matrix of the Kalman filter. This approach provides a mathematically correct and numerically stable initialisation of the vertex fit. A reduced size (2-dim instead of the usual 5-dim) of the measurement model makes the proposed Kalman filter very fast and therefore suitable for an online

application in the ATLAS Level 2 Trigger. A detailed description of the L2 vertex fitting algorithm can be found in Ref. [4].

### 3 Track reconstruction at EF

ID reconstruction at the EF is performed using ATLAS “New Tracking” software [5]. A common approach between offline and online is possible thanks to the modular New Tracking design which allows the replacement of time-critical components and full-featured offline modules by trigger-specific implementations. New Tracking currently covers two sequences, the main inside-out track reconstruction (track finding starts from the Silicon and then is extended to the TRT) and outside-in tracking (from the TRT to the Silicon). The primary pattern search concepts for both sequences have been to a large extent adopted from the already existing ATLAS ID reconstruction program xKalman [2], but integrated and incorporating additional components in the common New Tracking approach. In the following note, only the inside-out reconstruction of tracks is described since it is the only one used in the EF ID online reconstruction. In the future, an outside-in approach is intended to be used in the trigger in cases where photon conversions are present.

The EF ID reconstruction runs for many different signatures, such as electrons, muons, taus, and  $b$ -jets. Each of these triggers contains a very similar algorithm sequence as the ID inside-out tracking and is followed, depending on a given object, by dedicated event reconstruction algorithms including vertex finding,  $b$ -tagging or electron processing. In the EF realization of New Tracking dedicated algorithms steer the underlying tools with RoI-seeded input collections<sup>1</sup>. The tools used are directly taken from the offline reconstruction chain but operated in a RoI-seeded mode, where the trigger signature defines a width of the RoI.

The EF ID algorithm sequence is divided into three stages defined as pre-processing, inside-out track finding and post-processing. The pre-processing stage is responsible for building clusters and drift circles in the Silicon and TRT detectors, respectively, and the creation of space points as three-dimensional representations of the Silicon detector measurements.

The inside-out track finding starts from the Pixel and SCT to find track seeds and creates track candidates based on the seeds primarily found. The seeded track finding results in a very high number of track candidates, that have to be resolved before an extension into the TRT detector can be done. Many of these tracks share hits, are incomplete, or describe fake tracks, hence ambiguity resolution is necessary. The track extension from the Silicon to the TRT is divided into two modules. First, tracks found in the Silicon detector are used as an input to find a compatible set of TRT measurements. Then each extended track is evaluated with respect to the original Silicon track. A track scoring mechanism is then used to compare the original track with the one after refitting, and the best track is chosen.

The last stage, post-processing, starts from a primary-vertex search, which is based on the Billoir fitting method [6]. A track object is created which is a representation of the track reconstruction results aimed for analysis applications.

Currently several different fitting techniques are implemented in New Tracking and can be chosen at a configuration level:

- Kalman Fitter as a straightforward implementation of the Kalman filter technique [7] that has been adopted for the track fitting in high energy physics experiments. For the ATLAS Silicon detector, the Kalman Fitter has a dedicated extension for fitting of tracks from electrons, that lose stochastically a significant part of their energy due to bremsstrahlung effects. In that case, an assumption about purely Gaussian noise is far from being optimal. A special Dynamic Noise Adjustment tech-

---

<sup>1</sup>The FullScan operation is an exception which assumes track reconstruction in the entire detector.

nique has been developed [8]. It still uses a Gaussian error assumption but modifies the applied variance based on the amount of traversed material.

- Deterministic Annealing Filter is a deterministic annealing technique [9] which combines the standard Kalman filter formalism with a probabilistic description of the measurement assignment to a track.
- Gaussian Sum Filter is a special multi-Gaussian extension of the standard Kalman filter [10], dedicated to reconstruction of electron tracks. In the GSF approach, the highly non-gaussian probability density function of electron energy loss is modeled by a mixture of several Gaussians.
- Alignment Kalman Filter is an extended version of the Kalman filter [11] that integrates an update of the detector surface orientation and position into an intrinsic measurement update of a Kalman Fitter step.
- Global Chi2 Fitter [12] is a track fit through a minimization of  $\chi^2$  value. Given purely Gaussian process noise, the minimization of the  $\chi^2$  value that is built from hit residuals at every measurement surface gives the best set of estimators of the track trajectory. Material effects enter the  $\chi^2$  function as additional fitting parameters.

The Kalman Fitter approach without the Deterministic Annealing Filter extension is a default fitter at the EF ID. Other fitters described above can be chosen during the configuration step.

## 4 Performance

### 4.1 Timing measurement

This section presents a summary of CPU timing measurements for various steps of data preparation and track reconstruction in L2 ID and EF ID algorithms.

#### 4.1.1 L2 ID

The L2 ID timing has been measured on a quad-core 3GHz Woodcrest CPU machine. Timers provided by the standard trigger monitoring framework have been used for these measurements.

The data preparation timing measurements obtained on  $t\bar{t}$  data for the Pixel and SCT are shown in Table 1 for  $e/\gamma$ , muon, and tau triggers. The average cluster collection and space point multiplicities per RoI are presented in Table 2.

The track reconstruction timing measurements are summarized in Table 3 (note that SiTrack fit timing is included in the pattern recognition time). The average track multiplicity is presented in Table 4.

Tables 5, 6, 7, and 8 present a comparison between RoI-based and FullScan running for  $B$ -physics triggers on  $b\bar{b} \rightarrow \mu X$  data. These show, respectively, the time of data formation, average space point multiplicity, time of L2 ID track reconstruction, and average track multiplicity for the two cases.

#### 4.1.2 EF ID

The EF ID timing measurements are shown in Table 9. They were done on a 3 GHz Intel Xeon 5160 CPU with 8GB of memory. The EF ID software was run in the emulator of the event filter processing and execution times for the algorithms were obtained as mean values from the timing histograms provided by the HLT framework. The results are representative in terms of algorithm execution times but do not account for data collection times, which are platform dependent. Two event samples were used in the tests, one corresponding to a single electrons with 100GeV, the other was a simulation of  $t\bar{t}$  production.

Data preparation step	Mean time [ms]		
	$\mu$	$e/\gamma$	$\tau$
RegionSelector	0.23	0.26	0.32
RobDataProvSvc	0.02	0.02	0.02
Cluster IDCs retrieval	0.03	0.03	0.02
BS-to-clusters, Pixel	0.63	0.73	1.02
BS-to-clusters, SCT	0.60	0.69	0.95
Pixel space point formation	0.24	0.27	0.35
SCT space point formation	0.31	0.37	0.40
Total time	2.11	2.45	3.23

Table 1: The timing measurements of the data formation per RoI.

Data preparation step	Multiplicity		
	$\mu$	$e/\gamma$	$\tau$
Pixel cluster coll.	46.2	45.6	104.4
SCT cluster coll.	82.8	83.5	245.8
Pixel space points	66.4	65.9	131.6
SCT space points	36.5	38.8	87.1

Table 2: Average cluster/space point multiplicities per RoI.

The most CPU demanding operation is the track finding in the silicon detectors with typical execution times of 30 ms per RoI ( 300 ms in FullScan mode). Next is the processing of TRT extensions and resolution of ambiguities each with a CPU cost of about 20 ms per RoI (approximately 170 ms in FullScan). Another important contribution to the processing time is the data preparation step which takes about 20 ms per RoI for all detectors (and about 300 ms in FullScan mode). The total time to process  $t\bar{t}$  events in full-scan mode is about 1s.

## 4.2 Efficiency and resolution definition

In order to evaluate the performance of any tracking algorithm, three kinds of information have to be provided: track reconstruction efficiency, the percentage of fake reconstructed track candidates, and the

Track reconstruction step	Mean time [ms]		
	$\mu$	$e/\gamma$	$\tau$
IDScan : Pattern recognition	0.60	0.70	1.45
IDScan : Track Fit	0.28	0.29	0.49
IDScan : TRT data preparation	1.14	1.32	–
IDScan : TRT tracking	2.96	2.87	–
SiTrack : Pattern recognition	0.62	0.66	–
SiTrack : TRT data preparation	1.15	1.39	–
SiTrack : TRT tracking	2.85	3.66	–

Table 3: The timing measurements of the L2 ID track reconstruction with IDScan and SiTrack.

L2 ID algorithm	Tracks/RoI		
	$\mu$	$e/\gamma$	$\tau$
IDScan	1.92	1.63	4.50
SiTrack	2.05	2.66	–

Table 4: The average track multiplicity per RoI for L2 ID track reconstruction with IDScan and SiTrack.

Data preparation step	Mean time [ms]	
	RoI $0.75 \times 0.75$	FullScan
RegionSelector	0.67	4.76
RobDataProvSvc	0.02	0.41
Cluster IDCs retrieval	0.03	0.06
BS-to-clusters, Pixel	2.13	11.7
BS-to-clusters, SCT	1.89	13.1
Pixel space point formation	0.78	5.27
SCT space point formation	0.68	5.65
Total time	6.67	44.5

 Table 5: The timing measurements of the data formation for RoI-based and FullScan running of  $B$ –physics triggers.

resolution of the track parameters.

All the results shown in this section refer to reconstructed Monte Carlo (MC) simulated data samples, where the track parameters for both the reconstructed and the simulated tracks are available. In addition, each space point used to build a given track can be traced back to the MC particle that generated the corresponding charge deposit. This information is used by the ID trigger analysis packages to evaluate two additional quantities for each reconstructed track, which prove fundamental for the efficiency definition:

- the number of space points which trace back to the same MC track;
- the link between a reconstructed track and the MC track that generated most of its space points.

In this context we define:

- reconstructible MC particle: a particle passing a set of geometrical selection cuts (being contained in one of the processed RoIs, pointing to the primary vertex) and a  $p_T$  cut;

Data preparation step	Multiplicity	
	RoI $0.75 \times 0.75$	FullScan
Pixel cluster coll.	266.2	1744
SCT cluster coll.	824.7	8176
Pixel space points	246.2	1591.5
SCT space points	119.6	910.3

 Table 6: The average cluster/space point multiplicities for RoI-based and FullScan running of  $B$ –physics triggers.

Track reconstruction step	Mean time [ms]	
	RoI $0.75 \times 0.75$	FullScan
IDScan : Pattern recognition	3.00	34.6
IDScan : Track Fit	0.55	2.19
IDScan : TRT data preparation	2.05	9.50
IDScan : TRT tracking	5.43	19.5

Table 7: The timing measurements of the L2 ID track reconstruction for RoI-based and FullScan running of  $B$ -physics triggers.

L2 ID algorithm	Tracks/RoI	
	RoI $0.75 \times 0.75$	FullScan
IDScan	4.26	16.9

Table 8: The average track multiplicity for RoI-based and FullScan running of the  $B$ -physics triggers.

- good track: a reconstructed track linked to a reconstructible particle by the majority of its space points; the geometrical and  $p_T$  cuts used for the MC particles are applied to the reconstructed tracks too;
- best track: for each reconstructible particle, more than one good track can be available; the best track is defined as the one sharing the largest percentage of space points with the linked particle;
- fake track: a reconstructed track (passing geometrical and  $p_T$  cuts) which is not a good track;

The most natural choice for the definitions of efficiency, fake fraction and resolution is then:

- efficiency: ratio between the best tracks and reconstructible particles;
- fake fraction: ratio between fake tracks and all the reconstructed tracks passing the applied cuts;
- resolution: difference between the track parameter of a good track and that of the linked reconstructible MC particle;

These definitions are used to produce the set of plots used in the following subsections to summarize the performance of a given tracking algorithm.

The track reconstruction efficiency is shown as a function of the absolute value of  $\eta$  and  $p_T$  of the reconstructible MC particle while the fake fraction is shown as a function of the absolute value of  $\eta$  and  $p_T$  of the reconstructed track. The track parameter resolutions are shown as a function of the absolute value of  $\eta$  and  $p_T$  of the reconstructible MC particle: the resolutions on  $\phi$ ,  $1/p_T$ , transverse impact parameter ( $d_0$ ) and longitudinal impact parameter ( $z_0$ ) are shown as a function of the absolute value of  $\eta$  while resolutions on  $d_0$  and  $1/p_T$  are shown as a function of  $p_T$ . The track parameter resolutions are evaluated with a gaussian fit to the resolution distribution for each parameter.

### 4.3 Results with isolated electrons

The tracking performance for electrons was evaluated with a data sample of single electrons uniformly distributed over a transverse momentum range of 7 to 80 GeV. Figure 2 shows the reconstruction efficiency and the fake fraction as a function of  $\eta$  and  $p_T$  for SiTrack, IDScan and EF tracking algorithms. Figure 3 summarizes, for the same algorithms, the track parameters resolutions. As shown in the figures,

Algorithm		Mean time [ms]				
		single e 100GeV	$t\bar{t}$			
		Electron	Electron	Muon	Tau	FullScan
Data preparation	Pix	2	2	2	3	61
	SCT	8	8	10	10	85
	TRT	8	6	8	9	140
Space point finder		1	1	1	2	30
Track finding in Si		6	29	6	31	310
Ambiguity solving		4	15	5	11	135
TRT track extensions		1	3	1	1	31
TRT extension processing		5	19	8	13	170
Vertex finding		0.1	1	1	-	23
Particle creation		0.4	2	1	1	24
Total		35	86	43	81	1009

Table 9: Timing of EF reconstruction steps per RoI in two samples of events, single  $e^-$  of 100 GeV and  $t\bar{t}$  events. Electron, muon, and tau times were measured in the corresponding triggers, FullScan mode comes from the execution of B-physics triggers. The RoI sizes were  $0.1 \times 0.1$  ( $\Delta\phi \times \Delta\eta$ ) for the electron and muon triggers,  $0.2 \times 0.2$  for tau triggers.

the efficiency is typically 95% or greater, except for low  $p_T$  or high  $\eta$  where it drops to about 90%. The fake fractions tend to be below 2% except at low  $p_T$  or high  $\eta$  where they can exceed 6%. Resolutions are observed to be quite good and are also somewhat degraded at low  $p_T$  or high  $\eta$ .

#### 4.4 Results with isolated muons

The tracking performance for muons was evaluated with a data sample of single muons with transverse momenta of 6, 9, 21 and 30 GeV. Figure 4 shows the reconstruction efficiency and the fake fraction as a function of  $\eta$  and  $p_T$  for SiTrack, IDScan and EF tracking algorithms. Figure 5 summarizes, for the same algorithms, the track parameter resolutions. As shown in the figures, the muon performance is even better than for electrons, with close to 100% efficiency throughout the kinematic range and an extremely low fake rate. Resolutions are slightly better than for electrons, and show similar  $p_T$  and angular dependence.

Figure 2: Electron track reconstruction efficiency (top) for single electrons as functions of  $p_T$  and  $\eta$  for SiTrack (full triangles), IDScan (empty triangles) and EF tracking (empty circles). Bottom plots show fake fraction as a function of the reconstructed  $p_T$  and  $\eta$ .

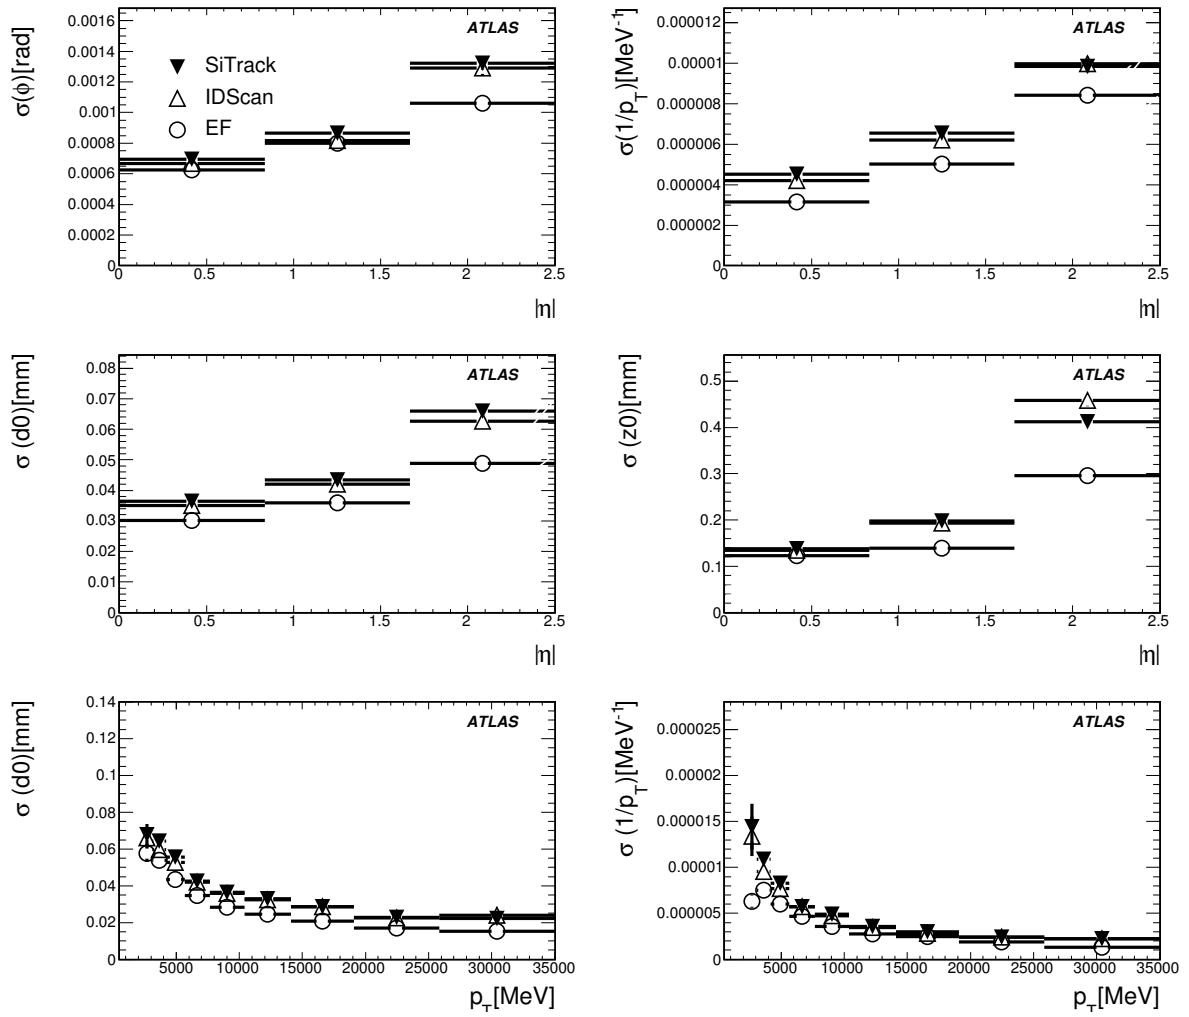

Figure 3: Track parameter resolutions for single electrons as a function of  $\eta$  and  $p_T$  for SiTrack (full triangles), IDScan (empty triangles) and EF tracking (empty circles).

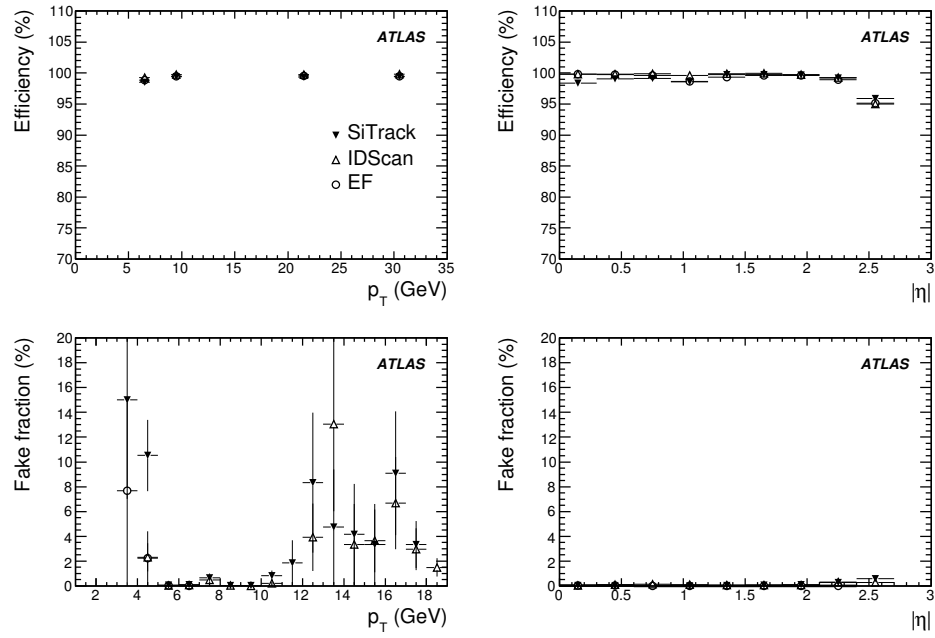

Figure 4: Muon track reconstruction efficiency (top) for single muons as functions of  $p_T$  and  $\eta$  for SiTrack (full triangles), IDScan (empty triangles) and EF tracking (empty circles). Bottom plots show fake fraction as a function of the reconstructed  $p_T$  and  $\eta$ .

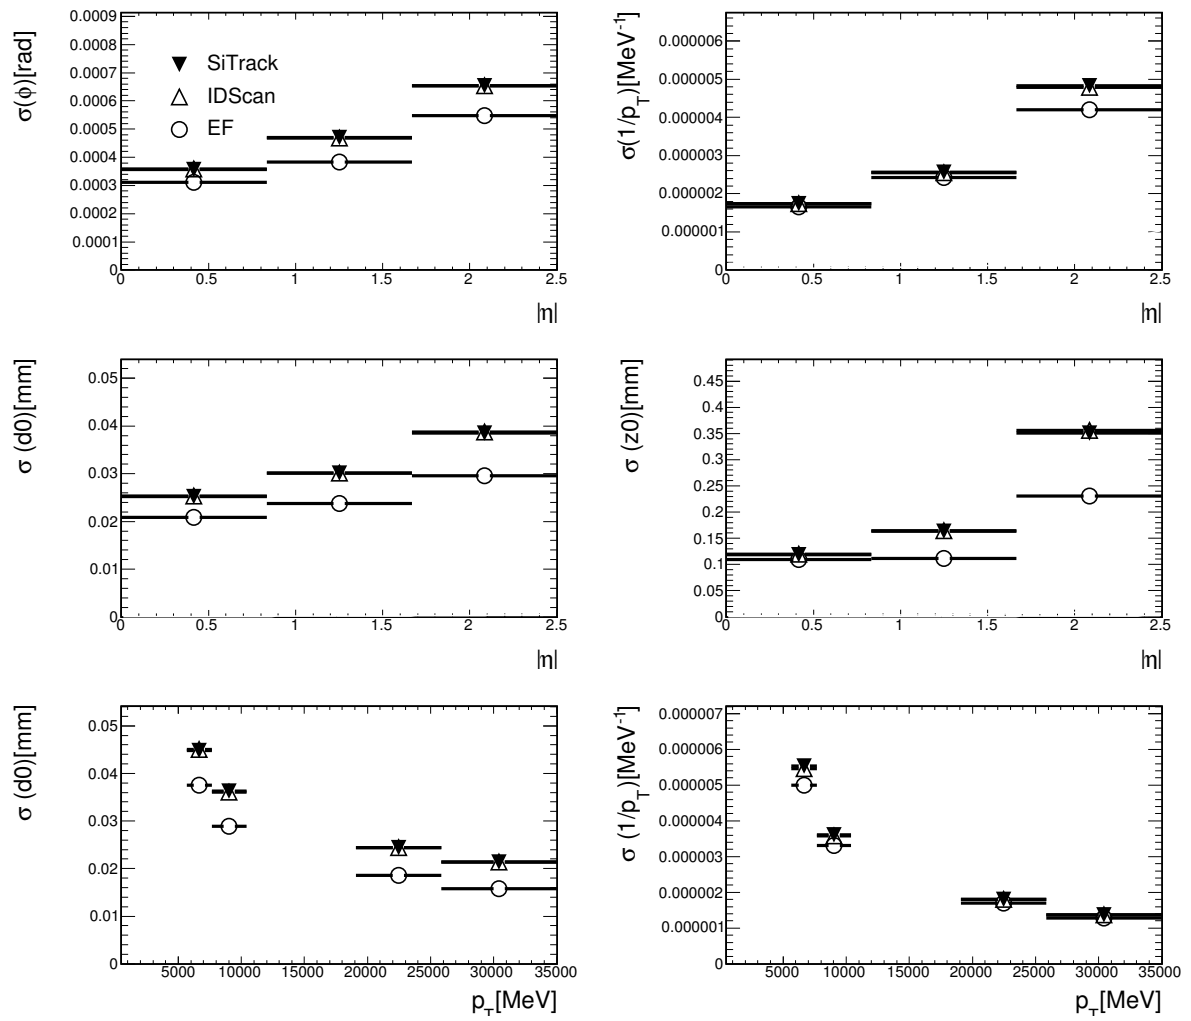

Figure 5: Track parameter resolutions for single muons as a function of  $\eta$  and  $p_T$  for SiTrack (full triangles), IDScan (empty triangles) and EF tracking (empty circles).

#### 4.5 Results with jets

The tracking performance has also been evaluated using a sample of  $b$ -jets produced in the decay of a Higgs boson (mass 120 GeV) produced in association with a leptonically-decaying  $W$  boson. This is the benchmark sample for  $b$ -tagging selection. Only tracks formed with at least four space points are considered.

Figure 6 shows the reconstruction efficiency and the fake fraction as a function of  $\eta$  and  $p_T$  for SiTrack, IDScan and EF tracking algorithms. Figure 7 summarizes, for the same algorithms, the track parameter resolutions. Not surprisingly, the efficiency for this sample is a bit lower (80 to 90 %) than the single electron and single muon samples, and has a bit higher fake rates. Resolutions are comparable or slightly worse.

Figure 6: Reconstruction efficiency (top) for tracks in  $b$ -jets yielded by Higgs decay as functions of  $p_T$  and  $\eta$  for SiTrack (full triangles), IDScan (empty triangles) and EF tracking (empty circles). The efficiency as a function of  $\eta$  is computed for tracks with  $p_T > 3$  GeV. Bottom plots show fake fraction as a function of the reconstructed  $p_T$  and  $\eta$ .

#### 4.6 Results with $\pi$ and $K$ in B-physics events

Using  $B_s$  decay to  $\phi\pi \rightarrow KK\pi$  the reconstruction efficiency for both kaons and pions have been evaluated.

Figure 8 shows the reconstruction efficiency as a function of  $\eta$  and  $p_T$  for SiTrack, IDScan and EF tracking algorithms. The efficiency is typically close to 95% dropping somewhat at low  $p_T$  or high  $\eta$ .

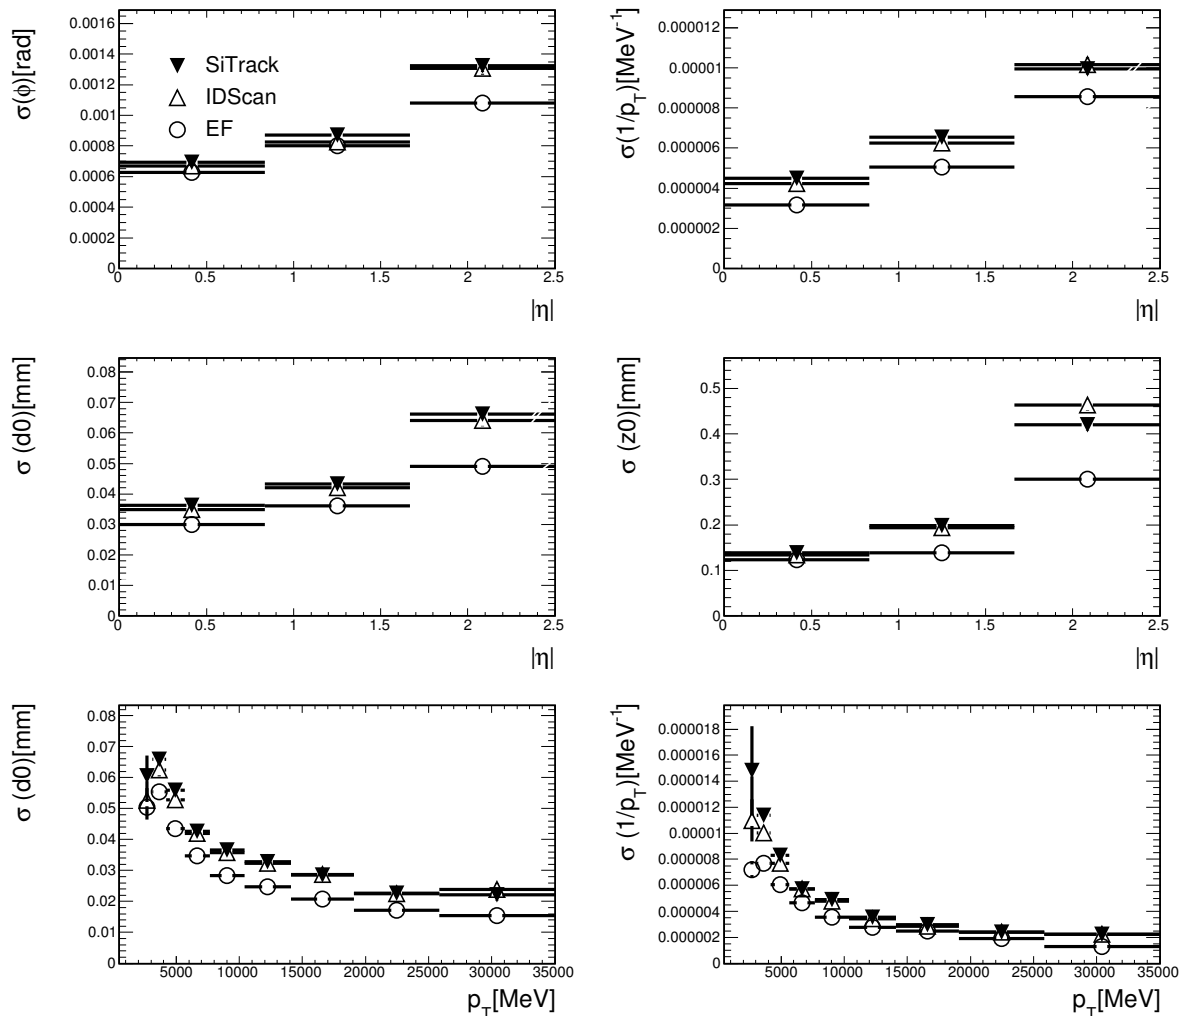

Figure 7: Track parameter resolutions for tracks in  $b$ -jets yielded by Higgs decay as a function of  $\eta$  and  $p_T$  for SiTrack (full triangles), IDScan (empty triangles) and EF tracking (empty circles).

Figure 8: Reconstruction efficiency for kaons (top plot) and pions (bottom plot) yielded from a decay of the  $B_s$  meson to  $\phi\pi \rightarrow KK\pi$  (sample 16701 with misaligned geometry), as functions of  $p_T$  and  $\eta$  for SiTrack (full triangles), IDScan (empty triangles) and EF tracking (empty circles).

#### 4.7 Comparison between the EF and the offline tracking performance

Since the track reconstruction in the EF is based on the same software as used for offline reconstruction, the EF tracking performance was studied under conditions equivalent to those used offline. This study was done using release 13.0.30.4 with perfectly aligned detector geometry.

To factorize out the bare EF performance, fake L1 RoIs were produced and passed through the L2 to seed the EF tracking, based on the MC truth information from particles with a  $p_T > 1$  GeV and a  $|\eta| < 3$ .

The same selection as normally used for offline studies was applied, where only particles within  $|\eta| < 2.5$ ,  $|d_0| < 2$  mm and  $|z_0 - z_v| \times \sin \theta < 10$  mm were taken into account. The accepted tracks had to pass the requirement that at least 80% of the their hits were caused by the matched MC particle as well as the quality requirement of having at least 7 hits in the Pixel or SCT detectors together.

Figure 9 (left) shows the reconstruction efficiency as a function of  $\eta$ , for single electrons and muons with a  $p_T = 5$  or 100 GeV. The efficiency is defined as the fraction of particles that produce an accepted track and the average efficiencies based on all electrons (muons) were found to be  $83.9 \pm 0.2\%$  ( $99.50 \pm 0.03$ ) for a  $p_T = 5$  GeV and  $92.9 \pm 0.1\%$  ( $99.52 \pm 0.03$ ) for a  $p_T = 100$  GeV. Figure 9 (right) together with Fig. 10 shows the muon resolution of  $1/p_T$ ,  $\phi$  and  $d_0$  for accepted tracks as functions of  $\eta$ , where the inverse  $p_T$  resolution is scaled by the  $p_T$  value for easier comparison. In accordance with the offline studies, the resolution is determined from the root-mean-squared of the tracks within a region containing 99.7% of the distributions, i.e. within 3 standard deviations from the mean of a Gaussian distribution. All results are shown together with the offline results presented in [1], which is represented in the plots by the superimposed lines. The results agrees well, however, small deviations are seen due to slightly different software setup with respect to Ref. [1].

Figure 9: Reconstruction efficiency (left) and scaled  $1/p_T$  resolution (right) as functions of  $|\eta|$ . The superimposed lines represent results from the offline track reconstruction.

### 5 Summary and conclusions

We have reviewed the track reconstruction algorithms used at the L2 and Event Filter stages of the High Level Trigger of ATLAS.

The algorithms performance and timing have been studied running on simulated data different chains of trigger selection.

Figure 10:  $\phi$  (left) and  $d_0$  (right) resolution as functions of  $|\eta|$ . The superimposed lines represent results from the offline track reconstruction.

# Data Preparation for the High-Level Trigger Calorimeter Algorithms

## Abstract

This note describes the data preparation necessary to enable the ATLAS High Level Trigger Calorimeter Algorithms. An overview of the infrastructure, which provides the transition from the calorimeter electronics to data reconstruction and trigger algorithm implementation, is given. This infrastructure is detailed as a separate note since it is relevant to all trigger algorithms requiring calorimeter information (electrons, photons, taus, jets, missing  $E_T$  and muons).

## 1 Introduction

The calorimeters and part of the muon system were designed to participate in the ATLAS first level hardware-based trigger (L1) [1–4], while all sub-detectors participate in the software-based high level trigger (HLT) [5], comprised of Level 2 (L2) and the Event Filter (EF). One important phase for any trigger software algorithm is the data preparation step which provides the conversion of the bytes of data produced by the detector electronics into a convenient form for the trigger algorithms. In the case of the calorimeters, the digital information provided by the detector must be converted into calorimeter cells as input to the reconstruction algorithms. A good data preparation step will provide the input to the trigger software in an organized manner, so that access to the prepared data is optimized. This note describes this step for the calorimeter trigger software in the HLT. The same software data preparation layer is used in algorithms that are used to identify electrons, photons, taus, jets and muons [6].

### 1.1 Calorimeter readout

The fundamental LAr calorimeter readout unit is the calorimeter cell. The cell electrodes receive the current due to the drift electrons in the liquid argon and form a triangular shaped signal [1]. The shaping and readout of this signal is performed by the Front-End Electronics. To preserve the dynamic range and the energy resolution, the signal is shaped with three possible gains. The Front-End Boards (FEBs) save analog samples of the signals coming from the detector at the bunch crossing rate (25 ns). Each FEB can process up to 128 LAr calorimeter cells.

The signals are converted by the FEBs to a digital format if the event is accepted by the L1 Trigger. The digital information is sent to the ReadOut-Drivers (RODs). These are Digital Signal Processor (DSP) based machines, fast enough to deal with a number of input channels (2 FEBs feed one ROD DSP). From the pulse shape digitized at the FEB, the energy deposited in any cell can be calculated.

Data from each ROD are sent to a ReadOut Buffer (ROB). The ROB keeps this data fragment until it is requested by L2 or the Event Builder (EB). While L2 only requests a limited amount of data fragments, the EB will request fragments from the whole detector for events approved by L2 for subsequent processing in the EF computer nodes.

In the Tile Calorimeter [2], the photons produced in the scintillators are measured by photomultipliers, which produce a negative shaped pulse. The digitized electronic signal is saved into an on-detector memory waiting for the accept signal from the L1 trigger. For each of the 256 Tile Calorimeter modules, a so-called drawer (inserted in the back of the calorimeter structure) contains up to 48 photomultipliers and all the readout electronics.

The analog signals from the detector cells are also summed up by dedicated hardware by detector regions in depth. Trigger Towers (TT) are coarse granularity combinations of the detector cells and can be

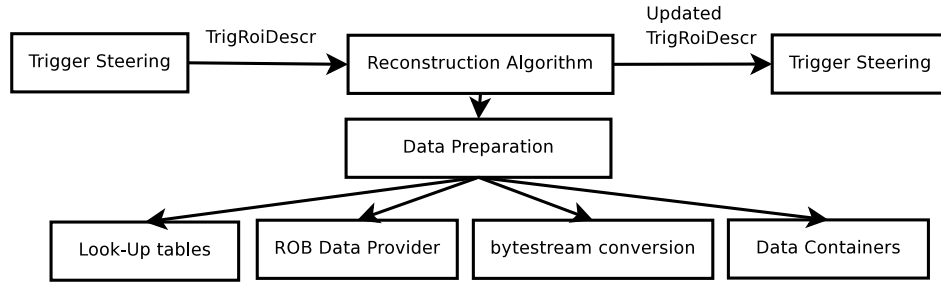

Figure 1: Different parts of the data preparation processing and their relation to the calorimeter algorithm at the L2. For details, see text.

provided in analog mode to the hardware L1 processing. Except for the very forward regions, the TT size is  $0.1 \times 0.1$  in  $\eta \times \phi$ . The L1 hardware algorithm uses some minimal TT energy and isolation quantities to define a possible L1 calorimeter candidate. A pointing to the found candidate  $\eta \times \phi$  position is sent as a seed for software trigger processing. This seed is used to open a region (usually defined in terms of TT coordinates) called Region of Interest (RoI), where the full detector granularity can be accessed by the reconstruction algorithms.

## 2 Data preparation

From a general point of view the preparation of the LAr and Tile Calorimeters data is similar. Figure 1 depicts the global scope of the data preparation for the L2 calorimeter algorithm as described below. The EF structure is similar and is discussed briefly later in the note (see Ref. [7] for additional details of the full HLT data preparation).

The L2 software component called Steering receives the L1 information on the acceptance of an event along with the  $\eta$  and  $\phi$  coordinates corresponding to the L1 triggered object. The reconstruction algorithm gathers a list of ROB identifiers which contain data for a given RoI. Each ROB may partially contain data from TTs not pertaining to the RoI (ROB data access is not usually defined by the RoI, but rather by the hardware cabling). An optimal way to map cells to the towers and to the addresses of the ROB must be provided.

The mapping of the ROBs and TT are part of the geometry description and are also used in the offline reconstruction software framework. The access to the offline detector description databases which maps any physical position into a set of identifiers is typically very slow, as the full detector description is comprised of a great amount of data. In order to provide faster access, compatible with the L2 speed requirements, a look-up table called the Region Selector is prepared in the initialization phase of the trigger software.

The ROB identifiers are translated to network addresses of the ROB machines and the data are subsequently requested. The processing of the trigger selection algorithms is inhibited while the network acquires the data. Operating in a multiprocessing environment, as foreseen for the ATLAS trigger, reduces this dead time [5, 8]. The ROB data provider receives the list of ROB identifiers and returns the detector data to the algorithms.

When data are received, pointers to the beginning of the different fragments are passed to the detector-specific bytestream conversion code. Bytestream conversion is the decoding of the data format produced by the detector RODs, and packaging of the data into an accessible format for the algorithms, in this case calorimeter cells. The last part of the data preparation is to provide the cells in a manner organized for the reconstruction algorithms. For instance, cells are provided by detector layer.

## 2.1 Data processing in the Read-Out Drivers

The LAr Digital Signal Processors (DSPs) are able to prepare data in different formats, the most important one is termed “physics mode.” In this mode the DSPs process the nominal 5 samples per cell provided by the front-end electronics. These samples are used to compute the energy deposited in the cell by the particles using an optimal filtering (OF) [9]. This processing is a simple weighted sum of the samples. The weights include the noise autocorrelation, electronics calibration constants, and a normalization factor that converts ADC counts to MeV. For cells with energy above a programmable threshold the timing of the signal and the quality of the pulse shape compared to the expectation are calculated. Finally, for each cell, the choice of electronic gain applied to the analog signal in the FEB is recorded.

Beyond the cell-based data, the DSP can also extract global information at the FEB or TT level, which can be used to improve the L2 and EF processing speed. The DSP can sum up the energy in a given region in space providing  $E_x$ ,  $E_y$ , and  $E_z$  sums for these regions. The cell energies are added within these regions using cell-position-based projection coefficients loaded in the DSP from a database. Zero suppression is applied for cells below a given threshold. FEB’s or TT’s can be used to reconstruct jets or missing  $E_T$  at L2 and EF if unpacking the full detector is too time consuming. Currently FEB’s are being used to provide the energy sums, however, using the TT information instead is under evaluation to improve jet and missing  $E_T$  resolutions.

The pulses from the Tile Calorimeter photomultipliers are also sampled and digitized by 10-bit ADCs. During a physics data taking, 7 samples (175ns) of the signal pulses are acquired and transmitted to the RODs. The information is processed using DSPs which also apply optimal filtering for cell energy reconstruction [10].

## 2.2 Region selector

As mentioned earlier, part of the information is stored in lookup tables for fast access to the detector description. In the LAr calorimeter case, the information unit to be correlated to the L1 position is the Trigger Tower. The  $\eta \times \phi$  minimum and maximum and the ROD identifier for each TT is arranged in a large matrix. Multiple tables corresponding to the different calorimeter layers are available. For the transition region from barrel to endcap calorimeter the data of the fiducial volume covered by a TT may be provided by more than one ROD. In the Tile Calorimeter case, the geometry information is associated with the calorimeter module identifier and, again, the ROB identifiers. The Look-Up tables with geometry information for LAr and Tile are prepared by accessing the relevant conditions database.

## 2.3 Data containers

The data structure of a calorimeter cell includes a part common to LAr and Tile, and parts specific to both subdetectors. In the software these cells are organized in vectors, called collections. For the Liquid Argon Calorimeter each cell collection holds data for a LAr ROD, corresponding to two FEBs or, at most 256 cells. In the case of the Tile cell collection, there are either 23 cells (in the Barrel) or 13 cells (in the Extended Barrel) per collection. Data for four cell collections are associated with a single ROD. A Tile Calorimeter ROD has data for at most 92 Tile cells. Finally, the collections are organized in a vector which is called a container.

The containers for LAr and Tile are stored permanently in memory and the cells and collections are never deleted. This way, on-the-fly memory allocation, which is typically a slow operation in a computing system, is avoided. One problem with reusing collections is that the container must keep track of which collections have already been decoded in a given event. This information is provided by the tools that access the container. If requested subsequently in the same event, the collection will not be decoded again.

## 2.4 Bytestream conversion

The ROD fragments, containing the energy encoded information are provided to the appropriate HLT bytestream conversion code. Based on the ROD fragment identifier, the corresponding cell collection is located by the proper container (LAr or Tile containers). Subsequently, subdetector specific code is used to perform the data unpacking.

The LAr bytestream conversion code automatically identifies the fragment type using the ROD version encoded in the bytestream itself. Depending on the detected format, the corresponding internal infrastructure is selected.

The bytestream conversion software unpacks the energy information using the DSP physics output format as described in Section 2.1. The conversion provides the cell energy, hardware gain, pulse peak time, and pulse-fit quality information (if available) for each of the ROD fragment channels. The channel number is used as an index to the cell position in the cell collection, so that each LAr channel is associated to a single predefined cell object in the collection. Each cell is updated with the current values of energy, time, quality and hardware gain. In the unpacking step, typically more cells are requested than those contained in the RoI as data from one FEB may extend over several TTs. Furthermore, the trigger reconstruction algorithms require data access on a layer-by-layer basis. This results in a very complex operation with many checks of cell layer and position. Maps between TT identifiers and the associated groups of cells are prepared prior to algorithm execution, to speed up the process. Using the TT identifier list obtained from the Region Selector, a chain of cells for those TTs can be obtained, simplifying the algorithm code.

The bytestream conversion software for the Tile calorimeter data also checks the ROD format, ensuring that the correct method of unpacking the data is chosen. The data is decoded and the energy values are stored in a pre-allocated raw data structure. This is again used to avoid online memory allocation. The energy, time, and quality are stored together with the ADC identifier for each cell in a Tile Calorimeter drawer. This raw data is copied into the cell structure. The mapping of raw data to cells is the same for every drawer in a given calorimeter sector. To speed up the processing a mapping is built to the indices of the cells that correspond to each raw data.

Each Tile drawer is unpacked into a cell collection. The data providing in this case is much simpler than in the LAr case. Algorithms are able to iterate through the whole collection after the unpacking is done.

## 2.5 Data preparation in the EF

The Data Preparation tools in the EF make use of the same data unpacking approach that is used by L2, dumping this information into an offline cell container. As the EF has a larger time budget, however, more sophisticated algorithms and tools developed for offline reconstruction are used to process the cells stored in this container.

For each of the subdetectors (EM, HEC, FCal and Tile), the EF cell container is filled. This provides the possibility of unpacking only selected calorimeter sections, as needed. Once the container has been filled with the corresponding calorimeter cells, a set of software tools are executed to organize and check the container, and to perform cell-based calibrations.

## 3 Algorithm performance

In this section, the performance of representative HLT algorithms ( $e/\gamma$  for L2 and missing  $E_T$  for EF) and data preparation is studied. The results are based on bytestream files prepared with a format similar to the ATLAS raw output data.

Figure 2: Number of cells used in the L2  $e/\gamma$  selection algorithm as a function of  $\eta$  for the LAr (EM, EM endcaps and HEC) Calorimeters (left) and for the Tile Calorimeter (right). The RoI size was  $0.4 \times 0.4$  in  $\eta \times \phi$ .

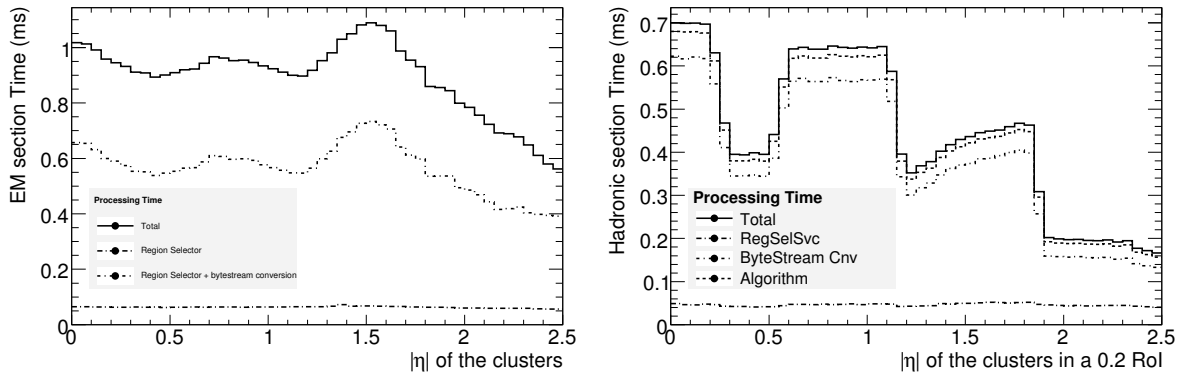

Figure 3: Cumulative time spent in the different phases (Region Selector, bytestream conversion, and algorithm) of the L2  $e/\gamma$  selection as a function of  $\eta$  for the electromagnetic part (left) and for the hadronic part (right) for an RoI size of  $0.4 \times 0.4$  in  $\eta \times \phi$  (a 2.3 GHz machine was used to perform these measurements).

The primary performance issue is processing time. The processing time depends on the number of cells required, which is a function of  $\eta$ . Figure 2 shows the number of cells separately for LAr (left) and Tile (right) calorimeters; the overlapping bins in the figure are due to variable  $\phi$  segmentation in transition regions between different calorimeter modules. The distribution on the left shows that the number of active cells in the barrel is quite uniform; since the endcap granularity is smaller, the number of unpacked cells decreases with increasing  $\eta$ . The distribution of the number of cells unpacked for the Tile Calorimeter depends on the number of drawers to be unpacked. In the very central region ( $|\eta| < 0.4$ ), data from negative and positive rapidities must be accessed to complete the RoI, doubling the amount of data to be unpacked. A similar effect is observed in the region between the TileCal Barrel and Extended Barrel.

For the standard L2  $e/\gamma$  selection based on a RoI size of  $0.4 \times 0.4$  in  $\eta \times \phi$ , the execution time for each of the processing steps was measured. The results, based on a sample of about 15,000 single electron events are shown in Fig. 3 separately for the EM (left: LAr) and for the hadronic (right: Tile and HEC)

Reco. step	Region Selector	bytestream conversion	Algorithm	Total
EM 2 <sup>nd</sup> layer	29 $\mu$ s	169 $\mu$ s	146 $\mu$ s	347 $\mu$ s
EM 1 <sup>st</sup> layer	13 $\mu$ s	171 $\mu$ s	113 $\mu$ s	301 $\mu$ s
EM other layers	21 $\mu$ s	158 $\mu$ s	56 $\mu$ s	243 $\mu$ s
Hadronic	46 $\mu$ s	334 $\mu$ s	43 $\mu$ s	438 $\mu$ s
Total	109 $\mu$ s (8%)	833 $\mu$ s (63%)	358 $\mu$ s (27%)	1.33 ms

Table 1: Processing time for different algorithm steps and for different actions. Improvements for the Tile calorimeter data preparation are envisaged. Time measurement excludes ROB data retrieval time (a 2.3 GHz machine was used).

sections. It is important to stress that the processing time per RoI does not depend on event type, since the cluster sizes are constant for a given RoI. It can be seen that the Region Selector comprises a small portion of the total time, and that the bytestream conversion is the dominant source of time, with the algorithm itself taking only about 35% (10%) of the total time for the EM (Hadronic) calorimeters. Even though fewer cells are used in the EM calorimeter crack region (around  $\eta = 1.5$  as shown in Fig. 2), these cells are distributed in two ROB's (one from the Barrel and another from the EM endcap), resulting in an overall increase in the processing time. Finally, we note that the conversion times are especially large in the regions covered by the Tile calorimeter and in proportion to the number of Tile calorimeter modules accessed. Work is ongoing to reduce these large processing times. The timing results averaged over  $\eta$  are also summarized in Table 1. ROB data retrieval times are not included, since they can only be evaluated during real data taking.

These time measurements indicate that the preparation of the Tile calorimeter data needs to be improved. Even though about six times fewer cells are accessed for the barrel region, the data preparation time to run the hadronic part is comparable to the EM part.

Other trigger algorithms such as tau or jet identification need larger RoI sizes and consequently require more time. As an example, a jet algorithm which uses a  $1.0 \times 1.0$  RoI size takes 10 to 12 ms.

### 3.1 EF missing $E_T$ performance

The EF missing  $E_T$  reconstruction algorithm accesses data from all the calorimeters and computes the missing  $E_T$  with its  $E_x$ ,  $E_y$  components as well as the total scalar energy sum. In addition, corrections due to energy deposits from muons can be taken into account by including the results from the EF muon reconstruction.

To access the calorimeter data the algorithm uses the same data preparation layer used by L2. Since the ATLAS calorimeters contains about 200,000 cells, the access to every single cell can become too time consuming at the trigger level. A faster option is to use energy sums at the FEB level (discussed earlier in Section 2.1). FEB unpacking has only been implemented for LAr data, where the impact on the unpacking time is most significant.

In Fig. 4 the processing time of the EF missing  $E_T$  algorithm is shown for full unpacking and FEB-based unpacking. On average, the time to process the whole calorimeter is dramatically reduced from 57 ms for the cell method to 2.4 ms for the FEB method.

The total scalar sum and the Missing  $E_T$  calculations were performed using the two unpacking methods. The missing  $E_T$  calculation does not depend on the method, while the scalar sum is systematically reduced in the FEB calculation due to the effect of the zero suppression. However, due to the drastic improvement in speed, the FEB algorithm is a valid option for the missing  $E_T$  reconstruction.

In addition to the timing studies detailed here, a thorough study of the memory usage and initial-

Figure 4: Processing time of the EF missing  $E_T$  algorithm. The timing distributions for the cell and FEB method are shown. A 2GHz machine was used for this test.

ization time was performed. A substantial fraction of the initialization time is taken by the detector geometry preparation, including the filling of the cell coordinates and the Region Selector tables. This initialization step requires access to databases containing information on detector conditions, and possibly files with complementary information. It was determined that the initialization time is acceptable and does not inhibit the running of any of the desired algorithms. Furthermore, the memory usage of the algorithms was measured to be stable and within acceptable operating limits.

## 4 Data preparation summary

This note describes the implementation of the whole data preparation step for the HLT calorimeter trigger from the detector electronics up to the reconstruction level. It is fundamental that a data preparation layer is efficient and fast, leaving time for the real physics algorithms. The High-Level Trigger Calorimeter tools described here have been used extensively with simulated data to commission the ATLAS trigger. A unique interface provides access to detector physics quantities (calorimeter cells) obtained with complex computations from the readout data. Knowledge of the detector details is, of course, a fundamental input into optimizing the strategy to be followed in this unpacking procedure. The critical performance issue for calorimeter data preparation is that it be accomplished within the online time budget, and this goal has been achieved with the current system. Even for special algorithms, like the missing  $E_T$  which process cells from the whole detector, the data preparation performance is still within the required processing interval restrictions. Whenever FEB summary information can be used, significant timing reductions can be achieved. Further optimization studies are still in progress.

In addition to studies with simulated data, the tools and algorithms discussed here have been applied to commissioning runs of the ATLAS detector using cosmic rays. Until the LHC begins taking data, this is the only exercise that can approximate the real trigger usage in LHC conditions. Many trigger objects, such as taus, jets, and missing  $E_T$  are being successfully debugged in this manner, providing important feedback to the algorithm developers.

# Tau Trigger: Performance and Menus for Early Running

## Abstract

The selection of events with hadronically decaying tau leptons is challenging due to high background rates at the LHC. On the other hand, efficient selection of events with tau leptons increases the discovery potential of ATLAS in many physics channels, notably Standard Model or Supersymmetric (SUSY) Higgs boson production. In this note we describe the ATLAS tau trigger system, focusing on the early data taking period, and present results from studies based on simulated events, including trigger rates and the acceptance of tau leptons from  $W$  and  $Z$  boson decays, Higgs Boson decays, and SUSY processes. In order to cope with the rate and optimize the efficiency of important physics channels, the results of the current simulation studies indicate that ATLAS tau triggers should include either relatively high transverse momentum single tau signatures, or low transverse momentum tau signatures in combination with other signatures, such as missing transverse energy, leptons, or jets.

## 1 Introduction

Tau triggers are designed to select hadronic decays of tau leptons, which mainly consist of one or three charged pions accompanied with a neutrino and possibly neutral pions. Leptonic tau decays are typically selected by electron [1] or muon [2] triggers. Tau triggers are an important part of the ATLAS trigger system, a fundamental component of the ATLAS detector [3].

ATLAS will collect data at different luminosities, starting from  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ . At the lowest luminosity the focus of tau triggers is to collect samples that are useful for understanding the detector and the tau reconstruction software. Tau signatures combined with missing transverse energy signatures are essential to provide data samples enriched in  $W \rightarrow \tau \nu$  events, which provide an important sample of real taus needed to refine tau identification algorithms. Additionally, single tau triggers with large prescale factors will provide samples for tau fake rates studies.

At higher luminosities, tau triggers will cope with the event rate increase by using higher  $E_T$  threshold requirements, more restrictive identification requirements, or demanding a combination of different signatures, such as missing transverse energy, jets, or leptons. At high luminosity, tau triggers will be essential to enable the collection of data samples for searches based on single tau lepton final states, like Minimal Supersymmetric Standard Model (MSSM)  $H^\pm \rightarrow \tau \nu$  [4] decays. They will also be used for final states with more than one tau lepton, like SM Higgs boson [5], MSSM neutral Higgs boson [6], or  $Z'$  boson [7] decays.

The results presented in this paper are based on events fully simulated with GEANT4. The text is organized as follows. An overview of the three-level trigger selection for single tau triggers is presented in Section 2, while the performance in terms of resolution, rates, and efficiencies is described in Section 3. Timing studies of tau trigger algorithms are presented in Section 4. The current tau trigger menu, which includes various single and combined tau triggers, is described in Section 5, with a focus on the early data taking period corresponding to a luminosity of  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ . Finally, a summary is presented in Section 6.

## 2 Overview of single tau trigger selection

### 2.1 Level 1 selection

The L1 tau trigger selection is closely related to the L1 electron/photon trigger ( $e/\gamma$ ), and is fully documented in [8]. It is a hardware trigger based on electromagnetic (e.m.) and hadronic calorimeter information, and uses trigger towers of approximate size  $\Delta\eta \times \Delta\phi = 0.1 \times 0.1$ , with a coverage up to  $|\eta| < 2.5$  (given by the inner-detector coverage and the high-granularity e.m. calorimetry).

The algorithm considers a rectangular Region of Interest (RoI) of  $4 \times 4$  towers ( $0.4 \times 0.4$  in  $\eta \times \phi$ ) in both the e.m. and hadronic calorimeters, and makes use of different elements, each formed by summing  $E_T$  over a group of towers. The algorithm uses the following quantities:

- the central  $2 \times 2$  *core* cluster is the energy measured in the central  $2 \times 2$  e.m. and hadronic towers
- the *TauCluster* is the energy defined by the two most energetic neighboring central towers in the e.m. calorimeter plus the central  $2 \times 2$  towers of the hadronic calorimeter
- *EmIsol* is the energy in the e.m. isolation ring (the region between  $2 \times 2$  and  $4 \times 4$  towers in the e.m. calorimeter).
- *HadIsol* is the energy in the hadronic isolation ring (region between  $2 \times 2$  and  $4 \times 4$  towers in the hadronic calorimeter).

The L1 tau trigger candidate is accepted if the core cluster is a local  $E_T$  maximum and also satisfies additional conditions on *TauCluster*, *EmIsol* and *HadIsol* [8]. Its position is taken as the center of the  $4 \times 4$  tower RoI, and its energy is calibrated using a procedure derived for jets (see Section 2.1.1). A maximum of eight trigger thresholds are available at L1 for taus. Each threshold is a combination of requirements of  $E_T$  thresholds for *TauCluster*, *EmIsol* and *HadIsol*. A L1 tau trigger candidate passing the requirements is then passed to L2 for further examination.

#### 2.1.1 Level 1 Calorimeter Calibration

Trigger towers are formed by the analogue summation of calorimeter cells. Calibration of the trigger consists of adjusting the overall gains of the towers. The e.m. towers are calibrated to optimize the e.m. trigger response. The gains of the hadronic towers are adjusted to provide a uniform jet response in  $\eta$  using a jet sample with an  $E_T$  range 50-100 GeV and making  $\eta$ -dependent adjustments to the trigger thresholds.

### 2.2 Level 2 selection

The L2 tau trigger selection uses the full calorimeter granularity and the inclusion of tracking information from the Inner Detector to refine the L1 selection. The selection is designed to further reject QCD jet backgrounds by exploiting more of the characteristics of a hadronic tau decay, such as collimation and low track multiplicity.

#### 2.2.1 Level 2 calorimeter selection

At this stage, the selection of the single tau triggers is based on the calorimeter shower shape variables and the energy of a reconstructed cluster within the RoI to enrich the sample of tau candidates. Shape variables are calculated using only the second e.m. sampling layer (out of four). The second sampling is where most of the e.m. energy is deposited, therefore it provides the most information about the

e.m. shower shape. The cluster energy is calculated with all available e.m. and hadronic layers. Three different rectangular windows are defined, centered on a *seed* cluster, with areas of  $\eta \times \phi = 0.1 \times 0.1$  (narrow, *Nar*),  $0.2 \times 0.2$  (wide, *Wid*), and  $0.3 \times 0.3$  (normal, *Nor*)<sup>1</sup>. The *Nor* window is equivalent to the RoI used at L2.

The algorithm consists of several steps. First, a *seed* cluster is found, using the second e.m. sampling. The algorithm unpacks cells in the *Nor* window centered around the L1 RoI position, and finds the cell with the highest energy deposition. In a *Wid* window around the most energetic cell, the cluster position is defined as the energy weighted mean position of the cells. Then, shape variables are reconstructed using the different windows around the *seed*, as described in the following. At the same time, the total energy in all calorimeter samplings is computed. Finally, the total energy is corrected with a simple sampling calibration.

The variables used by the L2 Calorimeter selection are the following:

- *EMRadius* is the energy weighted squared radius of the *seed*, which is obtained from the sum of the individual energy weighted squared cell distances from the *seed*. It is calculated in a *Nor* window around the *seed*, in the second sampling of the e.m. calorimeter, i.e.

$$EMRadius = \frac{\sum_{Nor} E_{cell} \cdot R_{cell}^2}{\sum_{Nor} E_{cell}}. \quad (1)$$

- *IsoFrac* is the difference in energy between the *Nar* and *Wid* window, normalized to the *Wid* window. It is calculated in the second sampling of the e.m. calorimeter. The definition is

$$isoFrac = \frac{\sum_{Wid} E_{cell} - \sum_{Nar} E_{cell}}{\sum_{Wid} E_{cell}}. \quad (2)$$

- *StripWidth* is the width of the energy deposition, defined as the energy weighted standard deviation in  $\eta$ . It is calculated in a *Nor* window around the *seed*, in the second sampling of the e.m. calorimeter. The formula is

$$stripWidth = \sqrt{\frac{\sum_{Nor} \eta_{cell}^2 \cdot E_{cell}}{\sum_{Nor} E_{cell}} - \left[ \frac{\sum_{Nor} \eta_{cell} \cdot E_{cell}}{\sum_{Nor} E_{cell}} \right]^2}. \quad (3)$$

- *EtCalib* is the calibrated total transverse energy, calculated in the e.m. and hadronic calorimeters, in a *Nor* region around the seed.

The distributions of *EMRadius*, *IsoFrac* and *stripWidth* are shown in Fig. 1 for tau trigger candidates from generated tau leptons decaying hadronically and for QCD jets for two different  $E_T$  regions. In the top row distributions for low  $E_T$  tau leptons from  $W \rightarrow \tau \nu$  decays are compared to background QCD jets distributions, while in the bottom row high  $E_T$  tau leptons from Supersymmetric neutral Higgs decays (with a mass of 800 GeV) are compared to QCD background. The top row shows the difficulty in triggering on low  $E_T$  taus as the separation between signal and background is not so dramatic; the separation is much better for high  $E_T$  taus.

<sup>1</sup>The window sizes are currently subject of optimization studies.

Figure 1: L2 Calorimeter variables to distinguish QCD jets from low  $E_T$  taus from  $W \rightarrow \tau \nu$  decays (top) and from high  $E_T$  taus from Supersymmetric Higgs  $A \rightarrow \tau \tau$  decays (bottom).

### 2.2.2 Level 2 calorimeter calibration

A simple *Sampling* calibration is used in the L2 calorimeter algorithm for reconstruction of the tau energy. This method is fast ( $\approx 7 \mu s$ ) because it applies a global weight to the energy of each sampling to compute a total calibrated energy, as opposed to other slower algorithms, such as the offline calibration [9], which use a cell-by-cell correction. In the current implementation only two layers are considered (e.m. and hadronic compartments) and the weights are energy and  $\eta$  dependent.

### 2.2.3 Level 2 tracking selection

The standard L2 track reconstruction [10] is used in the L2 tau triggers. To keep the L2 execution time within budget, data from the Transition Radiation Tracker is not used.

Tracks with  $p_T > 1.5 \text{ GeV}$  are reconstructed in a rectangular RoI of size  $\eta \times \phi = 0.6 \times 0.6$  centered on the L2 Calorimeter *seed*. The output of the L2 Tracking algorithm is a list of tracks found in the RoI. Within this region, two selection cones are defined, corresponding to a distance  $\Delta R = \sqrt{(\Delta \eta)^2 + (\Delta \phi)^2}$  of 0.15 (*Core*) and 0.3 (*Nor*) with respect to the direction of the highest  $p_T$  track found in the RoI. An isolation ring (*Iso*) with  $\Delta R$  between 0.15 and 0.3 is also defined.

The following selection variables are then calculated from the track list:

- *Pt leading* is the  $p_T$  of the track with the highest  $p_T$ . By requiring a minimum  $p_T$  this criterion also effectively requires that at least one track is found in the RoI.
- *Pt Iso/Core* is the ratio of the scalar sum of  $p_T$ s of all tracks in the *Core* and *Iso* region  $\sum p_T^{\text{iso}} / \sum p_T^{\text{core}}$ .
- *N Slow tracks* is the number of slow tracks found in the *Core* region. A slow track is defined as a track with  $p_T$  below a certain threshold, typically  $7.5 \text{ GeV}/c$ . The rejection power of this variable might depend on the pile-up conditions.

- *Charge* is defined as the absolute value of the sum of charges of all tracks found in the *Nor* region.
- *N Tracks* is the total number of tracks found in the *Nor* region.

The L2 tracking selection places requirements on these five variables. The set of requirements can be different for different single tau signatures. The three most important criteria are requiring that at least one track be found with a minimum *Pt leading*, an isolation cut on the maximum amount of energy deposited in the *Iso* region, and a cut on the maximum number of slow tracks. The requirements on charge and total tracks are very loose, due to the higher number of fake tracks found by the L2 tracking algorithm compared to the more sophisticated offline reconstruction. In addition, the offline reconstruction of single tau lepton final states (e.g. from  $W \rightarrow \tau\nu$ ) relies on an unbiased track distribution to estimate backgrounds and extract the number of signal events. The distributions of *Pt leading*, *N Slow tracks* and *Pt Iso/Core* are shown in Fig. 2 for tau trigger candidates from generated tau leptons decaying hadronically and for QCD jets for two different  $E_T$  regions. QCD jet background is compared to low  $E_T$  tau leptons from  $W \rightarrow \tau\nu$  decays (top row), and high  $E_T$  tau leptons from Supersymmetric neutral Higgs decays (bottom row). Tau trigger candidates are required to pass different L1 and L2 Calorimeter selection criteria based on their  $E_T$ . A L2 tau trigger candidate passing the calorimeter and tracking requirements is passed to the EF for further consideration.

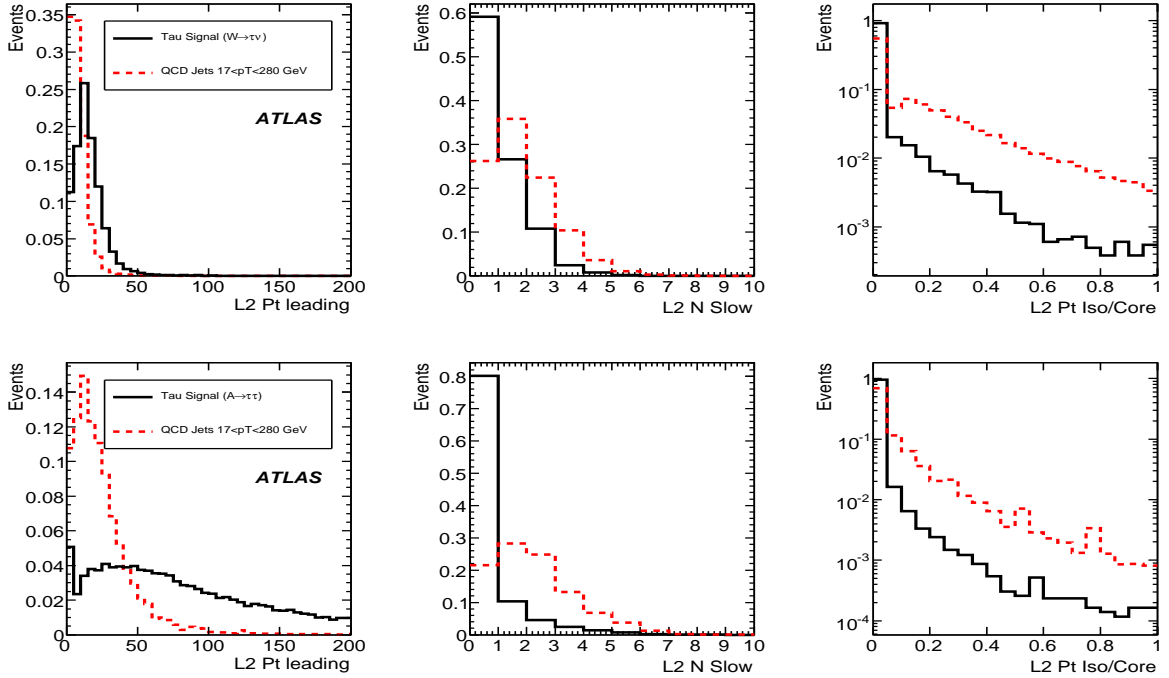

Figure 2: L2 Tracking variables to distinguish QCD background from low  $E_T$  taus from  $W \rightarrow \tau\nu$  decays (top) and from high  $E_T$  taus from Supersymmetric Higgs  $A \rightarrow \tau\tau$  decays (bottom).

### 2.3 Event Filter selection

At the EF level, the selection follows the offline reconstruction procedure as closely as possible. The EF calorimeter algorithm collects cells in a rectangular RoI of size  $\eta \times \phi = 0.6 \times 0.6$  centered around the L2 tau trigger candidate. The EF tracking reconstruction is described in [10]. Tracking is performed in a rectangular RoI of size  $\eta \times \phi = 0.4 \times 0.4$  centered around the L2 tau trigger candidate.

To create an EF tau trigger candidate, the EF single tau triggers execute the calorimeter based identification algorithm of the offline reconstruction [11] in the following way. The cells collected in the RoI are used to reconstruct the direction of the EF tau trigger candidate. Additionally, some very loose criteria are applied to tracks reconstructed in the RoI, and if more than one track is found a secondary vertex reconstruction is attempted. The transverse energy and the calorimeter shower shape variables are built from the cells collected in the RoI using the newly reconstructed direction. Unlike the offline reconstruction algorithm, no noise suppression is applied at the EF. The addition of electronic noise in the calorimeter cells gives a generally small change in the calorimeter shower shape variables. Finally, an overall hadronic calibration [9] is applied to all cells, and a tau specific jet calibration is applied to the tau trigger candidate. This final calibration is derived from simulated samples of high and low  $p_T$  tau lepton sources. A procedure using taus from  $Z$  bosons decays and exploiting the correlation between the tau absolute energy scale and the visible reconstructed  $Z$  boson mass will be applied to determine calibration constants from real data [11].

The following variables are used for the EF selection:

- *EMRadius* is an energy weighted radius, which exploits the small transverse shower profile of tau leptons. The mathematical expression used is

$$EMRadius = \frac{\sum_i E_{T,cell} \cdot \Delta R_{cell}}{\sum_{Nor} E_{T,cell}}. \quad (4)$$

where the sum includes not only the second sampling layer of the e.m. calorimeter (as in L2) but also all other samplings except the last one.

- *IsoFrac* is the energy deposited in an annular region between  $0.1 < \Delta R < 0.2$  divided by the energy deposited in  $\Delta R < 0.3$ . A similar expression is given in Eq. 2, where the square regions should be replaced by the annuli.
- *N Tracks* is the number of associated tracks with  $p_T > 2\text{ GeV}$  found in a  $\Delta R < 0.2$  region around the trigger candidate from L2.
- *Pt leading track* is the highest  $p_T$  track among the tracks found in a  $\Delta R < 0.2$  region around the trigger candidate from L2.
- *EtCalib* is the energy calculated in all e.m. and hadronic cells found in the  $\Delta R < 0.3$  region around the trigger candidate from L2, and calibrated with the procedure described in [9] and an additional tau specific jet calibration.

Some of the variables used in the EF selection, namely *EtCalib*, *IsoFrac* and *EMRadius*, are shown in Fig. 3 for tau trigger candidates from generated tau leptons decaying hadronically and for QCD jets for two different  $E_T$  regions. As for previous figures, QCD background is compared to standard tau signal samples. Events with a tau candidate that pass the EF thus pass the trigger and are recorded for offline analysis.

### 3 Performance of single tau triggers

#### 3.1 Performance overview

This section describes in detail the expected trigger efficiencies and background event rates obtained from the various single tau triggers available in the ATLAS trigger menu, while combined triggers including

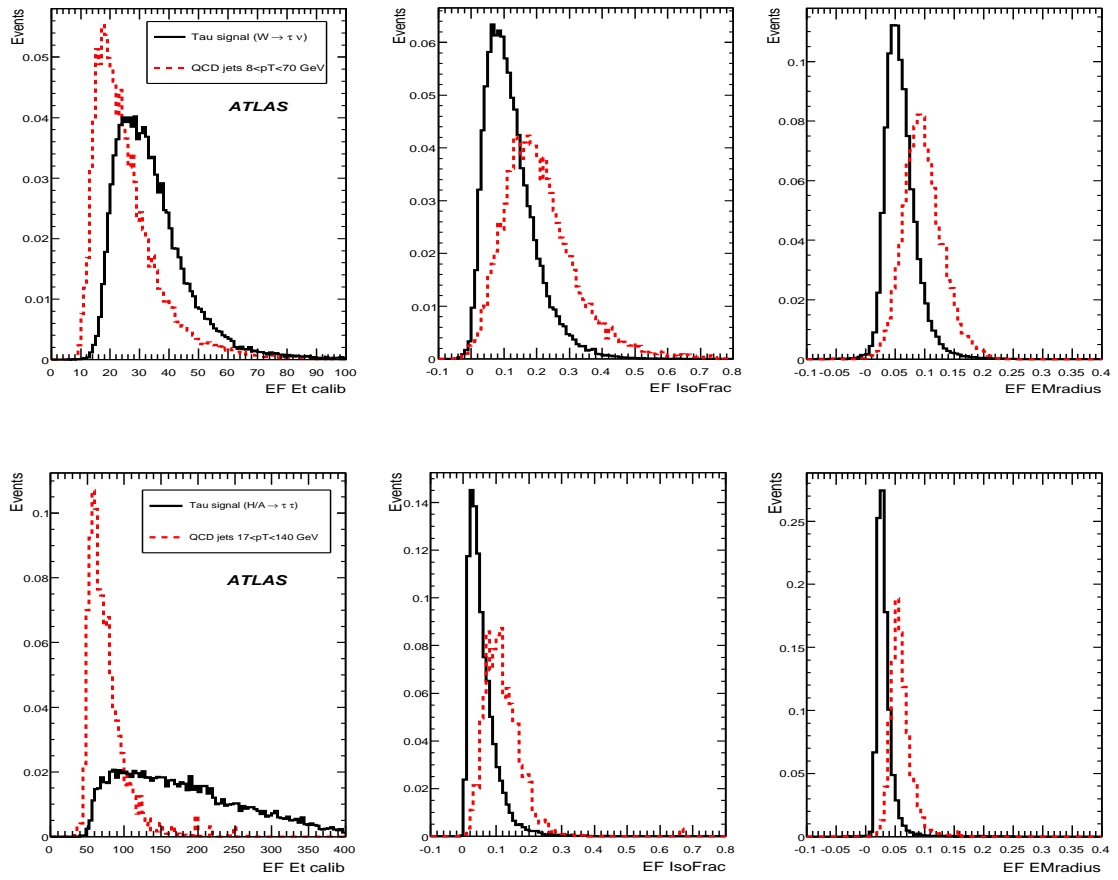

Figure 3: EF variables to distinguish QCD background from low  $E_T$  taus from  $W \rightarrow \tau \nu$  decays (top) and from high  $E_T$  taus from Supersymmetric Higgs  $A \rightarrow \tau \tau$  decays (bottom).

other types of signatures is given in Section 5. In addition, the optimization procedure applied to the selection at each level is introduced. The goal is to obtain at least 90% efficiency at each trigger level with sufficient rejection of background.

The various types of samples of GEANT4 simulated events used in this note together with the total number of events and the cross section are summarized in Table 1. It is appropriate to note at this point that the rates reported in this note are clearly affected by large uncertainties, because of the limited statistics available and because the simulation has yet to be validated with real data.

Sample	Events	$\sigma$ (pb)
Min.Bias	2900k	7.0E+10
QCD dijet $8 < p_T < 17$ GeV	742k	1.74E+10
QCD dijet $17 < p_T < 35$ GeV	395k	1.38E+9
QCD dijet $35 < p_T < 70$ GeV	824k	9.33E+7
QCD dijet $70 < p_T < 140$ GeV	272k	5.88E+6
$W_{\tau \rightarrow hX}$ (filtered $p_T > 12$ GeV)	24000	5.54nb
$Z_{\tau\tau}$	23000	0.246nb
$H_{\tau\tau \rightarrow \ell hX}(120)$	22924	0.145
$H_{\tau\tau \rightarrow hhX}(120)$	40950	0.073
$A_{\tau\tau}(800)$	26250	10
SU3	22250	18.59
$t\bar{t}$	41700	800

Table 1: GEANT4 simulated data samples used in the note.

### 3.1.1 Naming convention

In the ATLAS trigger menu, different single tau triggers are implemented, corresponding to different  $E_T$  threshold requirements <sup>2</sup>: tau10i, tau15i, tau20i, tau25i, tau35i, tau45i, tau60. For tau10i and tau15i the isolation criteria are only applied at the L2 and EF level. For some  $E_T$  thresholds, additional triggers are defined using looser isolation criteria (e.g. tau10). Hadronic isolation at L1 is not applied in any selection. Due to the  $E_T$  resolution at the three trigger levels, the actual cut applied on  $E_T$  at each stage is generally lower than the nominal  $E_T$  to maintain high efficiency.

### 3.1.2 Trigger efficiency definition

The tau trigger efficiency is optimized with respect to generated tau leptons decaying hadronically, where the visible tau momentum ( $p_{\text{vis}}^\alpha = p_\tau^\alpha - p_V^\alpha$ ) is in the sensitive region of the detector ( $|\eta| \leq 2.5$ ) and is greater than the nominal  $E_T$  threshold requirement for a given signature. Furthermore, the efficiency is optimized to select those tau leptons which are likely to be selected by the tau identification algorithms of the offline reconstruction software. This constitutes what we subsequently call the tau trigger reference.

More specifically, a geometrical match of a trigger candidate to a generated tau lepton within a cone region  $\Delta R < 0.2$  is requested. Generated tau leptons are considered for calculating signal efficiencies only if the tau lepton is also selected by either of the two tau offline reconstruction algorithms [11]: the calorimeter based or the track based algorithm. It should be noted here, that detailed optimization with respect to 1-prong (1 charged pion) and 3-prong (3 charged pions) tau lepton decays has not been

<sup>2</sup>The first symbol of the signature represents the particle type, the following number is the  $E_T$  threshold and the “i” indicates that an isolation requirement is applied.

performed for this study. This results in different efficiencies for these classes of events, as pointed out in the following sections. Total trigger efficiencies shown in this section are estimated on various physics processes which cover different kinematic ranges. The samples used are therefore specified in the text.

### 3.2 Energy and angular resolution

The relative resolutions (in %) on  $E_T$ ,  $\eta$ , and  $\phi$  as a function of visible  $E_T$  and  $\eta$  for tau trigger candidates at the different trigger levels are shown in Fig. 4 for tau20i. The visible four-momentum of the tau lepton is reconstructed from all decay products except neutrinos. The resolutions are rather flat as a function of the generated visible  $E_T$ , however, some dependence on the distributions as a function of the generated visible  $\eta$  is observed. In particular a degraded resolution in  $E_T$  and  $\eta$  in the transition region between the barrel and endcap calorimeters is clearly visible. Due to the inclusion of track information, the angular resolution at L2 is better than that of L1. The  $\eta$  and  $\phi$  of the tau trigger candidate at the end of the EF algorithm execution is set according to the calorimeter based tau reconstruction algorithm, hence the EF angular resolution is slightly worse than at L2 where tracking information is used.

Figure 4: Relative angular and energy resolution for  $\tau$  candidates as a function of generated visible  $E_T$  and  $\eta$ . Resolution (in %) is calculated using a variety of simulated tau lepton samples passing the tau20i trigger.

### 3.3 L1 performance studies

The standard reconstruction of the visible energy of L1 tau candidates (*TauCluster*) reveals a serious limitation when trying to obtain a high efficiency above a given  $E_T$  threshold at L1. A systematic shift of about 30% and a relative resolution of 33% are observed for the reconstructed energy with respect to the generated values. Therefore other possible reconstruction methods have been explored. The energy reconstructed with the standard algorithm (*TauCluster*) has been compared with other reconstruction methods: (1) E4 $\times$ 4, defined as the sum over all towers (e.m. and hadronic part) in the 4  $\times$  4 RoI region,

(2)  $\text{Jet}4 \times 4$ , obtained as the total energy in the  $4 \times 4$  RoI region calculated with the L1 Jet algorithm (which is described in Ref. [8]), and (3)  $\text{Jet}6 \times 6$ . An improvement of 10% in resolution can be achieved with  $\text{E}4 \times 4$  and  $\text{Jet}4 \times 4$  algorithms with respect to *TauCluster*. However, a comparison of the efficiencies of the different methods, shown in Fig. 5, indicates that the *TauCluster* algorithm efficiency is systematically the highest. While these other algorithms that more fully contain the  $E_T$  of the tau lepton give better resolution than *TauCluster*, this gain in resolution is accompanied by a loss in efficiency and discrimination, motivating the continued use of *TauCluster* as the default tau algorithm.

Figure 5: Efficiency curves as a function of the offline  $E_T$  for different L1 reconstruction methods; threshold requirements are chosen to give the same rate among the different cases.

Using *TauCluster*, the rates for a luminosity of  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  are evaluated by using simulations of the relevant QCD backgrounds (see Table 2). The expected rate including all physical processes (minimum bias rate) is shown as a function of the cut value applied to *TauCluster* in Fig. 6. The effect of the isolation cut can also be seen in Fig. 6.

The L1 selection used in tau trigger implementation is presented in Table 2; the cuts have been tuned to maintain a high efficiency, and the signatures are all observed to have an efficiency  $> 95\%$ <sup>3</sup>. The efficiency has been obtained using simulated samples of  $W \rightarrow \tau \nu$  and 800 GeV Supersymmetric Higgs  $A \rightarrow \tau \tau$  events, while background is evaluated using QCD events with two jets with hard parton  $8 < p_T < 140$  GeV. In Fig. 7, the efficiency is plotted as a function of the generated visible  $E_T$  for different tau signatures. The rather slow increase of the efficiency curves limits the overall performance of tau triggers.

### 3.4 L2 performance studies of the calorimeter selection

At L2, the full granularity calorimeter and tracking information is available, allowing a more sophisticated selection of tau leptons. As shown in Section 3.2, the angular and energy resolutions are improved with respect to L1.

The L2 calorimeter based selection of tau trigger candidates is optimized with respect to generated tau leptons that pass the L1 selection and are successfully reconstructed by the offline reconstruction software (offline details are given in Section 3.1.2). The optimization is obtained using simulated samples

<sup>3</sup>The efficiency definition is described in Section 3.1.2

Figure 6: Expected rate including all physical processes at a luminosity of  $\mathcal{L} = 10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ , as a function of the cut applied to *TauCluster* and with and without the isolation cut *EmIsol*.

Signature	$E_T$ threshold (GeV)	EmIsol (GeV)	Eff.(%)	Rate (Hz)
tau10i	6	-	97	13945
tau15i	6	-	98	13945
tau20i	9	6	96	4823
tau25i	11	6	96	2822
tau35i	16	6	96	990
tau45i	25	6	96	263
tau60	40	-	97	97

Table 2: Single tau signatures, associated L1 thresholds, and efficiency and rates determined from signal and background samples as described in the text ( $\mathcal{L}=10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ ).

of  $W \rightarrow \tau \nu$  and 800 GeV Supersymmetric Higgs  $A \rightarrow \tau \tau$  events, and simulated background samples of QCD events with two jets with hard parton  $8 < p_T < 140 \text{ GeV}$ .

The L2 variables based on calorimetry introduced in Section 2.2 are optimized in the following way:

- Since some correlation among the calorimeter shower shape variables (*EMRadius*, *isoFrac* and *stripWidth*) is expected, the three variables are simultaneously optimized. The thresholds are determined by scanning the possible cut values for each variable and choosing the set of cuts giving the lowest background rate for a requested minimum signal efficiency.
- The threshold for the variable *EtCalib* is determined by requiring that the efficiency becomes flat starting at the nominal  $E_T$  of the trigger (see Fig. 8).

The optimized L2 calorimeter requirements for tau signatures and the corresponding efficiencies and rates are presented in Table 3. The cut value on *EtCalib* increases for higher  $E_T$  signatures, as we aim to select higher  $E_T$  taus. The shower shape variables, a measure of the narrowness of the shower, are tighter for higher  $E_T$  signatures, since higher  $E_T$  taus are more boosted and their decay products are more collimated. The three shower shape variables requirements have been optimized to give an

Figure 7: L1 efficiency curves for different tau signatures.

efficiency of  $\approx 95\%$ , although the observed efficiency values are a little lower due to the additional *EtCalib* requirement.

The efficiency is detailed further in Table 4 for two typical tau signatures, one with low and one with high  $E_T$ . For each signature, efficiency is recalculated using as a reference different tau lepton samples reconstructed offline. Either the sample from each tau algorithm is considered separately, or the sample reconstructed by either of them (“OR”), or by both simultaneously (“AND”), is considered. The errors quoted are statistical only. In order to achieve the needed rejection of QCD backgrounds, the calorimeter-based algorithm of the offline reconstruction biases the distribution of decays towards 1-prong decays using calorimeter information. A similar rejection and efficiency is achieved in a different manner using the track-based algorithm, which requires a large transverse momentum for the leading track in the tau lepton decay. Therefore, the L2 calorimeter selection has a high and uniform efficiency for the sample reconstructed offline by the calorimeter-based algorithm, while it is lower on the sample reconstructed using the track-based algorithm in the 3-prong category.

Signature	<i>EtCalib</i> (GeV)	<i>EMRadius</i>	<i>IsoFrac</i>	<i>StripWidth</i>	Eff.(%)	Rate(Hz)	L1/L2 rate
tau10i	8.0	0.023	0.74	0.058	95	9251	1.51

Efficiencies have been estimated on low and high  $E_T$  generated samples of tau leptons. Errors are statistical only. Efficiencies are for L2 calorimeter selection only.

Figure 8: Efficiency curves of L2 selection relative to L1 for different tau signatures.

### 3.5 L2 performance studies of the tracking selection

The addition of tracking information at L2 allows an improvement in the discrimination between hadronic decays of tau leptons and QCD jet backgrounds, although at the cost of a non-negligible loss of trigger reconstruction efficiency. This loss is most noticeable for low  $E_T$  tau signatures, mainly due to the requirement of one leading track above a fixed  $p_T$  threshold. Overall, the L2 tracking algorithm is about 95% efficient for isolated tracks with  $E_T$  above 5 GeV (for example from  $W \rightarrow \tau\nu$ ). In  $W \rightarrow \tau\nu$  events, however, only 90% of generated tau leptons that are identified by the offline reconstruction and pass the L2 calorimeter selection have at least one track with  $p_T > 5$  GeV reconstructed at L2.

The L2 tracking selection of tau trigger candidates is optimized with respect to generated tau leptons that pass the L1 and L2 calorimeter selection and are found by the offline reconstruction software. Details of the offline reference and efficiency definition are described in Section 3.1.2. The optimization is obtained with the standard samples described previously.

The efficiency and rejection power of some of the L2 tracking variables can be seen in Fig. 9, where the integrated efficiency for tau samples and background are shown as a function of the applied cut value.

For low  $E_T$  signatures, the minimum requirement on  $Pt_{leading}$  along with the upper limit on  $Pt_{Iso/Core}$  are the two most important criteria. For higher  $E_T$  signatures, the upper limit on  $N_{Slow tracks}$  becomes more important, as background QCD jets tend to have a higher multiplicity of soft tracks compared to multi-track hadronic decays of tau leptons. The multiplicity requirement,  $N_{Track}$ , is potentially a useful discriminant for higher  $E_T$  signatures, although a tight cut tends to bias the multiplicity distribution of the tau leptons found by offline reconstruction. To avoid such bias a very soft cut is applied.

The optimized L2 tracking requirements for tau signatures and the corresponding efficiencies and rates are presented in Table 5. Aside from the  $Pt_{leading}$  requirement, which is tightened with increasing  $E_T$  threshold, the requirements on  $Pt_{Iso/Core} < 0.1$ ,  $N_{Slow tracks} \leq 2$ ,  $Charge \leq 2$  and  $1 \leq N_{Track} \leq 7$  are kept constant at values which work reasonably well for all signatures, and therefore are not shown in the Table.

The efficiency is detailed in Table 6 for two typical tau signatures, one with low and one with high  $E_T$ . For each signature, efficiency is recalculated using different reference samples based on offline reconstruction as in the previous section. Again, the errors quoted are statistical only. For the high  $E_T$  signatures, there is not a strong efficiency dependence on the particular reference sample chosen. For the low  $E_T$  signatures, however, the different selections used in the offline algorithms, particularly in selecting 1-prong tau lepton decays, are apparent. Since the track-based algorithm also requires a track with some minimum  $p_T$  when applied to these events the L2 tracking selection is quite efficient. The L2 tracking selection is considerably less efficient when applied to events selected with the calorimeter based algorithm, where no such requirement on the tracks is made.

The overall L2 trigger efficiency for various single tau signatures, using the optimized selection described in Sect. 3.4- 3.5, is shown in Fig. 8.

Signature	Pt lead (GeV)	Eff. (%)	Rate (Hz)	L2Calo/L2Track

For each plot, the closed circle data points show the cumulative efficiency (left-hand scale) for tau leptons as a function of cut value, while the open triangle data points show the QCD jet rates (right-hand scale) for a luminosity of  $\mathcal{L} = 10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ .

### 3.6 EF performance studies

As described in Section 2.3, the tau identification algorithm developed for offline reconstruction is adapted for EF use. The resolution in  $E_T$  and direction achieved at the EF are shown in Section 3.2, and provide a clear improvement in  $E_T$  determination with respect to L2.

The EF selection of tau trigger candidates is optimized with respect to generated tau leptons that pass the L1 and L2 selection and are found by the offline reconstruction software. Details of the offline reference and efficiency definition are described in Section 3.1.2. The optimization is performed using the standard samples described previously.

The cuts on calorimeter shape variables and  $E_T$  are optimized separately, in analogy to the L2 procedure previously described. First, the correlation between the  $E_T$  of the tau lepton and the  $p_T$  of the leading track associated with the tau lepton is studied in simulated samples, and then a combined requirement on these two variables is applied to each tau signature. Finally, the calorimeter shower shape variables are studied, and a further requirement is applied on these variables.

In Table 7 the optimized threshold requirements and corresponding efficiencies and background rates are presented. As for L2, the shower shape variables are tightened and the cut value on  $EtCalib$  and  $p_T$  lead are raised as a function of the  $E_T$  of the tau signature. The two shower shape variables requirements have been optimized to give an overall efficiency of  $\approx 90\%$ . The requirement on  $nTracks$  is not stringent, so as not to bias the distribution for this variable, which is a key offline variable for the evaluation of tau lepton purity. Fig. 10 shows the efficiency for various single tau signatures, using the optimized selection summarized in Table 7.

The efficiency is detailed in Table 8 as in previous sections. At EF clearly the efficiency is highest for the tau leptons identified by the calorimeter based algorithm of the offline reconstruction.

Figure 10: Efficiency curves of EF selection relative to L2 for different tau signatures.

Signature	$E_T$ Calib (GeV)	$p_T$ lead. (GeV)	$EMRadius$	$IsoFrac$	$nTracks$	Eff.(%)	Rate (Hz)

### 3.7 Combined performance of single tau triggers

After evaluating each trigger level separately, we now present the overall combined performance (L1 + L2 + EF) of the single tau triggers. Figures 11 and 12 show the dependence of the efficiency on  $E_T$ . The shape of the efficiency curves is determined by the  $E_T$  resolution, which is different for the different trigger levels. The  $E_T$  threshold requirement of the signature is selected such that the efficiency curve reaches a plateau at the visible  $E_T$  of the generated tau lepton greater than this threshold. Since the efficiency turn-on is slowest at L1, the cut on  $E_T$  at L1 is set significantly lower than for L2 and EF.

The efficiency is detailed in Table 9 for two typical tau triggers as in the previous sections. In addition to the observations of the individual trigger level sections, one can see that the overall performance for the low  $E_T$  tau trigger is about 70% with respect to the reference, while at high  $E_T$  it is about 90%. This is due to relatively tighter cuts needed to control the large backgrounds present for the low  $E_T$  signature. One can also see that the efficiency at low  $E_T$  is low in particular for 3-prong decays when the reference is the sample of tau leptons identified by the track-based algorithm. This reflects the previous observation of Section 3.4, and points to the need for the execution of the track-based algorithm at the EF as well as at L2.

## 4 Trigger timing studies

### 4.1 Online setup

Prior to first LHC collisions, it is desirable to test the trigger software and data acquisition system in conditions resembling real data taking. There are two type of tests which can be performed: *cosmic runs*, where the detector signals left by cosmic rays activate the L1 trigger, and *technical runs* where simulated L1 trigger signals are used. These runs allow the monitoring system to be assessed, the algorithm timing

to be measured (although the composition of the input events is not representative of the expected L1 trigger output when real data are taken) and the interplay between triggers to be studied. All studies are performed on CPUs dedicated to timing studies in order to minimize the possible influence of other users on timing results. Each of these machines is a dual-core Intel(R) XEON(TM) CPU 2.20GHz machine.

## 4.2 Timing results

The CPU time performance of the trigger is a crucial ingredient in the optimization of the trigger. Current design constrains the total execution time per event to 40 ms at L2 and 1 s at EF for the whole trigger. Recent timing studies performed on tau triggers include:

- tests of individual triggers to gauge the impact of increasing threshold levels on the total execution time of the trigger.

During this test, each of the tau triggers is run individually (and no other triggers are run at the same time). Although the average execution time of each algorithm remains roughly equal between triggers (see Table 10), the average total time per event decreases as a result of the lower number of RoIs per event for high energy triggers. The results shown in Table 10 indicate that the time performance of the tau trigger should be well within the constraint for total execution time at L2 and EF.

- a verification of caching of data from the liquid argon calorimeter in L2. This test requires running the tau algorithms and other calorimeter-based algorithms (electron algorithm, for example) for the same event. In case data in a given RoI is needed by more than one signature, then the caching procedure ensures that data are requested only once. Recent tests verify that caching is correctly implemented and provides roughly a factor of four time savings in the L2 calorimeter part.

Algorithm	Threshold Signature				
	tau10i	tau15i	tau20i	tau25i	tau35i
L2 Calo	8.1	8.0	8.0	8.1	8.1
L2 Tracking	15.4	15.5	15.0	14.9	14.7
L2 Combined	1.9	1.9	2.0	2.0	2.2
L2 TotalTime	41.6	35.9	19.7	14.1	7.9
EF Calo	12.3	12.5	13.4	13.0	14.0
EF Tracking	289.7	297.7	269.5	268.4	247.8
EF Combined	77.0	76.9	80.7	77.8	78.9
EF TotalTime	149.1	133.6	67.5	51.2	24.6

Table 10: Mean algorithm execution time for each of the tau triggers. All times are given in ms and per RoI, except the L2 and EF total times are given per event, in ms. The measurements are performed on a simulated sample of limited statistics, 950 QCD background events with hard parton  $35 < p_T < 70 \text{ GeV}$ .

- a timing comparison between the calorimeter-approach and tracking-approach in L2. Currently, the default order of L2 algorithms is that calorimeter data are analysed first and tracking data afterward. The alternative approach should also be evaluated. For the *tau15* signature alone, using a simulated sample of limited statistics (950 QCD background events with hard parton  $35 < p_T < 70 \text{ GeV}$ ), the calorimeter and tracking approaches have been evaluated and show roughly equal total execution times, 34.1 and 34.0ms respectively. On a simulated sample of 400 QCD background events with hard parton  $p_T > 2 \text{ TeV}$ , for the same tau trigger, the tracking approach is slightly faster than the calorimeter approach, 299 versus 330ms respectively. The longer execution time on high energy jet samples with respect to low energy ones is mainly due to the longer execution time of the L2 tracking algorithm. This result shows that the L2 tracking selection provides greater background rejection power than the L2 calorimeter one against high energy jets, and therefore suggests that the tracking-approach is advisable for high  $E_T$  tau triggers.

## 5 Tau trigger menu

The single tau signatures are the basic element in the ATLAS trigger menu for collecting hadronic decays of tau leptons. Therefore, Section 2 and 3 have been devoted to the selection and performance of the single tau signatures. In this section we describe the full tau trigger menu, with an emphasis on triggers that combine tau signatures with other signatures and the physics goals they address. Such combined triggers are very important for collecting samples of tau leptons of moderate  $E_T$  from several SM or even beyond the SM processes. As shown in Sect. 3, the minimal requirement on  $E_T$  for a single tau trigger must be high, even at low luminosity, to be allowed to run without prescale factors. A combined requirement of a moderate  $E_T$  tau signature with other signatures provides a way to achieve the necessary rejection against backgrounds and avoid prescale factors.

### 5.1 Combined tau triggers

The following triggers aiming at collecting hadronic decays of tau leptons are currently implemented in the ATLAS trigger menu, in addition to the single tau triggers already introduced:

- **tau+missing  $E_T$  (tau+ $E_T^{miss}$ ).** This type of trigger covers a wide spectrum of physics channels. At low luminosity, when the trigger rejection can be relaxed, the selection of events with  $W \rightarrow \tau \nu$  is

the priority.  $t\bar{t}$  events with tau leptons in the final state are also selected by this trigger. Such events are characterized by relatively soft  $E_T$  range of tau leptons as well as low  $E_T^{miss}$ . The tau+ $E_T^{miss}$  triggers at design luminosity are intended for SM or SUSY Higgs (neutral or charged) searches as well as for searches of new exotic particles like  $Z'$ . The  $E_T^{miss}$  trigger [14] uses the same threshold requirement at all trigger levels. The turn-on of the  $E_T^{miss}$  efficiency curve is mainly limited by the L1 missing  $E_T$  resolution. Since the average  $E_T^{miss}$  in  $W \rightarrow \tau\nu$  events is low, and the EF  $E_T^{miss}$  resolution is better, additional triggers where the  $E_T^{miss}$  requirement is applied only at EF are under study.

- **tau+ $\ell$ (+jets)**,  $\ell = e, mu$ . This type of trigger aims at selecting events with two relatively soft tau leptons in the final state. Two tau leptons are found in events with  $Z$  boson, neutral SM or SUSY Higgs. In addition, the tau+ $\ell$  combination selects events with multiple leptons like  $t\bar{t}$  or lepton flavor violating processes. The combination of two trigger signatures allows the use of lower threshold requirements than for the case of the single tau trigger. In case of excessive rates for this type of trigger at design luminosity, the additional requirement of jets or  $E_T^{miss}$  can be introduced.
- **tau+tau(+jets)**. This type of trigger records events where both tau leptons decay hadronically. While the rejection rate is less favorable than the tau+ $\ell$  case, the sample collected is complementary to the above and both increases statistics and allows the reduction of systematics uncertainties due to lepton identification. This trigger is highly relevant for searches of Higgs boson or new exotic particles like  $Z'$  and will also be beneficial for SUSY double tau end point analyzes.
- **tau+jets, tau+b-jets**. This type of trigger is an interesting alternative for  $t\bar{t}$  studies. At low luminosity, it allows the study of events with low jet  $E_T$  thresholds, while at high luminosities it is necessary to reduce QCD and multiple interaction background events.

## 5.2 Commissioning triggers

In addition to single tau triggers there are single *track* triggers, highly optimized to select RoIs with one track only. The main purpose of this type of trigger is alignment of the tracker or hadronic calibration. These triggers work in *parasitic* mode, taking all L1 RoIs passing 6GeV or 9GeV with isolation requirements in a given event. In this manner, a sufficient amount of tracks for commissioning can be obtained.

Furthermore, additional triggers like tau15i\_PT and 2tau25i\_PT are included in the ATLAS trigger menu (PT stand for pass-through). For pass-through triggers, all events that are accepted by the L1 algorithm are recorded for offline study of the HLT algorithms. At L2 and EF the algorithms are executed and their result is stored in the event record, however, their decision is not considered in the global trigger decision. As the output rate of these triggers is equal to the L1 rate, only a small fraction can be recorded, typically  $\sim 0.1$  Hz after prescale factors.

## 5.3 Tau trigger menu performance

In this section we summarize tau trigger efficiencies for various physics signals, see Table 11, and the corresponding rates estimated on minimum bias samples for  $100\text{ pb}^{-1}$ , see Table 12. For the results shown, the physics signal efficiencies are calculated per event, using the following references:

- trigger with one (two) tau leptons: at least one (two) tau leptons at generator level with visible  $E_T$  greater than the tau trigger threshold(s) are required. Furthermore, the generated tau leptons are identified by the offline reconstruction algorithms.

- trigger with tau+ $e$  and tau+ $\mu$ : besides the tau lepton requirement (see item above), the additional lepton is required at generator level to have an  $E_T$  greater than the chosen lepton trigger threshold. The generated lepton additionally is identified by the “loose” offline reconstruction algorithm [1], [2].
- trigger tau+ $E_T^{miss}$ : besides the tau lepton requirement (see item above), the missing  $E_T$  at generator level as well as the missing  $E_T$  reconstructed by the offline reconstruction algorithms [14] are required to be above the chosen trigger threshold.

Introducing the triggers described above is important for most physics signals with tau leptons in the final state because:

- allows increased statistics
- it is a robust approach against failure or inefficiency of a particular trigger (e.g. due to detector problems)
- allows reduction of systematic uncertainty by comparing results of the same analysis repeated on samples selected with different triggers.

In Table 11 and Table 12 the symbol tau+xe stands for the tau+ $E_T^{miss}$  triggers, and j stands for the jet triggers.

#### 5.4 Tau trigger menus for different luminosity periods

According to the foreseen LHC start-up plans, ATLAS will commence data taking at a low luminosity of about  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ . Over the course of the first year or so, it is expected that the luminosity will increase to a rather high luminosity of about  $10^{33} \text{ cm}^{-2} \text{ s}^{-1}$ . While the input rate rapidly increases during this period, the maximal output rate of the complete trigger is expected to be constant at about 200Hz (due to limitations on storage capacities and recording speed), putting a significant burden on the trigger system.

As mentioned in Section 1, the low luminosity period will be used to commission the detector and trigger system. During this period, the focus of the trigger selection is Standard Model physics and events necessary for calibration and efficiency studies. The total sample collected is expected to be of the order of  $100 \text{ pb}^{-1}$ . Concerning hadronic decays of tau leptons, the absolute scale of tau leptons and the characteristics and rate of QCD jets misidentified as tau leptons are estimated from simulated data studies only, and need to be verified and understood with collider data. To address this, several triggers are proposed, and outlined in the next section. For each trigger, a method of measuring the efficiency on real data should also be proposed.

The transition to higher luminosity is foreseen to be done smoothly, dropping triggers of the low luminosity period menu which were used for commissioning or with unacceptably large rate, and keeping or introducing triggers without any prescale factors which focus on discovery physics.

The high luminosity menu will be obtained either by tightening the threshold requirements and cuts of triggers present in the low luminosity menu, or adding new triggers, especially combinations of several signatures. Only some ideas for a tau trigger menu for a luminosity of  $\mathcal{L}=10^{33} \text{ cm}^{-2} \text{ s}^{-1}$  currently exist.

Given the current background rates, shown in Section 3, the high luminosity menu will include single high  $E_T$  signatures with threshold requirements higher than what shown in Section 3 (most probably tau100). Furthermore, the high luminosity menu will be composed mostly of combined triggers like tau35i\_xe45, tau25i\_e25i, tau25i\_mu20, 2tau35i, tau20i\_j150 and tau20i\_4j50.

Table 12: Minimum bias event rates without prescale factors. The cross section value used is  $\sigma = 70\text{mb}$  and the peak luminosity used is  $\mathcal{L} = 10^{31}\text{cm}^{-2}\text{s}^{-1}$ . Errors are statistical only.

### 5.4.1 Running at $\mathcal{L}=10^{31} \text{ cm}^{-2} \text{ s}^{-1}$

The trigger menu for a luminosity of  $\mathcal{L}=10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  covers largely SM physics channels ( $W \rightarrow \tau\nu$ ,  $Z \rightarrow \tau\tau$ ,  $t\bar{t}$ ). A fair amount of the bandwidth is given to commissioning triggers ( $< 1 \text{ Hz}$  each), which are needed to monitor trigger rates and variables used for tau lepton identification in different  $E_T$  ranges.

Table 13 gives the trigger menu proposed for initial data taking, including expected prescale factors and corresponding trigger rates, with overlap between triggers taken into account. The prescale factors are necessary to restrict the total rate from low  $E_T$  tau triggers, since there are many physics topics that need to share limited bandwidth. The initial prescale values have been determined from simulation, and will be optimised based on experience with early data. Event yields for several tau-based physics topics are shown in Table 14. In this table the results of only one typical trigger are reported for a set of triggers, corresponding to the one currently considered as the most suitable for the physics signals targeted at low luminosity. However, as physics simulation studies are progressing and as background rates are verified on data, it is likely that the trigger menu will be modified.

## 6 Summary

This note describes in detail the ATLAS tau trigger system, which is dedicated to the selection of hadronic decays of tau leptons. These results are obtained from simulations prior to LHC operations. In the selection at L1, energy deposition in the e.m. and hadronic calorimeters are used, while at L2 and EF calorimeter shower shape and energy information is combined with tracking information from the Inner Detector. At design luminosity, tau triggers are envisaged to be used without prescale factors to select single tau trigger candidates with  $E_T$  above 100 GeV. The events with tau trigger candidates with lower  $E_T$  will be selected using combined triggers which employ tau signatures in conjunction with missing  $E_T$  electron, muon, jet or another tau signatures. The largest contribution to the rate will be misidentified low  $E_T$  QCD jets, that are narrow and contain few particles mimicking hadronic decays of tau leptons.

In the first months of LHC operation a low luminosity of  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  is anticipated, and the data will primarily be used for commissioning the detector and trigger system. At that time the main focus of tau triggers will be on Standard Model physics such as  $W \rightarrow \tau\nu$ ,  $Z \rightarrow \tau\tau$  and  $t\bar{t}$  events with hadronic decays of tau leptons in the final state. The typical tau trigger efficiency at low luminosity for generated tau leptons reconstructed by the algorithms of the offline reconstruction is expected to be around 80% for a wide range of physics channels, resulting in a total tau trigger rate of 28 Hz.

# Physics Performance Studies and Strategy of the Electron and Photon Trigger Selection

## Abstract

This note gives an overview of the implementation and performance of the electron and photon selection by the ATLAS trigger system. Trigger menus for commissioning as well as for the first physics run are presented together with the strategy for the early data taking phase. The physics performance in terms of selection efficiency and background rejection has been estimated using Monte Carlo simulations for various luminosity scenarios. An example of a method to determine trigger efficiency from real data using  $Z \rightarrow ee$  events is discussed.

## 1 Introduction

This note gives an overview of the implementation and performance of the electron and photon selection by the ATLAS trigger system. Electron and photon trigger baseline signatures and menus for LHC commissioning and first physics run are presented. The principles that have determined their design are:

- Coverage of the physics needed for commissioning the trigger and detector systems as well as the offline reconstruction.
- Coverage of the physics channels that allow standard model studies and searches for new physics.
- Keeping the rates within the allowed bandwidth.

Events with electrons and photons in the final state are important signatures for many physics analyses envisaged at the LHC. A good selection by the electron/photon ( $e/\gamma$ ) triggers will be important for many analyses from searches for new physics, such as the Higgs boson, SUSY,  $Z'$  boson to standard model (SM) precision physics such as top quark and  $W$  boson mass measurement, rare  $B$  decays, etc. In the early running processes such as  $Z \rightarrow ee$ ,  $J/\psi \rightarrow ee$ ,  $W \rightarrow e\nu$  and  $\gamma$ -jet events will be crucial for the understanding of the detector. These decays are important benchmark channels for the calibration, alignment and monitoring of the detector performance. The  $e/\gamma$  trigger needs to cover the transverse energy range between a few GeV and several TeV. An overview of some relevant physics channels with electrons and photons in the final state, classified according to the corresponding transverse energy thresholds is given in Table 1.

To achieve this physics reach the trigger algorithms have to be optimized in terms of physics performance (signal efficiency, background rejection) and system performance (execution time, data requirements, etc). The trigger menu has to ensure a good selection of the above physics channels within the allocated rate for the various luminosities during LHC running.

In the following sections the implementation, performance and selection strategy are described in detail. Section 2 explains how  $e/\gamma$  candidates are reconstructed and selected at the different trigger levels. Section 3 presents the selection strategy for LHC start-up, describing the schema currently envisaged for: commissioning, first menu for an initial luminosity of  $L \sim 10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  and the subsequent development towards higher luminosity scenarios. In Section 4 the performance of the various electron and photon triggers for a startup luminosity of  $L \sim 10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  and a luminosity scenario of  $L \sim 10^{33} \text{ cm}^{-2} \text{ s}^{-1}$  is discussed. Examples of trigger efficiencies for physics processes with electrons and photons in the final state over the transverse energy ( $E_T$ ) spectrum from a few GeV up to several TeV are included. A discussion of the robustness of the trigger selection follows in Section 5. Section 6 explains how the trigger efficiency will be determined from real data using  $Z \rightarrow ee$  events.

Momentum range	Examples of some important processes
low $p_T \sim 5\text{--}15$ GeV	$B_d \rightarrow J/\psi K_s^0 \rightarrow ee\pi\pi$ $B_s \rightarrow K^* \gamma$ $J/\psi \rightarrow ee$ , Drell-Yan
high $p_T \sim 20 - 100$ GeV	$H \rightarrow \gamma\gamma$ (for $m(H) < 130\text{ GeV}$ ) $H \rightarrow ZZ^{(*)} \rightarrow eeee, ee\mu\mu$ (for $130 < m(H) < 700$ GeV) top physics, $Z \rightarrow ee, W \rightarrow e\nu$ , direct photon production
very high $p_T \sim 100 - 1000$ GeV	$Z' \rightarrow ee, W' \rightarrow e\nu$ $G \rightarrow \gamma\gamma, G \rightarrow ee$ , $pp \rightarrow ee^* \rightarrow ee\gamma$

Table 1: Examples of some important processes requiring a good electron and photon trigger selection

## 2 Electron and photon trigger selection

In this section the electron and photon trigger reconstruction and selection are described. The reconstruction and selection variables for each of the trigger levels are summarized in separate subsections.

### 2.1 L1 selection

At L1 trigger information from the electromagnetic (EM) and hadronic calorimeter system in the form of so-called trigger towers is used. A trigger tower has a dimension  $\Delta\eta \times \Delta\phi \sim 0.1 \times 0.1$ . In this region all the cells are summed over the full depth of either the electromagnetic or hadronic calorimeter. The L1 selection algorithm for electromagnetic clusters is based on a sliding  $4 \times 4$  window of trigger towers which looks for local maxima [1].

Figure 1: L1 calorimeter trigger schema, showing how trigger towers (each spanning a  $0.1 \times 0.1 \eta \times \phi$  region) are used to determine the energy for the electromagnetic cluster as well as for the electromagnetic isolation, hadronic core and hadronic isolation.

The trigger object is considered to contain an electron or photon candidate if the following requirements are satisfied:

- The central  $2 \times 2$  ‘core’ cluster consisting of both EM and hadronic towers is a local  $E_T$  maximum. This requirement prevents double counting of clusters by overlapping windows.

- The most energetic of the four combinations of two neighboring EM towers passes the electromagnetic cluster threshold.

Figure 1 shows the L1 trigger tower schema used to determine the L1 selection variables. Isolation requirements can be imposed if required to control the rate:

- $E_{isol}^{EM}$ : The total  $E_T$  in the 12 EM towers surrounding the  $2 \times 2$  core cluster is less than the electromagnetic isolation threshold.
- $E_{core}^{HAD}$ : The total  $E_T$  in the 4 towers of the hadronic calorimeter behind the  $2 \times 2$  core cluster of the electromagnetic calorimeter is less than the hadronic core threshold.
- $E_{isol}^{HAD}$ : The total  $E_T$  in the 12 towers surrounding the  $2 \times 2$  core cluster in the hadronic calorimeter is less than the hadronic isolation threshold.

The distributions of these isolation variables for signal and background are shown in Fig. 2 from Monte Carlo simulations. For signal, single electrons with an  $E_T$  between 7 and 80 GeV with a flat distribution are used (solid line, hatched histogram). In comparison, background candidates from a simulated sample of QCD background (referred to as dijets) with  $E_T > 17$  GeV are shown (dashed line, hollow histogram). Most of the samples discussed in this note, unless otherwise specified, use the Pythia 6.403 [2] Monte Carlo event generator. The ATLAS detector Monte Carlo simulation is based on GEANT4 [3]. The Monte Carlo simulations store details of the generated particles including the type and kinematic variables, this so-called *MC-Truth* information can then be used as a control in subsequent analyses of the simulated data. In this case the truth information has been used to guarantee that no real electrons are included in the background distributions in Fig. 2. The distributions shown have been normalized to unit area. It can be seen that isolation, in particular L1 EM isolation, provides a good handle to reduce jet background rate, typically needed at low transverse energy thresholds. As isolation depends on the topology and energy distribution of the event, as well as on other parameters such as luminosity and beam conditions, isolation cuts need to be well understood and applied carefully during data taking.

Figure 2: L1 isolation variables for single electrons with an  $E_T$  between 7 and 80 GeV with a flat distribution (solid line, hatched histogram). In comparison, background candidates from the  $E_T > 17$  GeV dijet sample are shown (dashed line, hollow histogram). For the background, only clusters that do not match to a true electron within a  $\Delta R$  cone of 0.1 are considered. The distributions for electromagnetic isolation (left), hadronic core energy (middle), and hadronic isolation (right) are shown.

## 2.2 L2 selection

L2 is seeded by the L1 EM Region of Interest (RoI). Thus L2 receives the reconstructed L1 object with the  $\eta$  and  $\phi$  positions and the transverse energy thresholds passed. L2 accesses a subsample of the

detector data around the given  $\eta$  and  $\phi$  position and applies trigger specific reconstruction algorithms characterized for their speed and robustness. Both photon and electron selection use the full granularity, full precision calorimeter information now available in the first selection step. The transverse cluster energy and various shower shape variables calculated in the different layers of the EM calorimeter are used to identify  $e/\gamma$  candidates. The electron selection uses in addition inner detector information. Tracks are reconstructed in the inner detector and matched to the calorimeter energy clusters. Thus track finding and track-cluster matching variables can be used to select electrons.

### 2.2.1 Calorimeter based electron and photon selection

L2 calorimeter reconstruction is seeded by the  $\eta$  and  $\phi$  positions provided by L1. Calorimeter cells in a window of size  $\Delta\eta \times \Delta\phi = 0.4 \times 0.4$  are retrieved (for more details on the data preparation see [4]). At the L2 trigger the cluster building algorithm scans the cells in the second layer of the EM calorimeter and searches for the cell with highest  $E_T$ . Subsequently, a cluster of  $0.075 \times 0.175$  in  $\eta \times \phi$  is built around this seed cell. The larger cluster size in  $\phi$  reduces the low-energy tails due to photon conversion and electron bremsstrahlung. Electrons and photons deposit nearly all of their energy in the EM calorimeter and deposit typically less than 1% of their energy into the hadronic calorimeter. In addition, showers from electrons and photons are typically smaller in the plane transverse to its direction than showers from jets. These quantities are used to select a low-background sample of electrons and photons.

In detail, the L2 electron and photon calorimeter algorithms select events base on the following quantities:

- Transverse energy of the EM cluster ( $E_T^{EM}$ ): Due to the energy dependence of the jet cross-section, a cut on  $E_T^{EM}$  provides the best rejection against jet background for a given high  $p_T$  signal process.
- Transverse energy in the first layer of the hadronic calorimeter ( $E_T^{Had}$ ): This is required to be below a given threshold. This cut is relaxed for high  $E_T$  triggers (90 GeV and above) as the leakage into the hadronic calorimeter increases with energy.
- Shower shape in  $\eta$  direction in the second EM sampling: The ratio of the energy deposit in  $3 \times 7$  cells (corresponding to  $0.075 \times 0.175$  in  $\Delta\eta \times \Delta\phi$ ) over that in  $7 \times 7$  cells is calculated:  $R_{core} = E_{3 \times 7} / E_{7 \times 7}$ . Photons and electrons deposit most of their energy in  $3 \times 7$  cells and thus the corresponding ratio is typically larger than 80 %.
- Search for a second maximum in the first EM sampling: After applying the cuts in the hadronic calorimeter and the second sampling of the EM calorimeter, only jets with very little hadronic activity and narrow showers in the calorimeter remain. The fine granularity in rapidity in the first sampling of the EM calorimeter allows checks to be made for substructures within a shower for a further rejection of background such as single or multiple  $\pi^0$ s or  $\eta$ s decaying to photons. The energy deposit in a window  $\Delta\eta \times \Delta\phi = 0.125 \times 0.2$  is examined. The shower is scanned for local maxima in the  $\eta$ -direction. The ratio of the difference between the energy deposited in the bin with highest energy  $E_{1st}$  and the energy deposited in the bin with second highest energy  $E_{2nd}$  divided by the sum of these two energies is calculated:  $R_{strips} = (E_{1st} - E_{2nd}) / (E_{1st} + E_{2nd})$ . This ratio tends to one for isolated electrons and photons, and tends to zero for photons coming for example from  $\pi^0$  decay.

Figure 3 shows typical distributions of the above shower shape variables for a signal sample of Higgs decaying into  $\gamma\gamma$  and a the dijet background sample. A clear rejection power against background of the  $E_T$  is seen for a cut above 20 GeV. The shower shape variables in the first and second EM sampling of the calorimeter provide a good discrimination power above 0.8. These shower shape variables will have a

narrower distribution for photons compared to electrons. The high granularity of the first EM sampling of the ATLAS detector permits efficient photon identification using only calorimeter information, tracking information is not used at all in the selection.

Figure 3: Selection variables for a L2 calorimeter energy cluster. The distributions are shown for signal candidates from a simulated  $H \rightarrow \gamma\gamma$  sample (dashed line) and for dijet background candidates that do not have a photon or electron matched within a  $\Delta R$  cone of 0.1 and that have at least 1 jet with  $E_T > 17$  GeV (black solid line). Both distributions have been normalized to unity. The plots show the transverse energy of the EM cluster (top left), transverse energy deposited in the first layer of the hadronic calorimeter (top right), shower shape in the  $\eta$  direction in the second EM sampling ( $R_{core}$ ) (bottom left), and the search for a second maximum in the first electromagnetic sampling ( $R_{strips}$ ) (bottom right).

### 2.2.2 Inner detector electron selection

If all the criteria of the calorimeter based electron selection are fulfilled, a search for tracks is performed in front of the cluster, electron trigger candidates are identified by the presence of a matching reconstructed tracks [5].

### 2.2.3 Combined calorimeter and inner detector based electron selection

A further rate reduction, while maintaining a high electron efficiency, can be achieved by combining the calorimeter and inner detector information. The background rate can be reduced by cutting on  $\eta$  and  $\phi$  between the EM cluster and the extrapolated track into the calorimeter. As shown in Fig. 4 these distributions are narrower for electrons than for jets. Another quantity useful for electron selection is the ratio of the cluster  $E_T$  and the track  $p_T$ . This quantity is affected by bremsstrahlung effects which cause

a tail in the  $E_T/p_T$  distribution towards high values (see Fig. 4), so it is not intended to use an upper cut on  $E_T/p_T$  in the early data-taking.

Figure 4: L2 (top) and EF (bottom) electron selection variables based on the combined calorimeter and inner detector information. From left to right the following distributions are shown: the difference in  $\eta$  (left) and  $\phi$  (middle) between the cluster and track (extrapolated to calorimeter) position. and are shown: ratio of the  $E_T$  of the EM cluster and the  $p_T$  of the reconstructed tracks (right). Distributions are shown for signal (solid line, hatched histogram) and background (dashed line, hollow histogram). The reconstructed electrons come from a  $7 < E_T < 80$  GeV sample. The background candidates come from a filtered dijet simulated sample, only candidates with no match to a truth electron within a  $\Delta R$  cone of 0.1 rad are selected.

### 2.3 EF selection

At the EF trigger level offline reconstruction algorithms and tools are used as much as possible. An important difference, however, between the offline and the EF reconstruction is that the offline reconstruction is run once per event accessing the whole detector, while the EF uses a seeded approach; runs several times per event, once for each RoI given by L2, accessing only the corresponding subsample of the detector.

Currently, in the photon trigger selection only calorimeter information is used. EM clusters are searched for and reconstructed in RoIs of size  $\Delta\eta \times \Delta\phi = 0.4 \times 0.4$ . The EF calorimeter clustering algorithm searches for a local energy maximum with calorimeter trigger tower granularity. For electron and photon reconstruction only the data from the EM calorimeter is used, in contrast with L2 where the hadronic energy is also computed. The clusters should have an  $E_T$  above a given threshold. The default cluster size used is  $0.125 \times 0.125$  in  $\eta \times \phi$  (whilst the offline reconstruction algorithms perform clustering with different window sizes, a single clustering option is used in the EF). Once found by the clustering algorithm the cluster parameters (position, energy, etc.) are computed and further refined by a set of cluster correction (position and energy calibration) tools [5]. Also, corrections for the transition region between barrel and end-cap calorimeters are possible using the information from a set of scintillators.

For electron triggers, tracks are subsequently reconstructed in the inner detector. The EF tracking currently implements an inside-out track reconstruction (track finding starts from the inner silicon de-

tectors and then is extended to the transition radiation tracker). In the future, an outside-in approach is intended to be used in the trigger in cases where photon conversions are present. There is the possibility to attempt bremsstrahlung recovery using offline tools. This option is not foreseen to run in the electron triggers for start-up but might be applied when running at higher luminosities with tighter selections. At  $L \sim 10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  bremsstrahlung effects do not affect the trigger efficiency since the selection cuts are sufficiently loose to be insensitive to the performance improvements.

Electron and photon identification in the EF is very similar to the offline [6]. Calorimeter shower shapes, leakage into the hadronic calorimeter and the  $E_T$  of the EM cluster are used for the calorimeter based selection for electrons and photons. Compared to L2 more shower shape variables are used. Together with improved calibrations this results in a further rate reduction. For electrons track-cluster matching variables, track quality cuts, transverse impact parameter and for high luminosity running potentially transition radiation information could be used to further reduce the rate.

As an example a loose electron EF selection will use the following selections: longitudinal leakage, shower shapes in the middle layer of the EM calorimeter, and very loose track-cluster matching cuts. Tighter selections might also use the shower shapes in the first EM calorimeter layer, information on the transverse impact parameter and on the track quality (number of hits in the pixels and strip silicon detectors and number of hits in the first pixel layer). Distributions for the track-cluster matching variables at EF are shown in Fig. 4. The distributions are very similar to those of the L2 track-cluster matching, but more refined algorithms are available at this stage, with more up-to-date calibration and alignment information.

### 3 Electron and photon trigger selection strategy

In this section the foreseen trigger selection strategy from the start-up phase up to physics running at nominal low luminosity is discussed. First the various commissioning steps at start-up are explained. This is followed by a discussion of a possible electron and photon trigger menu for the first physics run assuming a luminosity of  $L \sim 10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ .

When LHC turns on the trigger menus will need to provide data for commissioning and for analysis. In these paragraphs analysis is used to mean standard model measurements and searches for new physics. Typically these two objectives require very different trigger selection criteria. Commissioning usually demands loose selections to allow for more basic understanding of the detector and trigger, but loose selections accept more background events. Analysis is favoured with tight trigger selections that maximize the signal to background ratio in the allocated bandwidth. At start-up commissioning tasks would be prioritized, though signatures that provide data for a physics analysis will be included in the menu whenever possible. Following the progress on commissioning, loose trigger selections will be substituted by tighter ones that increase the analysis capabilities. The main challenge for the ATLAS trigger is the big difference (approximately six orders of magnitude) between the collision rate and the rate at which data can be stored. This imposes tight constraints on the trigger menus.

These principles used to determine the trigger menus, are developed in more detail in the following subsections, which also include early trigger menu tables.

The naming conventions for the various  $e/\gamma$  triggers used in the following sections are as follows. The name for L1 electromagnetic candidates is EM. This is followed by the  $E_T$  threshold applied for this triggers and if isolation criteria are applied an “i” is added at the end of the name. The number preceding EM indicates the object multiplicity. For example 2EM13I requires that at least two isolated electron or photon candidates are identified at L1 passing a  $E_T = 13 \text{ GeV}$  threshold. The naming conventions for L2 and EF are very similar. For example  $2\gamma 17i$  denotes a trigger which selects events in which two isolated photons are found passing a  $E_T$  threshold cut of 17 GeV at EF level. Similarly a possible e20\_xe15

trigger selects events in which at least one electron candidate with  $E_T$  ( $EF$ )  $> 20$  GeV is identified, in addition, the missing transverse energy at EF exceeds 15 GeV.

### 3.1 Commissioning

At LHC start-up an initial luminosity of  $L \sim 10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  is expected. This will allow lower  $E_T$  thresholds compared to those at the nominal LHC luminosity. The start-up menu has to provide the data samples needed to commission the trigger and detectors and at the same time provide useful data to be used for physics analysis. Therefore, the trigger has to guarantee the selection of the following standard model channels:  $W \rightarrow e\nu$ ,  $J/\psi \rightarrow ee$ ,  $\Upsilon \rightarrow ee$ , Drell-Yan, and direct photon production. For example:  $Z \rightarrow ee$ ,  $J/\psi \rightarrow ee$  and  $\Upsilon \rightarrow ee$  will provide input for the electromagnetic calibration, alignment, efficiency measurements, etc. Electrons from bottom and charm quark decays will be useful for studies of  $E/p$ . Direct photon production will provide input for the jet calibrations using  $\gamma$ -jet events where the photon and jet are back-to-back. For comparison, in the first  $100 \text{ pb}^{-1}$  of data we expect 235k of  $J/\psi \rightarrow ee$ , 40k of  $\Upsilon \rightarrow ee$ , 10k of Drell-Yan events, 10M  $b, c \rightarrow e$ , 100k direct photons and 250k of  $W \rightarrow e\nu$ .

The strategy is to apply L1 selections and run the High-Level Trigger (HLT) in pass-through mode (the selection criteria are tested and the trigger decision is recorded but no event is rejected). Table 2 shows the  $e\gamma$  triggers foreseen. This will provide the first data samples for the low and high- $p_T$  spectrum and the rates for the various  $e/\gamma$  triggers. Fig. 5 shows the expected L1  $e/\gamma$  rate for a luminosity of  $L \sim 10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  with and without isolation criteria applied as a function of the transverse energy threshold.

Trigger	L1 item	Rate w/o prescale [Hz]	Pre-scale	HLT Rate [Hz]
em5_passHLT	EM3	40000	20000	2
em10_passHLT	EM7	5000	1300	4
em15_passHLT	EM13	800	200	4
em15i_passHLT	EM13I	390	100	4
em20_passHLT	EM18	280	70	4

em25i_passHLT	EM23I	41	10	4
em105_passHLT	EM100	1	1	1
2em5_passHLT	2EM3	6500	1600	4
2em15_passHLT	2EM13	80	20	4
2em20_passHLT	2EM18	35	10	4

Table 2: ‘L1-only selection’ trigger menu items for the LHC start-up including prescale factors. Depending on the rate, prescale factors might be readjusted. The L1 selection is applied and HLT selection is run in pass-through mode.

This will provide the input, based on real data, to devise a trigger menu best suited for the first commissioning and physics run with HLT selection enabled. Note that current rate estimates are affected by an uncertainty factor of two or three coming from the theoretical uncertainties in the jet cross-section. Though the L1 pass-through triggers will mainly select background events they are useful samples and can be used to look for clusters and tracks in the whole  $\eta - \phi$  space and check that known dead and noisy channels and/or disconnected regions are correctly flagged. In addition the distributions of the  $e/\gamma$  selection variables from data can be compared to those from Monte Carlo simulations. For example, signal over background distributions will be studied for variables with good discrimination power (e.g. Rcore).

L2 and EF performance can be checked and studies undertaken to evaluate the tracking performance of the different L2 tracking algorithms.

In the next phase of the commissioning the HLT selection will be progressively enabled. Several mon-

Figure 5: L1 rate for single (left) and double (right)  $e/\gamma$  triggers for a luminosity of  $L \sim 10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ . The open correspond to non-isolated triggers. Errors are statistical only.

itoring triggers will be kept, though with increased prescale factors applied. For example, L2 and EF in pass-through mode or loose  $\gamma$  triggers (to monitor tighter calorimeter cuts as well as tracking efficiency for the electron triggers).

### 3.2 First physics run

After the commissioning phase of the detector the first physics run is foreseen. At the physics run, each of the trigger menu signatures including the HLT will be enabled as soon as the understanding of the detector and trigger allow. Table 3 gives an overview of the main electron and photon physics triggers. The aim is to select events with at least one electron above  $\sim 10 \text{ GeV}$  or one photon above  $\sim 20 \text{ GeV}$ , in addition to the relevant double object triggers, e.g. for selecting  $J/\psi$ ,  $\Upsilon$ , and  $Z$  events.  $J/\psi \rightarrow ee$  and  $\Upsilon \rightarrow ee$  events are particularly demanding events for the trigger system. The trigger rates errors for each trigger menu are statistical. Due to their relatively low masses, the electrons produced in the  $J/\psi$  and  $\Upsilon$  decays are very soft (with an average transverse momenta of less than  $5 \text{ GeV}$ ). This poses a huge challenge to the L1 calorimeter trigger. Its performance at the low-energy end is limited by the noise of typically  $0.5 \text{ GeV}$  per RoI. A  $3 \text{ GeV}$  threshold is the limit for the L1 trigger. The  $6.5 \text{ kHz}$  L1 output rate for  $2e5$  makes it one of the biggest consumers of the total bandwidth.

To keep the rate at an acceptable level selections for the electron triggers at low- $p_T$  (e.g.  $2e5$ ) have to apply tighter HLT selections compared to the higher- $p_T$  triggers. A prescaled  $e5$  trigger will allow measurement of the efficiencies and optimization of the selection cuts. A range of signatures is foreseen in the trigger menu to adapt to running conditions. If the trigger rate should prove to be too high back-up items with higher thresholds are included and/or prescale factors can be adjusted. Note, the uncertainties related to the detector response and the theoretical uncertainties on the jet cross-section. To ensure the selection of important physics channels, redundant triggers are present. As an example Table 4 shows the various triggers which will be useful for triggering on  $W \rightarrow e\nu$ , these include triggers which combine electrons and missing transverse energy.

Signature	L1 item	EF selection	L1 Rate	Pre-scale	HLT Rate	Motivation
e10	EM7	medium	5.0 kHz	1	21 Hz	$e^\pm$ from b,c decays, E/p studies
$\gamma$ 20	EM18	loose	0.3 kHz	1	$5.4 \pm 0.2$ Hz	direct photon production, jet calibration using $\gamma$ -jet events, high- $p_T$ physics
e20	EM18	loose	0.3 kHz	1	$4.3 \pm 0.2$ Hz	high- $p_T$ physics, $Z \rightarrow ee, W \rightarrow e\nu$
em105_passHLT	EM100		1 Hz	1	$1.0 \pm 0.1$ Hz	New physics, check for possible problems
2e5	2EM3	medium	6.5 kHz	1	6 Hz	$J/\psi \rightarrow ee, Y \rightarrow ee$ , Drell-Yan production
2 $\gamma$ 10	2EM7	loose	0.5 kHz	1	$< 0.1$ Hz	di-photon cross-section
2e10	2EM7	loose	0.5 kHz	1	$0.4 \pm 0.2$ Hz	$Z \rightarrow ee$

Table 3: Summary of the main electron and photon triggers envisaged for the first physics run at  $L \sim 10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ . In this table the main physics triggers are listed including their expected rates and their physics motivation.

Signature	L1 item	EF selection	Pre-scale	Rate [Hz]	Motivation
e20	EM18	loose	1	$4.3 \pm 0.2$	main physics trigger
$\gamma$ 20	EM18	loose	1	$5.4 \pm 0.2$	redundancy, check of tracking eff. and performance
e15_xe20	EM13_XE20	loose	1	$1.0 \pm 0.4$	access to lower $p_T$ -range
e10_xe30	EM7_XE30	medium	1	$0.3 \pm 0.3$	access to lower $p_T$ -range
e20i	EM18I	loose	1	$2.8 \pm 0.1$	backup if rate too high
e25i	EM23I	loose	1	$1.4 \pm 0.1$	backup if rate too high
e20_xe15	EM18_XE15	loose	1	$1.6 \pm 0.1$	backup if rate is too high
$\gamma$ 20_xe15	EM18_XE15	loose	1	$1.9 \pm 0.2$	backup if rate is too high, check tracking eff and performance

Table 4: Summary of the main and redundant triggers for selecting  $W \rightarrow e\nu$  events foreseen for the  $L \sim 10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  trigger menu.

### 3.3 Electron and photon trigger menus

This section collects detailed examples of the foreseen trigger menus. Table 5 shows a summary of the trigger menu for the first physics run assuming a luminosity  $L \sim 10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ . Each row corresponds to a different trigger signature. The convention to interpret the name of a trigger signature is explained in Section 3. For each signature the table has three blocks of information. The first block of three columns gives L1 information:

- Name of the L1 trigger item. Which includes the transverse energy threshold required and an "I" if isolation cuts (as described in Section 2.1) are applied.
- Prescale factor applied after L1 selection.
- Corresponding rate after prescale factors applied.

The second block of three columns summarizes the EF:

- Tightness of the EF selection cuts.
- Prescale factor.
- Corresponding HLT rate.

The last column illustrates some relevant channels that the corresponding trigger would collect.

Tables 6 and 7 have the same structure described above. Table 6 gives examples of trigger signatures with tighter selection cuts, to be used if the rates given by the ones presented in Table 5 are too high.

A summary of the main trigger signatures foreseen for a higher luminosity scenario of  $L \sim 10^{33} \text{ cm}^{-2} \text{ s}^{-1}$ , is shown in Table 7.

## 4 Electron and photon trigger physics performance

In this section the performance of the different signatures is presented with trigger efficiency plots as a function of transverse energy  $E_T$  and pseudo-rapidity  $\eta$ .

The trigger efficiency optimization of a given electron/photon trigger menu is a compromise between several factors: trigger efficiency for signal, QCD background rate which depends on the luminosity (constrained by allowed HLT bandwidth) and constraints of the average execution time at each trigger level. The performance of the main electron and photons triggers has been evaluated for a start-up luminosity of  $L \sim 10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  and for a higher luminosity of  $L \sim 10^{33} \text{ cm}^{-2} \text{ s}^{-1}$ . In sections 4.2 and 4.3 the performance of these triggers is discussed for electrons and photons respectively. For these studies two types of events have been used, the so called ideal and the misaligned detector geometry. The misaligned detector geometry simulation contains expected distortions of the detector and in addition contains extra material coming from a more accurate description of cooling, powering and cabling services. This increases significantly the amount of material in the region  $1.4 < |\eta| < 1.8$  compared to the ideal geometry, thus affecting the calorimeter energy calibration which was extracted using the ideal geometry. In section 4.2 a comparison is given for the performance based on these two layouts for one of the electron triggers.

### 4.1 Data Samples

The signal samples used for electron and photon trigger performance studies in this note are summarized in Table 8. For the electron and photon trigger optimization and turn-on curves samples with an energy range of  $7 < E_T < 80 \text{ GeV}$  (flat energy spectrum) are used.

Signature	Item	Level-1		Sel- ection	HLT		Motivation
		Pre- scale	Rate [kHz]		Pre- scale	Rate [Hz]	
e5	EM3	60	0.7	medium	1	$4.8 \pm 0.2$	$J/\Psi \rightarrow ee, Y \rightarrow ee$ , Drell-Yan
2e5	2EM3	1	6.5	medium	1	6	$J/\psi \rightarrow ee, Y \rightarrow ee$ , Drell-Yan
Jpsiee	2EM3	1	6.5	medium	1	1	$J/\psi \rightarrow ee, Y \rightarrow ee$
e10	EM7	1	5.0	medium	1	21	$e^\pm$ from b,c decays, E/p studies
$\gamma$ 10	EM7	1	5.0	medium	100	$0.6 \pm 0.1$	$e^\pm$ direct photon cross-section, e-no-track trigger
e10_xe30	EM7_ XE30	1	0.2	medium	1	$0.3 \pm 0.3$	access low $p_T$ -range for $W \rightarrow e\nu$
2 $\gamma$ 10	2EM7	1	0.5	loose	1	$< 0.1$	di-photon cross-section

Photon+Jet6	560-1120	misaligned

Table 8: Main electron/photon signal and physics samples.

$p_T(\text{hard})$	jet filter	$\sigma$ after filtering
6GeV	default	4.214 mb
7GeV	loose	6.531 mb
7GeV	default	3.788 mb
17GeV	loose	0.373 mb
17GeV	default	0.191 mb
35GeV	loose	0.039 mb
35GeV	default	0.021 mb

Table 9: Main background samples and their cross sections.

Background samples and their expected cross-sections are summarized in Table 9. The minimum bias Monte Carlo sample corresponds to our best knowledge of the inclusive expected backgrounds (including both hard and soft processes). Unfortunately most of the events in it are at low energies  $< 7$  GeV and it is not very practical for high-statistics studies above this energy. To increase our efficiency for the events with electrons and photons we use a filter which is based on the combination of the EM cluster  $E_T$  cut and the area of the EM cluster. Two types of the filter, “default” and “loose” are used to check for the potential biases in the L1 trigger rate which could occur if the area required by the filter is too small or the  $E_T$  cut too high for the trigger threshold studied.

For the trigger rate studies in the intermediate energy range 6 – 17 GeV we use minimum bias events with a transverse energy above 6 GeV and default filter (a rejection factor of 16.61). Above 17 GeV the dijet processes become the most prominent background for electrons and photons. Dijet samples with a threshold cut of 15 GeV and different level of filters (default and loose respectively) are used to provide background estimates in that area (the physics processes such as W, Z, direct photons have been added). For the very high energy studies dijet samples with a threshold cut of 35 GeV are used.

For this note two detector geometries are used:

- “ideal” which uses the detector geometry to our best knowledge.
- “misaligned” where the detector has misalignments and material distortions.

The misaligned detector geometry has been generated to test the robustness of our reconstruction and trigger algorithms with respect to incorrect alignment and calibration of the detector due to unexpected excess of material. Extra material was added in the misaligned detector geometry with respect to the ideal:

- For the inner detector, extra thin layers of material were added in the azimuthal angle range of  $0 < \phi < \pi$  only. The amount of material added varies in the  $z$  direction, from a few percent of  $X_0$  on the active detector elements up to 1  $X_0$  in the areas occupied by services.
- For the electromagnetic calorimeter, more material was added in the barrel cryostat ( $\sim 8 - 11\%$  of  $X_0$ ), between the barrel presampler and first calorimeter sampling ( $\sim 5\%$   $X_0$ , always for positive  $\phi$ ), and in the gap between the barrel and endcap cryostats (factor 1.7 increase of material density).

## 4.2 Electron trigger performance

The performance of the electron trigger has been evaluated for the trigger menus foreseen for the luminosity expected at early running  $L \sim 10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  and for a higher luminosity of  $L \sim 10^{33} \text{ cm}^{-2} \text{ s}^{-1}$ . The trigger efficiencies are quoted with respect to electrons identified with offline particle identification cuts [6]. The trigger efficiencies have been evaluated using simulated single electron samples with a transverse energy spectrum of  $7 < E_T < 80$  GeV and other physics samples such as  $J/\psi \rightarrow ee$ ,  $Z \rightarrow ee$ , etc. Rates have been estimated using simulated dijet events or minimum bias background depending on the trigger thresholds.

In the following the performance for the start-up trigger items e5, e10, e20, e105 and for a possible e22i trigger for higher luminosity running are discussed.

Figure 6 shows the efficiencies as a function of  $E_T$  and  $|\eta|$  of the low- $p_T$  e5 trigger for the three trigger levels L1, L2 and EF. The e5 trigger menu is a trigger with prescale factor at  $L \sim 10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  and the main trigger is the 2e5 trigger, which applies the same selection cuts. The efficiencies are obtained for electrons from a misaligned detector geometry  $J/\psi \rightarrow ee$  sample. In the offline analysis these electrons typically will be identified via the “medium set” of offline “soft-electron” selection cuts (see [7] for more details). Therefore, the efficiencies shown in Fig. 6 are normalized with respect to such an offline

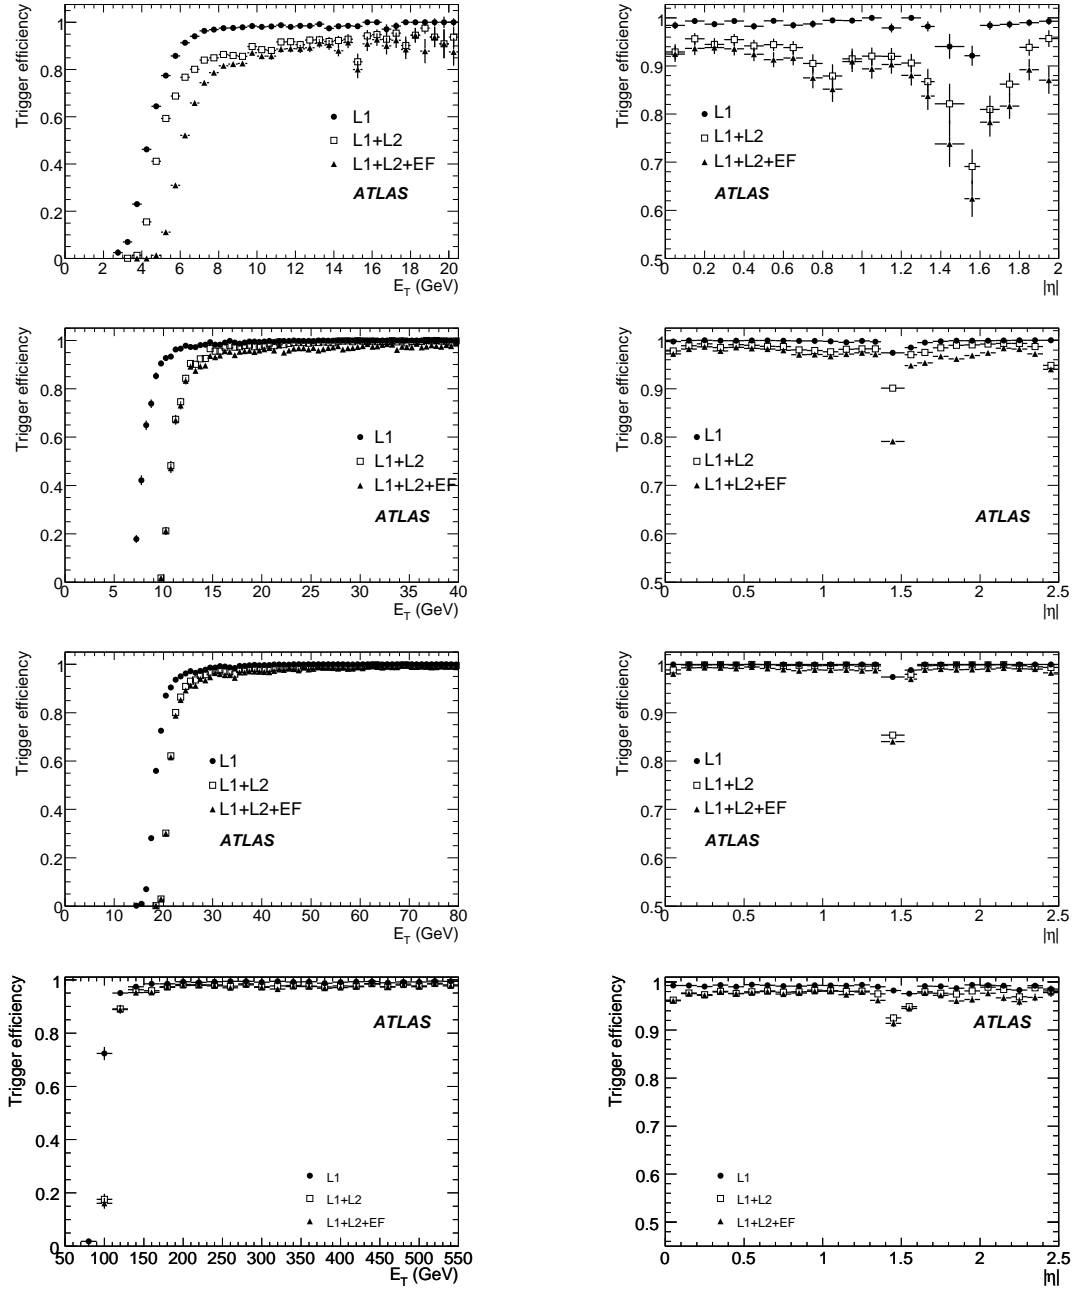

Figure 6: Trigger efficiencies at L1 (solid circles), L2 (open squares) and EF (solid triangles) as a function of true electron  $E_T$  (left) and  $|\eta|$  (right) for the e5 (top), e10 (second from top), e20 (third from top) e105 (bottom) menu items. The efficiencies are obtained from the following Monte Carlo simulated samples:  $J/\psi \rightarrow ee$  decays simulated with misaligned detector geometry for e5 trigger item,  $Z' \rightarrow ee$  (1 TeV) for e105 and single electrons simulated with ideal detector geometry for e10 and e20. Trigger efficiencies are normalized with respect to the medium set of offline soft-electron cuts for e5, with respect to the medium set of offline electron cuts for e10 and with respect to the loose set of offline electron cuts for e20 and e105. For trigger efficiency versus  $|\eta|$  plots, an  $E_T$  cut according to the corresponding menu item has been applied: for e5  $E_T > 10$  GeV, for e10  $E_T > 15$  GeV, for e20  $E_T > 30$  GeV and for e105  $E_T > 130$  GeV. For e5 trigger item no data is shown for electrons for  $|\eta| > 2$  as this is beyond the coverage of the transition radiation tracker whose information is used for the offline electron selection. Errors are statistical only.

selection. As seen in the right figure, the efficiencies drop significantly in the transition region between the barrel and end-cap calorimeter. A better optimization of the trigger selection cuts in this region might help to recover part of the inefficiencies. Figure 6 shows L1, L2 and EF efficiencies as a function of  $E_T$  and of  $|\eta|$  of the e10 trigger, which is the lowest  $p_T$  unprescaled single electron trigger foreseen for running at  $L \sim 10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ . The e10 trigger selects events with at least one good electron candidate with  $E_T > 10 \text{ GeV}$ . The efficiencies are obtained for single electrons using ideal detector geometry and are normalized with respect to the medium set of offline electron cuts as discussed in Section 2.3. The efficiency reaches a plateau value for  $E_T$  approximately above 15 GeV and is quite uniform as a function of  $|\eta|$ , except for a 10 – 20% dip in the transition region between the barrel and end-cap calorimeters. In Fig. 7 e10 trigger efficiencies are compared for samples that use ideal and misaligned detector simulation. The biggest effects are observed at lower  $E_T$  for the turn-on curve (left) and in the region  $1.4 < |\eta| < 1.8$  (right) where a significant increase of material in the so-called misaligned geometry with respect to the ideal one was introduced. Trigger efficiency plots as a function of  $E_T$  and  $|\eta|$  for the electron triggers e20 and e105 are shown in Fig. 6. Compared to the e10 trigger signature, the e20 trigger applies looser electron identification cuts. The e105 trigger is aimed at selecting very high  $p_T$  electrons with very loose selection cuts for  $L \sim 10^{32} \text{ cm}^{-2} \text{ s}^{-1}$ . At  $L \sim 10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  this trigger will only apply the L1 selection.

For several physics channels a global trigger efficiency with respect to the offline loose selection is shown in Table 10 for each trigger level. An average trigger efficiency of  $\sim 98\%$  is obtained after the EF level trigger. An efficiency close to 100% is expected for very high  $p_T$  electrons, therefore the selection has been optimized towards this goal.

Figure 8 (left) shows L1, L2 and EF efficiencies as a function of  $E_T$  of the signature e22i, the menu item selecting an electron with  $E_T > 22 \text{ GeV}$ . The efficiencies are obtained for single electrons using ideal detector geometry are normalized with respect to a loose set of offline electron cuts as discussed in [6]. The efficiency reaches a plateau value for  $E_T$  approximately above 25 GeV.

Figure 8 (right) shows an example of trigger efficiency dependency on the offline electron identification cuts. Trigger efficiency has been determined with respect to loose, medium and tight offline electron identification selections as described in [6] for e15i. This menu item applies medium electron identification cuts at EF, therefore its efficiency with respect to loose offline reconstructed electrons is significantly lower than with respect to medium or tight offline electrons.

Figure 7: Ratio of trigger efficiencies for single electrons reconstruction in misaligned and ideal detector geometry as a function of true electron  $E_T$  (left) and  $|\eta|$  (right) for the e10 menu item. Events in the  $|\eta|$  plot are required to verify  $E_T > 15 \text{ GeV}$ . Errors are statistical only.

Figure 8: Trigger efficiencies at L1, L2 and EF as a function of true electron  $E_T$  for the e22i menu item (left). The efficiencies are obtained for single electrons using ideal detector geometry and are normalized with respect to loose set of offline electron cuts. Trigger efficiency dependency on the offline electron identification (right). Trigger efficiency for the e15i signature is determined with respect to loose, medium and tight offline electron identification selection (described in [6]). Errors are statistical only.

### 4.3 Photon trigger performance

The physics performance of the photon trigger menus presented in Section 3 has been evaluated for early running at  $L \sim 10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  and for a luminosity of  $L \sim 10^{33} \text{ cm}^{-2} \text{ s}^{-1}$ . The performance has been evaluated in terms of trigger efficiency after each trigger level using simulated single photons with transverse energies between 7 and 80 GeV. Rate estimates were calculated using dijet background simulations. A  $\gamma 20$  trigger with loose selection has been defined for the first physics run at  $L \sim 10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ . At this stage the selections still need to be understood and the photon trigger is also used to check the tracking part of the electron selection. Therefore, the same calorimeter selection cuts are used as for electrons.

Figure 9 (top right) shows the relative rate for each trigger level as a function of  $|\eta|$ . Photons in the transition region between barrel and end-cap calorimeters ( $1.37 < |\eta| < 1.52$ ) are not well measured and are excluded in the physics analysis.

The single photon trigger at  $L \sim 10^{33} \text{ cm}^{-2} \text{ s}^{-1}$  selects photons above  $E_T = 55 \text{ GeV}$ . To keep the rate under control, this trigger has to apply very tight L2 and EF calorimeter selections.

Figure 9 shows the trigger efficiencies as a function of  $E_T$  and  $|\eta|$  for the  $\gamma 55$  trigger using single photons. Only photons with  $|\eta| < 1.37$  or  $1.52 < |\eta| < 2.45$  are considered. With respect to loosely selected offline photons the  $\gamma 55$  trigger is 95.5% efficient.

The double object trigger  $2\gamma 17i$  is another of the main photon triggers for running at  $L \sim 10^{33} \text{ cm}^{-2} \text{ s}^{-1}$ . Since the single photon dataset only contains one photon per event, the  $2\gamma 17i$  trigger efficiency was estimated as the square of the single photon trigger efficiency ( $\text{Eff}_{2\gamma 17i} = \text{Eff}_{\gamma 17i}^2$ ). The overall trigger efficiency estimated from this sample is  $93.9 \pm 0.2\%$ .

Figure 9 shows the  $\gamma 17i$  turn-on curve and efficiency as a function of  $|\eta|$  using single photon events. The trigger efficiencies shown for the turn-on are normalized with respect to tight offline photon selection criteria. In addition, the photons are required to be within the region  $|\eta| < 1.37$  or  $1.52 < |\eta| < 2.45$ . This plot shows that the  $\gamma 17i$  trigger is well set up and is fully efficient at 25 GeV.

The photon trigger performance has been studied not only for single photon samples but also for several physics channels. Table 11 shows a summary of photon trigger efficiencies for simulated samples of standard model direct photon decays, Higgs decaying into two photons (low mass range 120 GeV)

Dataset (geometry)	Trigger Level	Trigger efficiency (%)
$W \rightarrow e\nu$ (misaligned) (e20)	L1	$98.2 \pm 0.1$
	L1 + L2	$96.0 \pm 0.2$
	L1 + L2 + EF	$94.3 \pm 0.2$
$Z' \rightarrow ee$ (misaligned) (e105)	L1	$99.7^{+0.3}_{-0.7}$
	L1 + L2	$98.9 \pm 0.7$
	L1 + L2 + EF	$98.8 \pm 0.7$
electrons 500 GeV (misaligned) (e105)	L1	$99.1 \pm 0.6$
	L1 + L2	$97.6 \pm 0.5$
	L1 + L2 + EF	$97.5 \pm 0.5$

Table 10: Global trigger efficiencies for the trigger items e20 and e105. The signal efficiencies are determined from several different signal samples:  $W \rightarrow e\nu$   $Z' \rightarrow ee$  and a sample of single electrons of fixed transverse energy of 500 GeV. The simulation used misaligned detector geometry. Trigger efficiencies are determined with respect to loose offline electron selection. In the  $W \rightarrow e\nu$  case the offline reconstructed electron is required to be within the  $|\eta| < 2.5$  region and to have a transverse energy above 25 GeV. Efficiencies for the e105 item are determined in the kinematic region  $|\eta| < 2.5$ , the transition region between barrel and end-cap calorimeters removed ( $1.37 < |\eta| < 1.52$ ), and with a minimum true transverse energy of 130 GeV.

Dataset (luminosity)	Trigger Level	Trigger efficiency (%)
$\gamma$ +Jet ( $L \sim 10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ ) ( $\gamma$ 20)	L1	$100.0 \pm 0.0$
	L1 + L2	$99.8 \pm 0.1$
	L1 + L2 + EF	$95.0 \pm 0.3$
$G \rightarrow \gamma\gamma$ ( $L \sim 10^{32} \text{ cm}^{-2} \text{ s}^{-1}$ ) ( $\gamma$ 105)	L1	$99.5 \pm 0.1$
	L1 + L2	$98.8 \pm 0.1$
	L1 + L2 + EF	$98.7 \pm 0.2$
$H \rightarrow \gamma\gamma$ ( $L \sim 10^{33} \text{ cm}^{-2} \text{ s}^{-1}$ ) ( $2\gamma$ 17i)	L1	$95.6 \pm 0.2$
	L1 + L2	$93.6 \pm 0.2$
	L1 + L2 + EF	$91.2 \pm 0.2$

Table 11: Trigger efficiencies after each trigger level, normalized with respect to the loose  $\gamma$  selection, for different physics channels covering a wide range in  $E_T$ . In the case of  $H \rightarrow \gamma\gamma$  standard kinematical cuts are applied in addition. For each physics process the efficiencies for the main physics trigger to select these events for a given luminosity scenario are shown.

and an exotic signature: graviton decaying into a pair of photons  $G \rightarrow \gamma\gamma$  (500 GeV).

Trigger efficiencies after each level are given. Efficiencies are determined with respect to a loose offline selection using the main physics trigger for a given luminosity to select these events. In the case of  $H \rightarrow \gamma\gamma$  standard kinematical cuts are also applied. A more detailed study of trigger efficiencies for different physics channels can be found in [8] and [9].

## 5 Trigger robustness studies

The electron/photon HLT selection must be robust against detector effects such as mis-calibration, mis-alignment, dead and noisy read-out cells or sectors, luminosity and beam conditions changes etc. This

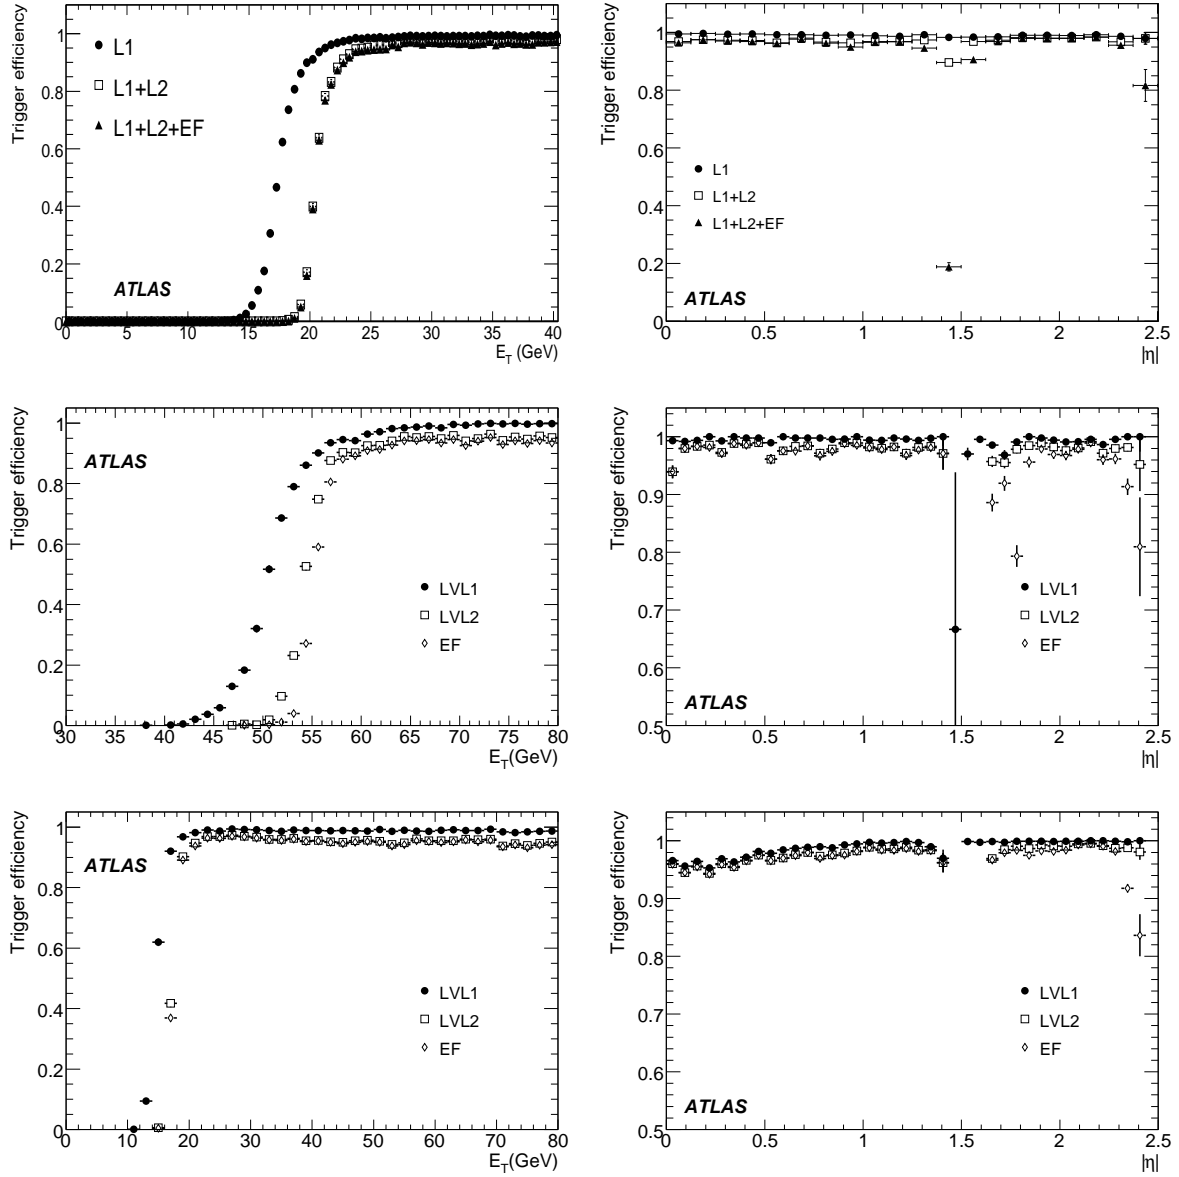

Figure 9: Trigger efficiencies at L1, L2 and EF as a function of the generated photon  $E_T$  (top left) and  $|\eta|$  (top right) for the  $\gamma_{20}$  trigger. The efficiencies are obtained for single photons simulated with ideal detector geometry and are normalized with respect to the loose set of offline photon cuts. Note, the  $|\eta|$  plot includes an additional cut of  $E_T > 23$  GeV. Trigger efficiencies at L1, L2 and EF as a function of the generated photon  $E_T$  (middle left) and  $|\eta|$  (middle right) for the  $\gamma_{55}$  trigger. The efficiencies are normalized with respect to photons with  $E_T > 55$  GeV passing the loose set of offline photon cuts. Trigger efficiencies at L1, L2 and EF as a function of the generated photon  $E_T$  (bottom left) and  $|\eta|$  (bottom right) for the  $\gamma_{17i}$  trigger. The efficiencies are normalized with respect to the tight set of offline photon cuts. Errors are statistical only.

will be especially important during early running. Depending on the bunch structure of the LHC, the effect of pile-up might already be important even at a luminosity of  $L \sim 10^{32} \text{ cm}^{-2} \text{ s}^{-1}$ . More than

Trigger Level	e12i no pile-up	e12i with pile-up	e22i no pile-up	e22i with pile-up
L1	$94.8 \pm 0.1\%$	$94.8 \pm 0.3\%$	$96.0 \pm 0.1\%$	$95.5 \pm 0.3\%$
L1 + L2	$86.8 \pm 0.2\%$	$86.7 \pm 0.4\%$	$90.2 \pm 0.2\%$	$89.4 \pm 0.4\%$
L1 + L2 + EF	$81.5 \pm 0.2\%$	$81.3 \pm 0.5\%$	$88.7 \pm 0.2\%$	$88.0 \pm 0.4\%$

Table 12: The e12i and e22i trigger efficiency from a sample of electrons of  $7 < E_T < 80$  GeV, with and without pile-up at a luminosity of  $L \sim 2 \times 10^{33} \text{ cm}^{-2} \text{ s}^{-1}$

one proton-proton interaction might occur per bunch crossing, the proton-proton interactions that are not interesting for analysis but happen in the same bunch crossing that the interesting one are typically denoted as 'pile-up'. At  $L \sim 2 \times 10^{33} \text{ cm}^{-2} \text{ s}^{-1}$  around 4.6 minimum bias events are expected per bunch crossing. In this section only the effects of pile-up and mis-calibrations due to additional detector material in front of the calorimeter are discussed.

### 5.1 Effect of pile-up

The robustness of several electron triggers was studied with simulated data which included overlapping events ("pile-up") for a luminosity  $L \sim 2 \times 10^{33} \text{ cm}^{-2} \text{ s}^{-1}$ . The presence of pile-up might have effects in reconstruction efficiency, (mostly for tracks but also for calorimeter energy clusters), as well as in the identification of isolated electrons and photons, both at the trigger and offline reconstruction level.

Table 12 shows the effect of pile-up on the e12i and e22i trigger for single electron events. As can be seen the effect of pile-up on the trigger efficiency at  $L \sim 2 \times 10^{33} \text{ cm}^{-2} \text{ s}^{-1}$  is  $\sim 3\%$ . There is a  $\sim 2\%$  effect due to the isolation criteria at L1 when tight isolation cuts are applied (e12i) and a  $\sim 1\%$  loss at the HLT level. This results show that the trigger efficiency is only slightly more affected by pile-up effects than offline electron reconstruction. The effect of pile-up on trigger performance determined with respect to *MC-Truth* electrons as well as on the background rate is being studied.

### 5.2 Effect of additional detector material

A simulated data sample consisting of single electrons as described above was used to study the effect of additional inactive material in the detector. Despite the efforts to accurately describe the detector in Monte Carlo simulation it is not expected to be perfect. The biggest and more problematic differences between simulation and reality are expected to come from the description of inactive material (for example pipes for cooling, power and signal cables, etc). Trigger robustness against those possible distortions has to be tested. Methods to identify and correct those effects have to be developed. The detector simulation used to produce this data sample included distorted material distributions in both the inner detector volume and the electromagnetic calorimeter.

A detailed description of the material added in the Monte Carlo sample is given in Section 4.1 The amount of extra material with respect to the non-distorted simulation, grows from a few percent of a radiation length at  $\eta = 0$  up to  $\sim 1X_0$  at  $1.5 < |\eta| < 1.8$ , and then decreases towards higher values of  $|\eta|$ . The amount of material added in front of the active elements was larger than the uncertainty on the material distribution.

The effect of the extra inactive material on the electron trigger was studied by comparing the trigger efficiency for  $\phi > 0$ , where extra material was added in the detector simulation, and for  $\phi < 0$ , where no extra material was added. The resulting efficiencies are shown in Fig. 10. The efficiency is plotted as a function of the kinematic variables of the electron candidate reconstructed offline. A loose offline electron selection was used for normalization.

Figure 10: Effect of additional inactive material in the detector on the electron trigger efficiency. The trigger efficiency is compared for the nominal material distribution (at  $\phi < 0$ ) and for increased inactive material (at  $\phi > 0$ ) for the electron triggers e10 and e15i. The efficiency is plotted as a function of  $|\eta|$  (left) and  $E_T$  (right) of the electron candidate reconstructed offline. The left histograms correspond to the e15i trigger only. Errors are statistical only.

It can be seen that the effect of the added material is more pronounced for the e15i signature than for e10. The e15i signature applies tighter selection cuts than the e10. In particular e15i requires the so-called medium electron identification cuts in EF, this explains the lower trigger efficiency for e15i. If trigger efficiency was computed with respect to medium or tight offline electron identification selection, the trigger efficiency would be higher, as shown in Fig. 8.

## 6 Trigger efficiency determination from real data

The trigger efficiency will need to be determined from data, reducing the dependence on Monte Carlo simulation as much as possible. Before data-taking starts some of the methods to study the trigger performance without relying on the *MC-Truth* information are being developed, an example is given in this section.

The so-called “tag and probe” method has been studied using a Monte Carlo simulation sample of  $Z \rightarrow ee$ . In the first subsection the basis of this method is explained, followed by the detailed explanation of the selection criteria chosen for this study, the trigger efficiency computation and its comparison with *MC-Truth* information. In the following subsection the performance of the method is presented for some loose trigger selections that will be used in early running.

### 6.1 Efficiency extraction method

The so-called “tag and probe” method uses offline identification of  $Z \rightarrow ee$  decays to select a clean sample of electrons, which are then used to determine the electron trigger efficiency. During data-taking a data sample to perform an analysis will be characterized by a given trigger signature being satisfied. In the study summarized in this section the data sample is defined by a given single electron trigger signature. The electron candidate that has satisfied the trigger is reconstructed and identified offline, it is the so-called “tag” electron.  $Z \rightarrow ee$  decays are selected requiring a second electron to be identified offline together with some identification conditions on the  $Z$  particle. This second electron is the so-called “probe” and it is used to study the trigger performance, since it is known to be a “good electron” it can be used to verify if electron trigger selection cuts are efficient to identify electrons.

The discrimination criteria applied to identify offline the tag and probe electrons and the  $Z$  can vary. In the following paragraphs we specify the identification criteria chosen to perform the study presented in this section.

Selection of the tag electron involves tight electron identification cuts [6] in the offline reconstruction to reduce background, and this electron must also trigger the event on its own, through a single electron trigger chain. As trigger efficiencies are measured with respect to one of the established offline electron definitions (the so-called “loose”, “medium” or “tight” electron identification set of cuts, described in [6]), this selection is the one initially applied to the probe electron.

Additionally, both offline reconstructed electrons must pass kinematic cuts, *i.e.*  $E_T > E_T^{cut}$  and  $|\eta| < 2.4$ , and not lie in the region between the barrel and endcap calorimeters ( $1.37 < |\eta| < 1.52$  region is excluded). The value of  $E_T^{cut}$  is chosen to be where the efficiency reaches its high-energy plateau in curves that show trigger efficiency versus transverse energy (such as the one shown in Fig. 11). When a trigger efficiency is plotted as a function of  $E_T$  or  $\eta$ , the relevant kinematic selection is relaxed. Finally, there are topological constraints, namely that the two electrons have opposite charge, and that their combined invariant mass lies in the range  $70 < m_{ee} < 110$  GeV.

At this point, the pair of electrons (tag and probe) may be considered for analysis. The trigger efficiency is defined by the frequency with which the probe electron in this sample passes the relevant trigger selection.

It is perfectly possible for the probe electron to satisfy the tag selection as well. In this case, the roles of tag and probe may be swapped, the tag becoming the probe and vice versa. Because the tag selection is at least as tight as the probe selection at every stage, the new probe passes the trigger selection automatically. Thus, tag and probe events fall into one of three categories:

- $N_{1f}$  events where only one electron passes the tag cuts and the probe fails the trigger selection
- $N_{1p}$  events where only one electron passes the tag cut and the probe passes the trigger selection
- $N_{2p}$  events where both electrons pass the tag selection

Counting these events, the measured efficiency may be expressed as

$$\mathcal{E}^{\text{“tag and probe”}} = \frac{N_{1p} + 2N_{2p}}{N_{1f} + N_{1p} + 2N_{2p}} = \frac{N_p}{N_T} \quad (1)$$

where  $N_p$  and  $N_T$  are defined by this equation. Assuming that the uncertainty in each variable is simply  $\sqrt{N}$ , the statistical error on  $\mathcal{E}$  is

$$\sigma_{\mathcal{E}} = \frac{1}{N_T} \sqrt{[(1 - 2\mathcal{E})N_p + \mathcal{E}^2 N_T + (1 - \mathcal{E})^2 \cdot 2N_{2p}]}. \quad (2)$$

Equation 2 may be generalized to allow for a more comprehensive uncertainty in  $N_p$  and  $N_T$ . Equations 1 and 2 can be extended to be used for differential trigger efficiency measurements.

When using Monte Carlo simulated events, the truth record (*MC-Truth*) can be used to provide another estimate of the trigger efficiency. To understand the systematic uncertainty of the tag and probe method, the fractional efficiency difference between the trigger efficiency determined using tag and probe method ( $\mathcal{E}^{\text{“tag and probe”}}$ ) and the trigger efficiency determined with respect to the *MC-Truth* information ( $\mathcal{E}_{MC-Truth}$ ) can be used:

$$\text{Fractional Efficiency Difference} = \frac{\mathcal{E}^{\text{“tag and probe”}} - \mathcal{E}_{MC-Truth}}{\mathcal{E}_{MC-Truth}}. \quad (3)$$

To reduce kinematic bias, the *MC-Truth* events have been required to satisfy the same kinematic cuts as the tag and probe events, although some bias can remain from the detector resolution. To reduce this, and

estimate just the bias from the tag and probe method itself, reconstructed quantities ( $E_T$  and  $\eta$ ) are used to determine the acceptance. Non-reconstruction of a true electron is not a problem here, as the trigger efficiency is always measured relative to some level of offline reconstruction.

Trigger Level	<i>w.r.t.</i> loose (%) (truth)	<i>w.r.t.</i> medium (%) (truth)	<i>w.r.t.</i> tight(%) (truth)
L1	$99.995 \pm 0.005$ ( $99.994 \pm 0.002$ )	$99.995 \pm 0.005$ ( $99.995 \pm 0.002$ )	$99.997 \pm 0.005$ ( $99.998 \pm 0.001$ )
L2	$98.74 \pm 0.07$ ( $98.67 \pm 0.03$ )	$99.59 \pm 0.04$ ( $99.54 \pm 0.02$ )	$99.68 \pm 0.04$ ( $99.62 \pm 0.02$ )
EF	$98.66 \pm 0.07$ ( $98.59 \pm 0.03$ )	$99.15 \pm 0.06$ ( $99.12 \pm 0.02$ )	$99.96 \pm 0.01$ ( $99.96 \pm 0.06$ )
L1 + L2 + EF	$97.41 \pm 0.09$ ( $97.28 \pm 0.04$ )	$98.74 \pm 0.07$ ( $98.65 \pm 0.03$ )	$99.63 \pm 0.04$ ( $99.57 \pm 0.02$ )

Table 13: Single object tag and probe efficiencies for the e10 selection used in the 2e10 signature, with comparison to efficiencies derived using truth information from simulation. Efficiencies are given with respect to the previous trigger level(s), as well as for the whole trigger (rows) and the given offline electron identification selection (columns). The errors given are statistical only. Errors on tag and probe values are scaled up, to correspond to  $50 \text{ pb}^{-1}$  of data. For this table, the invariant mass cut is  $70 < m_{ee} < 100 \text{ GeV}$ . A signal sample of  $Z^0 \rightarrow ee$  Monte Carlo simulation without background was used to obtain these results.

## 6.2 Efficiency extraction for early running

Early running at ATLAS will be vital for understanding the performance of the detector as well as the trigger and the offline reconstruction. There will be several single object triggers with low thresholds and loose selections that will be impossible to use later on in the experiment. Table 13 shows example results for the e10 trigger selection used to build the 2e10 signature. The single object efficiency is shown, as the tag electron has been required to pass the tighter single electron trigger e10. Both trigger signatures are listed in Table 3. Table 13 displays the relative trigger efficiency for each trigger level as well as the overall one, comparing results obtained from tag and probe method and from simulation truth information, that show a good agreement within the statistical error. Figure 11 shows these results differentially, along with the fractional efficiency difference defined in Equation 3. This shows good agreement between the two methods, and that the loose e10 trigger has high efficiency for  $Z^0 \rightarrow ee$  electrons. The results presented in this Section have been obtained from a sample of  $Z^0 \rightarrow ee$  Monte Carlo simulation without adding possible background. Studies performed adding Monte Carlo simulated background have shown that the presence of background could degrade the resolution of the method to a few percent level. The use of a low  $E_T$  threshold and the loose electron identification cuts on the probe offline selection means that backgrounds will be significantly higher than in standard data-taking at higher luminosities, in which tighter selection cuts would be applied. The  $E_T$  low threshold will, however, mean that background will be present in the invariant mass distribution of the two electrons for values smaller than the  $Z$  mass, allowing both sidebands to be used for background subtraction below the  $Z$  peak. Even with higher  $E_T$  thresholds, where only one sideband can be used, it is possible to extract the correct signal with a small additional systematic error [10].

The e20 signature foreseen for early running phase has looser electron identification cuts than the other single electron signature present in this menu, e10. Even though no isolation to other electromagnetic or hadronic activity in the calorimeters is required, the threshold of the transverse energy is

Figure 11: Single object tag and probe efficiencies for the e10 selection of the 2e10 trigger signature. The efficiencies shown are relative to a tight offline electron identification selection as described in [6], as a function of the reconstructed  $E_T$  (left) and  $\eta$  (right). The tag and probe method (points) is compared to MC truth (lines). The lower two plots show the fractional efficiency difference (see Equation 3) between the two. The number of events used corresponds to  $50 \text{ pb}^{-1}$ . For this figure, the invariant mass cut is  $70 < m_{ee} < 100 \text{ GeV}$ . Errors are statistical only. A signal sample of  $Z^0 \rightarrow ee$  Monte Carlo simulation without background was used to obtain these results.

sufficient to sustain a manageable rate. The trigger efficiencies for the different trigger levels with respect to the offline electron identification selections for the probe electron are shown in Table 14, both for the “tag and probe” method and with respect to *MC-Truth*, showing good agreement within the statistical error, and high trigger efficiencies. In Fig. 12 the trigger efficiency for e20 signature as a function of  $E_T$  and  $\eta$  is presented. It can be seen that the L2 efficiency is close to 100% with respect to the L1 efficiency already at very low transverse energy, the EF is almost 100% efficient with respect to L2. The optimization for this trigger item made to minimize the loss of efficiency in these areas, especially not losing efficiency in the HLT with respect to L1 at large transverse energy. In the bottom part of the same figure the fractional efficiency difference between the “tag and probe” and *MC-Truth* method as defined in Eq. 3 is shown, good agreement between both methods is observed.

Trigger Level	<i>w.r.t.</i> loose (%) (truth)	<i>w.r.t.</i> medium (%) (truth)	<i>w.r.t.</i> tight(%) (truth)
L1	$99.74 \pm 0.03$ ( $99.84 \pm 0.01$ )	$99.83 \pm 0.03$ ( $99.93 \pm 0.01$ )	$99.88 \pm 0.02$ ( $99.95 \pm 0.01$ )
L2	$98.55 \pm 0.07$ ( $98.48 \pm 0.03$ )	$99.48 \pm 0.04$ ( $99.44 \pm 0.02$ )	$99.58 \pm 0.04$ ( $99.53 \pm 0.02$ )
EF	$98.67 \pm 0.07$ ( $98.60 \pm 0.03$ )	$99.16 \pm 0.06$ ( $99.13 \pm 0.02$ )	$99.96 \pm 0.01$ ( $99.959 \pm 0.06$ )
L1 + L2 + EF	$97.0 \pm 0.01$ ( $96.95 \pm 0.04$ )	$98.48 \pm 0.08$ ( $98.51 \pm 0.03$ )	$99.41 \pm 0.05$ ( $99.44 \pm 0.02$ )

Table 14: Tag and probe trigger efficiencies for the e20 signature, with comparison to efficiencies derived using truth information from simulation. Efficiencies are given with respect to the previous trigger level(s), as well as for the whole trigger (rows) and the given offline electron identification selection (columns). The errors given are statistical only. Errors on tag and probe values are scaled up, to correspond to  $50 \text{ pb}^{-1}$  of data. For this table, the invariant mass cut is  $70 < m_{ee} < 100 \text{ GeV}$ . A signal sample of  $Z^0 \rightarrow ee$  Monte Carlo simulation without background was used to obtain these results.

Figure 12: Trigger efficiency from the “tag and probe” method with  $Z \rightarrow ee$  for the e20 trigger signature. The efficiencies are shown *w.r.t.* a tight offline electron selection as described in [6], as a function of the reconstructed  $E_T$  (left) and the reconstructed  $\eta$  (right). The “tag and probe” method (points) is compared with the *MC-Truth* method (solid line) for all three trigger levels, L1 (solid circles), L2 (open triangles), and the EF (solid squares). The fractional efficiency difference (see Eq. 3) between the “tag and probe” and *MC-Truth* methods is shown in the bottom two plots. The number of  $Z \rightarrow ee$  events used corresponds to  $100 \text{ pb}^{-1}$ . Errors are statistical only. A signal sample of  $Z^0 \rightarrow ee$  Monte Carlo simulation without background was used to obtain these results.

## 7 Summary

An electron and photon trigger baseline for LHC commissioning and the first physics run have been presented. Many studies and tests have been summarized, without finding any problems that could compromise the successful start-up of ATLAS data-taking. Electron and photon trigger performance have been studied in detail in a wide energy range using single electron and single photon simulated samples. Trigger efficiency dependencies on transverse energy ( $E_T$ ) and pseudo-rapidity ( $\eta$ ) have been observed and studies are ongoing to explore the possibility to minimize them. Trigger efficiencies for the  $e/\gamma$  selection have been evaluated for simulations of different physics samples such as  $H \rightarrow \gamma\gamma$ ,  $Z \rightarrow ee$ ,  $W \rightarrow e\nu$  and some exotic channels. The electron and photon trigger menus for these selections have proven to be efficient above the threshold of the corresponding transverse energy cut with respect to offline reconstruction. The corresponding background rates have been estimated to be within the allocated bandwidth. It should be noted that due to current uncertainty in the cross-sections used for background estimations, rates could vary significantly. This could require the use of tighter selections with corresponding loss of signal efficiency. Some examples of backup signatures for such situations have been shown. Trigger robustness studies have been started, and are currently being extended. Trigger reconstruction and selection efficiencies do not show significant drops with respect to offline reconstructed electrons and photons. A method of trigger efficiency determination from data using  $Z \rightarrow ee$  decays has been studied in depth. This results compare well to trigger efficiency computed with respect to Monte Carlo truth. The extension of this method to other channels and samples are being developed.

# Performance of the Muon Trigger Slice with Simulated Data

## Abstract

The overall functionality and performance of the muon trigger system with respect to data produced as part of the ATLAS Computing System Commissioning effort is described. The physics performance in terms of trigger efficiency and accepted rates is studied for the muon inclusive signatures for different luminosity scenarios. Dedicated studies on physics samples with single and double muon final states are also performed in order to evaluate the trigger efficiencies on realistic data and background rejection capabilities. Methods to evaluate muon trigger efficiencies from real data are discussed. Furthermore, strategies to use the ATLAS calorimeters to tag and select isolated muons are presented.

## 1 Introduction

Triggering and identifying muons will be crucial for many LHC physics analyses. In accordance with the ATLAS general trigger scheme, the muon trigger system has three distinct levels: L1, L2, and the Event Filter (EF). The paper discusses the software tools used for muon trigger reconstruction and the algorithm selection strategy and trigger configuration. Next, the resolution and selection efficiencies of the various muon triggers are presented, followed by a discussion of the trigger rates for various luminosities. Subsequently, the rejection of background from in-flight meson decays and selection of isolated muons using calorimeter information is discussed. Finally, the trigger performance on the di-muon final states  $Z \rightarrow \mu\mu$  and  $Z' \rightarrow \mu\mu$  is presented along with a description of plans to determine the trigger efficiency from collider data.

## 2 Detector simulation and data samples

The samples used in this paper were produced using a full GEANT4 based simulation of the ATLAS detector. The trigger simulation options included both standard and  $B$ -physics trigger simulation configurations, which correspond to the standard and the low trigger thresholds (see Section 3). The deterioration of efficiency due to the geometrical acceptance and the limited size of coincidence window are taken into account in the L1 simulation and trigger logic emulator.

Large samples of single prompt muons, simulated uniformly in  $\eta - \phi$ , with fixed  $p_T$  ranging from 2 GeV to 1 TeV, have been used to study the muon trigger performance. One of the main backgrounds for the muon trigger selection comes from in-flight decays of charged kaons and pions. This has been evaluated using samples of minimum bias events and single pions, where the mesons are forced to decay inside the Inner Detector cavity in order to facilitate the production of a sizable sample of in-flight  $\pi/K$  decays. Muon trigger rates were determined using both single muons and minimum bias events. The selection of muons using the Tile Calorimeter has been studied using low  $p_T$  (4 and 6 GeV) single muons and semi-inclusive  $b$  quark decays,  $b\bar{b} \rightarrow \mu X$ . Muon trigger studies on high- $p_T$  dimuon final states and the determination of trigger efficiency from data have been performed using  $Z \rightarrow \mu\mu$  and  $Z' \rightarrow \mu\mu$  as signal processes and  $B \rightarrow \mu\mu$ ,  $W$  boson decays,  $Z \rightarrow \tau\tau$  and top-pair events as background processes.

## 3 Muon trigger algorithms and configuration

The L1 muon trigger selects active RoIs, in the event using Resistive Plate Chambers (RPC) [1] in the barrel ( $|\eta| < 1.05$ ) and Thin Gap Chambers (TGC) [1] in the endcaps ( $1.05 < |\eta| < 2.4$ ). The

trigger algorithms look for hit coincidences within different RPC or TGC detector layers inside the programmed geometrical windows which define the transverse momentum region. A coincidence is required in both  $\eta$  and  $\phi$  projections. The information about muon candidates in both the barrel and the end-cap is transmitted to the Muon to Central Trigger Processor Interface (MuCTPI) [1], which calculates the number of L1 muon candidates for six different  $p_T$  thresholds and takes overlaps between the trigger sectors into account by using look-up-tables (LUT). There are several L1 signatures each corresponding to a different  $p_T$  threshold:

- mu0, mu5, mu6, mu8, mu10 for the low  $p_T$  selection;
- mu11, mu20, mu40 for the high  $p_T$  selection.

The integer numbers after the “mu” symbolize the required  $p_T$  threshold. L1 also provides the coordinates in  $\eta$  and  $\phi$  of the selected RoIs. The mu0 threshold represents a L1 configuration with completely open coincidence windows; it is also called the “Cosmic” threshold as it can be used to trigger on cosmic rays during the detector commissioning phase and between the LHC fills. Similar thresholds, labeled with “muXX”, have been defined for L2 and EF.

The muon HLT runs L2 and EF algorithms. It starts from the RoI delivered by the L1 trigger and applies trigger decisions in a series of steps, each refining the existing measurement by acquiring additional information from the ATLAS detectors. A list of physics signatures, implemented in the event reconstruction and selection algorithms, are used to build signature and sequence tables for all HLT steps. This stepwise and seeded processing of events is controlled by the trigger steering. The reconstruction progresses by calling feature extraction algorithms. These typically request detector data from within the RoI and attempt to identify muon features. Subsequently, a hypothesis algorithm determines whether the identified feature meets the criteria necessary to continue. The decision to reject the event or continue is based on the validity of signatures, taking into account prescale and pass-through factors. Thus, events can be rejected after an intermediate step if no signatures remain viable.

The main algorithm of the muon L2 system, muFast, runs on full granularity data within the RoI defined by L1. An optimized strategy is used to avoid heavy calculations and access to external services to reduce the execution time of the algorithm. After pattern recognition driven by the trigger hits which selects Monitored Drift Tubes (MDT) regions crossed by the muon track, a track fit is performed using MDT drift time precision measurements. The  $p_T$  evaluation is performed using LUT. Reconstructed tracks in the Inner Detector can be combined with the tracks found by muFast by a fast track combination algorithm called muComb.

The L2 algorithm (muIso) is used to discriminate between isolated and non-isolated muon candidates by examining energy depositions in the electromagnetic and hadronic calorimeters. The algorithm is seeded by muons selected by muFast or muComb and decodes LAr and Tile Calorimeter quantities in cones centered around the muon direction. For the muon selection two different concentric cones are defined: an internal cone chosen to contain the energy deposit deposited by the muon itself, and an external cone, containing energy only from detector noise, pile-up and jet particles.

A strategy for tagging muons at L2 in the TileCal is implemented in the TileMuId algorithm. It can provide additional redundancy and robustness to the muon trigger, as well as enhance the efficiency in the low  $p_T$  region. The search starts from the outermost calorimeter layer, which contains the cleanest signals, and once a deposited energy is compatible with a muon, the algorithm checks the energy deposition in the neighboring cells for the internal layers. Candidates are considered tagged muons when muon compatible cells are found following a  $\eta$ -projective pattern in all the three TileCal layers. There are two different variants of this algorithm : one (TrigTileLookForMuAlg) is fully executed on the L2 Processing Unit (L2PU) while the other (TrigTileRODMuAlg) has a core part executed on the Readout Driver (ROD).

The EF accesses the full event with its full granularity. Given the larger admissible latency, it is possible to adapt algorithms developed for the off-line reconstruction to the on-line framework, an approach that minimises algorithm development. The EF processing starts by reconstructing tracks in the Muon Spectrometer around the muons found by L2 and is done by three instances of the EF algorithm; the first instance reconstructs tracks inside the Muon Spectrometer, starting with a search for regions of activity within the detector, and subsequently performing pattern recognition and full track fitting. The second step extrapolates muon tracks to their production point. Finally the information from the first two steps is combined with the reconstructed tracks from the Inner Detector.

The hypothesis algorithms define a set of HLT trigger thresholds by applying cuts on the  $p_T$  of the muon candidate. The muon trigger efficiency is defined as

$$\frac{\text{The number of events with a triggered muon}}{\text{The number of events with a muon}} \quad (1)$$

The effective trigger thresholds are obtained in such a way that at the nominal threshold value the efficiency is 90% of the corresponding efficiency without cuts. For this reason effective thresholds are slightly lower than nominal thresholds.

## 4 L1 performance

### 4.1 Barrel muon trigger performance

As mentioned earlier, studies of muon trigger performance were conducted using simulated samples of single muon events generated over a large  $p_T$  and angular range. L1 selection algorithms show an efficiency greater than 99% for muons with  $p_T$  above threshold. The overall acceptance (82% low- $p_T$ , 78% high- $p_T$ ) is due exclusively to geometrical regions of the Muon Spectrometer not covered by the RPC. Figure 1 shows the inefficient regions corresponding to the magnet support structures ( $-2.3 \leq \phi \leq -1.7$  and  $-1.4 \leq \phi \leq 0.9$ ) and the spectrometer central crack at  $\eta \sim 0$ , not covered by RPCs. The overall loss in geometrical acceptance due to the  $\eta = 0$  crack is approximately 7% while the loss due to the support structure is about 5%. Moreover smaller inefficiency patterns are clearly visible which are due to magnetic ribs in small trigger sectors. The geometrical acceptance effects are visible also in Fig. 2 where the L1 efficiency above threshold is shown with respect to  $\eta$  and  $\phi$ .

Figure 1: L1 geometrical acceptance in the  $\eta$ - $\phi$  plane.

 Figure 2:  $\eta$  and  $\phi$  dependence of barrel trigger efficiency for single muons with a  $p_T=75$  GeV.

Threshold	Plateau Efficiency	Effective Threshold (GeV)	Sharpness(GeV)
mu6	0.82	5.3	2.2
mu8	0.82	6.1	1.9
mu10	0.82	6.7	2.2
mu11	0.78	10.9	3.7
mu20	0.78	15.3	7.1
mu40	0.78	27.8	19.7

 Table 1: Plateau efficiencies, effective thresholds, and sharpness for L1 signatures. Sharpness is defined as the difference of  $p_T$  corresponding to 90% and 10% of the plateau efficiency.

Figure 3 shows turn-on curves for low- $p_T$  and high- $p_T$  thresholds; the efficiencies at plateau and effective thresholds are summarized in Table 1.

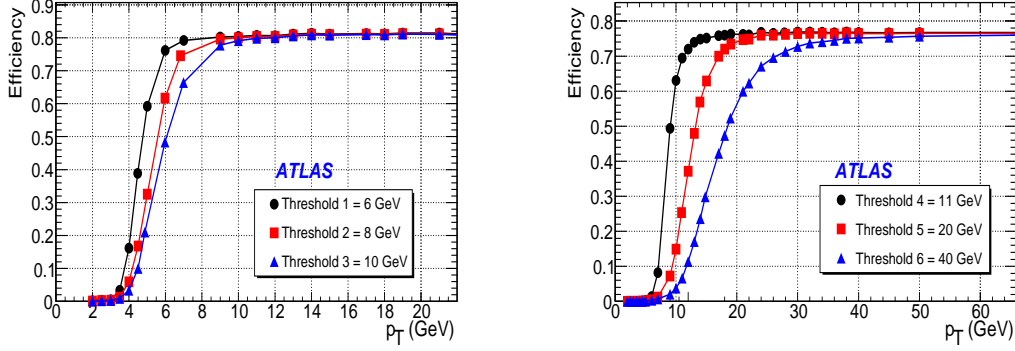

Muon tracks are deflected in the  $r - \eta$  plane under the action of the toroidal magnetic field. Their trajectories are symmetrical under charge exchange and reflection with respect to the plane  $z = 0$ , but the layout of the Muon Spectrometer is not. This asymmetry, could, in principle, produce a bias in the trigger efficiency calculation. From the single muon data sample, it was found that for muons with  $p_T$  greater than the L1 threshold the asymmetry in the efficiency is quite small ( $< 1\%$ ).

Particular attention was devoted to the study of muons with  $2 < p_T < 3.5$  GeV in the barrel region ( $|\eta| < 1.05$ ). Given the large inclusive cross-section with muons in the final state, this very low- $p_T$  region represents the most significant contribution to the total expected muon rate. Table 2 shows the fraction of these events that produce hits in the RPCs and the L1 barrel efficiency for passing the mu6 trigger. Most of the low  $p_T$  muons that pass L1 have  $|\eta| \simeq 1$ .

Muon $p_T$ (GeV)	Percentage of events with hits in RPC	L1 Efficiency
2	0.15%	$(1.4 \pm 0.1) \cdot 10^{-3}$
2.5	0.35%	$(3.4 \pm 0.1) \cdot 10^{-3}$
3	0.48%	$(4.8 \pm 0.1) \cdot 10^{-3}$
3.5	3.36%	$(33.4 \pm 0.3) \cdot 10^{-3}$

 Table 2: L1 RPC efficiency for very low- $p_T$  single muon events with  $|\eta| < 1.05$ .

 Figure 3: L1 barrel efficiency as a function of  $p_T$  for low-pt (left) and high-pt (right) thresholds.

Very low- $p_T$  muons produced in the acceptance of the TGC ( $|\eta| > 1.05$ ) sometimes give hits in the RPC ( $|\eta| < 1.05$ ) because they are strongly deflected by the magnetic field. The fraction of muons with  $|\eta| > 1.05$  that give RPC hits ranges from 46% at  $p_T = 2$  GeV to about 10% at 3.5 GeV, and is negligible above 4 GeV. The overall efficiency for such muons to pass the mu6 trigger is about  $10^{-3}$ .

Figure 4 shows L1 end-cap efficiency curves for low  $p_T$  (left) and high  $p_T$  thresholds (right). Efficiencies at the threshold and plateau are summarized in Table 3. The efficiency of mu6 at threshold is 77%, relatively lower than other cases. This is due to the limited window-size of the three-station coincidence for muons having  $p_T$  of 6 GeV. The  $\eta$  dependence of the mu6 and mu20 efficiency are

 Figure 4: The end-cap trigger efficiency curves for each  $p_T$  threshold. The left plot shows the low- $p_T$  thresholds of 6, 8, and 10 GeV and the right plot shows the high- $p_T$  thresholds of 11, 20 and 40 GeV.

$p_T$ threshold (GeV)	6	8	10	11	20	40
Threshold	77%	84%	88%	88%	92%	90%
Plateau	95%	95%	95%	95%	94%	93%

 Table 3: Trigger efficiencies at threshold and plateau for various muon  $p_T$  thresholds.

shown in Fig. 5 (at threshold) and Fig. 6 (at plateau) with respect to the sign of charge of muon  $q \times \eta$ . Because the two muon end-cap stations are made as mirror images,  $\mu^{-(+)} with  $\eta > (<) 0$  behaves the same as  $\mu^{+(-)}$  with  $\eta < (>) 0$ . The difference of efficiency between the two signs of  $q \times \eta$  is large at the geometrical boundary for muons near the  $p_T = 6$  threshold as shown in Fig. 5. One more point$

worth noting is the dip at  $\eta=2$  for the mu6 signature. Muons in the dip region pass through chambers which belong to different trigger sectors, consequently the requirement of a three-station coincidence is not satisfied and trigger efficiency is reduced. Figure 7 shows the  $\phi$  dependence of mu6 (left) and mu20 (right) trigger efficiencies at the plateau and at threshold. The effect of octant symmetry of the magnetic field is seen in the plot of the mu6 efficiency for threshold muons. For the mu6 signature at plateau and for the mu20 signature, this effect is not observed, resulting in an approximately uniform efficiency.

Figure 5:  $\eta$  dependence of end-cap trigger efficiency for mu6 (left) and mu20 (right). The solid circles represent  $q \times \eta > 0$ , the open circles represent  $q \times \eta < 0$ .

Figure 6:  $\eta$  dependency of end-cap trigger efficiency at plateau for mu6 (left) and mu20 (right). The solid circles represent  $q \times \eta > 0$ , the open circles represent  $q \times \eta < 0$ .

## 5 Performance of L2 muon algorithms

As described in Section 2, algorithm performance is evaluated on samples of single muons generated with different transverse momenta. The resolution of the inverse of the measured momentum with respect to the generated transverse momentum is studied. Due to the non-uniform magnetic field in the Muon Spectrometer it is divided into four regions according to the pseudorapidity of the muon candidate: the Barrel region with  $|\eta| < 1.05$ , and three end-cap regions with  $1.05 < |\eta| < 1.5$ ,  $1.5 < |\eta| < 2.0$ , and  $2.0 < |\eta| < 2.4$ .

For the Muon Spectrometer standalone reconstruction (muFast), the resolution of inverse  $p_T$  as a function of the muon transverse momentum is shown in Fig. 8(left). The degradation in the resolution

Figure 7:  $\phi$  dependence of end-cap trigger efficiency for mu6 (left) and mu20 (right) for muons with  $p_T = 45$  GeV. The open circles show the efficiency at threshold and the solid circles show the efficiency at plateau.

with respect to previous results [2] is caused by the realistic geometry misalignment introduced in the muon simulation. Resolution as function of  $\eta$  and  $\phi_{Loc}$ <sup>1</sup> is shown in Fig. 8(right). The degradation of the resolution in the endcap regions is evident. The muFast efficiency with respect to L1 selection as a

Figure 8:  $1/p_T$  resolution (Muon Spectrometer StandAlone) as a function of  $p_T$  (left) and  $\eta - \phi_{Loc}$  (right).

function of muon momentum are shown for mu4, mu6, and mu20 selections in Fig. 9. The low rejection at small momentum ( $2.5 < p_T < 4.5$  GeV), in particular in the barrel region, is caused by candidate tracks not pointing to the nominal interaction vertex due to large scattering angles.

Efficiencies of the MS standalone reconstruction (muFast) (mu6 trigger selection) with respect to L1 selection as a function of  $\eta$  and  $\phi_{Loc}$  for muons with  $P_T = 6$  GeV are shown in Fig. 10.

The combination of a Muon Spectrometer standalone muon candidate with an Inner Detector track found by the L2 tracking algorithms is performed by muComb. For muons with  $p_T < 50$  GeV the Inner Detector measurement has a better resolution than the Muon Spectrometer standalone measurement. Therefore, the combination of the two measurements gives better resolutions in the low- $p_T$  range. Figure 11 shows the  $1/p_T$  resolution as a function of  $p_T$  and also the resolution as function of  $\eta$  and  $\phi_{Loc}$ . The muComb efficiency with respect to muFast as a function of  $p_T$  for mu4, mu6, and mu20 is shown in Fig. 12. The problem of low rejection for low- $p_T$  muons is partially solved when the Muon Spectrometer candidates are combined with Inner Detector tracks.

<sup>1</sup> $\phi_{Loc}$  is the azimuthal angle folded up in  $[0, \pi/16]$  such to cover half of an odd MS sector ( $[0, \pi/32]$ ) and half of an even MS sector  $[\pi/32, \pi/16]$ .

Figure 9: muFast efficiency with respect to L1 selection for the mu4, mu6, and mu20 triggers for different  $\eta$  regions.

Figure 10: Efficiency of muFast as a function of  $\eta$  (right) and  $\phi_{Loc}$  (left) for muons with  $p_T = 6$  GeV.

Efficiencies of muComb (mu6 trigger selection) with respect to muFast selection as a function of  $\eta$  and  $\phi_{Loc}$  for muons with  $p_T = 6$  GeV are shown in Fig. 13.

Figure 13: Efficiency of muComb as a function of  $\eta$  (right) and  $\phi_{Loc}$  (left) for single muons with  $p_T = 6$  GeV.

## 6 Event filter performance

The full reconstruction in the Muon EF has been executed on the simulated samples described in Section 2. The reconstruction in the Muon Spectrometer is carried out by the MOORE algorithm, the extrapolation to the vertex of the muon track found in the Muon Spectrometer is performed by the MuId standalone algorithm and the combination of the tracks found in the Muon Spectrometer and in the Inner Detector by the MuId Combined algorithm.

Efficiency for single muon events is defined as the ratio of events with a reconstructed track at the EF after the execution of each reconstruction step to all events which have passed L1 and L2. The efficiency with respect to L2 as a function of muon  $p_T$  is shown in Fig. 14 for all three EF algorithms. The efficiency is defined on an event basis, and counts only once events having L2 muon-feature or EF

Figure 14: Efficiency as a function of muon  $p_T$  for MOORE, MuId Standalone and MuId Combined.

track multiplicity greater than 1. According to this definition, the efficiency to trigger an event with more than one muon is expected to be higher with respect to what is estimated here.

The efficiencies are lower for  $3 < p_T < 6$  due to multiple scattering and energy loss fluctuation effects. Moreover, in the case of MuId Combined, at very high  $p_T$  the increasing probability of muon showering is responsible for a small loss in efficiency. The efficiencies as a function of  $\eta$  and  $\phi$  show a structure, especially at low momentum, explainable with some residual dependence in  $\eta$  and  $\phi$  on the Muon Spectrometer geometrical acceptance and on the magnetic field inhomogeneities which affect less previous levels. It can be seen in Fig. 15 where the efficiency is shown for 6 GeV muons. In Fig. 16

Figure 15: Efficiency of MuId Combined as a function of  $\eta$  (left) and of  $\phi$  (right) for 6 GeV muons.

the MuId combined efficiency with respect to L2 for different thresholds is shown on the left, while the overall trigger efficiency (L1 + L2 + EF) with respect to the generated muons is shown on the right. All efficiency values are averaged over the whole  $|\eta| < 2.4$  range.

Figure 16: MuId combined efficiencies for various  $p_T$  thresholds with respect to L2 (Left) and with respect to generated truth muons (Right).

In Fig. 17, the  $1/p_T$  resolution is shown as a function of muon  $p_T$  for all EF algorithms. For a muon with  $p_T$  below 50 GeV the Inner Detector dominates the reconstruction precision so the combination of measurements greatly improves the resolutions. For a muon with  $p_T$  above 100 GeV, the Muon System dominates the measurement of the muon combined transverse momentum.  $1/p_T$  resolution as a function of  $\eta$  is shown in Fig. 18 for 20 GeV muons. The worsening of the resolution in the region  $1.0 < |\eta| < 1.5$  can be attributed to the highly inhomogeneous magnetic field in the transition regions of the Muon Spectrometer. This effect is recovered by means of the combined reconstruction which exploits the Inner Detector performance.

 Figure 17:  $1/p_T$  resolution as a function of  $p_T$  for MOORE, Muld Standalone and Muld Combined.

 Figure 18:  $1/p_T$  resolution for Muld Combined as a function of  $\eta$  for muons with  $p_T = 20$  GeV.

## 7 Muon trigger rates

The trigger rates for single muon event originating from all the physical processes expected in ATLAS were obtained using the EF MuiD combined algorithm (the events must of course also pass the L1 and L2 muon algorithms). Various luminosity scenarios expected during LHC operation (from  $\mathcal{L} = 10^{31}$   $\text{cm}^{-2} \text{s}^{-1}$  to  $10^{34}$   $\text{cm}^{-2} \text{s}^{-1}$ ) were considered. Trigger rates were typically computed by convolving, over a given  $p_T$  range, the estimated efficiencies with the cross-sections of processes representing the main muon sources at LHC. For the  $i$ -th process with cross-section  $\sigma_i$ , the rate is

$$R_i = \mathcal{L} \int \frac{d\sigma_i}{dp_T} \varepsilon(p_T) dp_T \quad (2)$$

where  $\mathcal{L}$  is the instantaneous luminosity and  $\varepsilon(p_T)$  is the muon trigger efficiency for a given  $p_T$  value. In order to take into account the  $\eta$  dependence, separate estimates for different  $\eta$  regions have been considered. An 0.5 GeV step has been applied in the numerical integration. The inclusive muon cross-sections at the LHC for  $b \rightarrow \mu$  and  $c \rightarrow \mu$  decays have been parameterized by using PYTHIA 6.403 [3]

Table 7: Single muon trigger rates at EF muon combined, for various low and high  $p_T$  thresholds, at  $\mathcal{L} = 10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ ,  $10^{33} \text{ cm}^{-2} \text{ s}^{-1}$ , and  $10^{34} \text{ cm}^{-2} \text{ s}^{-1}$ .

Figure 19: Expected EF rates at  $\mathcal{L} = 10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  for single muon processes as a function of muon  $p_T$  threshold integrated over  $|\eta| < 2.4$ .

which produces conservative estimates since it predicts cross-sections about 2 to 3 times higher than previous descriptions [4]. Top quark and W/Z decays were simulated using PYTHIA 5.7 [5]. Rates of muon in-flight decays from  $\pi/K$  mesons have been computed using the DPMJET Monte Carlo program [6].

To verify the results obtained with this method and to understand the systematics, an alternative approach, relying on event counting, has been applied to the minimum bias events (*counting method*). The convolution and counting methods give EF final rates which are in good agreement, within statistical errors due to the limited size of the minimum bias sample, starting from  $p_T$  threshold of 6 GeV. The values obtained with the counting method for lower  $p_T$  thresholds (4 and 5 GeV) are a factor of two to four less for muons from  $\pi/K$  decays with respect to the convolution (provided by DPMJET) of Eq. 2.

The rates obtained for some low and high  $p_T$  thresholds in the barrel and in the endcaps after L1, L2 muFast, L2 muComb and EF selection are shown in Tables 4, 5, 6 and 7.

In Fig. 19 the total (barrel+endcaps) EF rates at  $L = 10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  are shown as a function of the  $p_T$  threshold. In this figure, to keep uniformity among the rate results, mostly provided by PYTHIA 6.403, it has been chosen to report for the 4 and 5 GeV thresholds the EF rates obtained with the counting procedure.

### 7.1 Fake dimuon trigger rate

A single muon can be detected in multiple muon trigger sectors, causing such events to erroneously satisfy dimuon triggers. Such fake triggers can be suppressed by the overlap handling implemented in the MuCTPI. For the single muon samples used in the analysis, the fake dimuon trigger probability is defined as

$$P_{\text{fake}} = \frac{\text{Number of events with more than one muon triggered}}{\text{Number of events with a triggered muon}} \quad (3)$$

Four sources of fake double-counts have been considered :

- Barrel-Barrel double counts (BB): When a single muon is detected by two overlapping RPC sectors.

- Barrel-Endcap double counts (BE): When a single muon is detected by an overlapping RPC-TGC sector pair.
- Endcap-Endcap double counts (EE): When a single muon is detected by two overlapping “Endcap” TGC sectors.
- Forward-Forward double counts (FF): When a single muon is detected by two overlapping “Forward” TGC sectors.

The probabilities that a single muon would cause any of these fake double counts have been calculated separately. The effect of the MuCTPI overlap handling can be seen in Fig. 20, where the left plot shows the BE fake dimuon trigger probabilities for the 6  $p_T$  thresholds in the 2 to 50 GeV range without using the overlap handling, while the right plot shows the probabilities after applying the MuCTPI overlap handling.

Figure 20: Barrel-Endcap fake dimuon trigger probabilities without (a) and with (b) using the overlap handling of the MuCTPI.

The probabilities for 6 and 20 GeV single muons to produce a fake dimuon trigger if they caused a single-muon trigger, for all available L1 muon thresholds, can be seen in Table 8.

The fake probabilities can be used to calculate the single-muon trigger rates according to

$$R_{\text{fake}} = \mathcal{L} \int_{p_T^{\text{cutoff}}}^{p_T^{\text{inf}}} \sigma_p(p_T) \varepsilon(p_T) P_{\text{fake}}(p_T) dp_T \quad (4)$$

where  $\mathcal{L}$  is the instantaneous luminosity of the accelerator,  $\sigma_p$  is the inclusive muon production cross-section at LHC and  $\varepsilon$  is the L1 trigger efficiency. The fake dimuon trigger rates are presented in Table 9.

## 8 Rejection of muons from $\pi/K$ decays

Despite the large theoretical uncertainties on the rates of the muon production processes at low transverse momentum, it is clear that in flight decays of pions and kaons are a significant source of single muons and, therefore, a strategy must be developed to reject these events in the trigger. Rejection of muons from  $\pi$  and  $K$  decays at the EF is described below. A study describing rejection at L2 can be found in [7].

Trigger item	$p_T$ [GeV]	BB prob. [%]	BE prob. [%]	EE prob. [%]	FF prob. [%]
2mu4	6.0	$1.56 \pm 0.07$	$1.39 \pm 0.08$	$1.00 \pm 0.07$	$0.81 \pm 0.06$
	20.0	$1.43 \pm 0.06$	$0.13 \pm 0.02$	$0.49 \pm 0.05$	$0.55 \pm 0.05$
2mu5	6.0	$1.14 \pm 0.06$	$1.17 \pm 0.07$	$0.40 \pm 0.05$	$0.56 \pm 0.06$
	20.0	$1.43 \pm 0.06$	$0.13 \pm 0.02$	$0.49 \pm 0.05$	$0.55 \pm 0.05$
2mu6	6.0	$1.11 \pm 0.05$	$0.97 \pm 0.06$	$0.39 \pm 0.04$	$0.55 \pm 0.05$

## 8.1 Data samples and their validation

Minimum bias samples would be the most suitable for studies involving pion and kaon decays. However, the probability that pions or kaons produced in low or moderate  $p_T$  QCD scattering would decay before interacting hadronically in the calorimeters is low, between 0.1% and 1% depending on the meson  $p_T$ . In order to enhance the number of charged pion and kaon decays in the sample, the simulation of events without any charged meson with  $p_T$  above a given threshold is aborted and one  $\pi^\pm$  or  $K^\pm$  is forced to decay in the Inner Detector cavity.

The samples produced are:

- $10^6$  single pions with  $p_T > 2.5 \text{ GeV}$  and kinematics ( $p_T \times \eta$ ) generated according to a double differential cross-section of primary pions in minimum bias events
- $10^5$  minimum bias events, where one charged  $\pi$  or  $K$  with  $p_T > 2 \text{ GeV}$  per event is forced to decay;

In order to estimate cross-sections or trigger rates, the abundance of forced decays must be re-weighted on an event by event basis according to meson decay probability. In addition to the above samples, standard minimum bias events have been used as a reference to cross check the results obtained from these dedicated productions.

The muon  $p_T$  spectra observed in minimum bias events and single pions, forced to decay, were found to be consistent, after appropriate re-weighting, with each other and in agreement with previous predictions and unforced minimum bias events.

## 8.2 Rejection strategy at the event filter

The fraction of in flight decay muons retained at the EF, normalised to the L2 efficiency, for the mu6 trigger item, has been measured as a function of the muon  $p_T$ . There is a very poor rejection capability ( $\lesssim 90\%$ ) for muons coming from pion decays, which demonstrates that the standard muon identification procedures are not very sensitive, as expected, to the small kink between the pion and muon tracks. The kinematics of charged kaon two-body decays, which are the dominating kaon contribution to the muon rate, is much more favorable toward rejection due to the larger average value of the angle between the kaon and the muon tracks. In order to improve the rejection capability, additional measured parameters providing some discriminating power between background and primary muons have been identified:

- the impact parameter,  $d_0$ , of the track reconstructed in the inner tracker;
- the number of hits associated to the Inner Detector track in the Pixel Detector ( $N_{\text{hits}}(\text{Pixel})$ ), in the pixel B-layer ( $N_{\text{hits}}(\text{B}_{\text{layer}})$ ) and in the Silicon Tracker ( $N_{\text{hits}}(\text{SCT})$ );
- the ratio  $p_{T\text{ID}}/p_{T\text{MS}}$  between the transverse  $p_T$  in the Inner Detector and in the Muon Spectrometer, after back-extrapolation to the interaction point and correction for the measured energy loss in the calorimeters;
- the  $\chi^2_{\text{matching}}$  of the matching between the track parameters as reconstructed in the Muon Spectrometer and in the Inner Detector.

The discrimination power of each variable has been studied by measuring the fraction of accepted events as a function of the cut applied for both isolated muons and fake muons above a given  $p_T$  threshold. The results, shown in Fig. 21, are based on the simulations of single muons and single pions with forced decays. For each variable, the fraction of events retained after the cut is normalised to the number of events passing the EF reconstruction before the application of any hypothesis algorithms. From the analysis of the exclusive rejection power of the individual variables, the set of cuts listed below have been defined. These cuts try to minimize the efficiency loss for prompt muons while reducing the background:

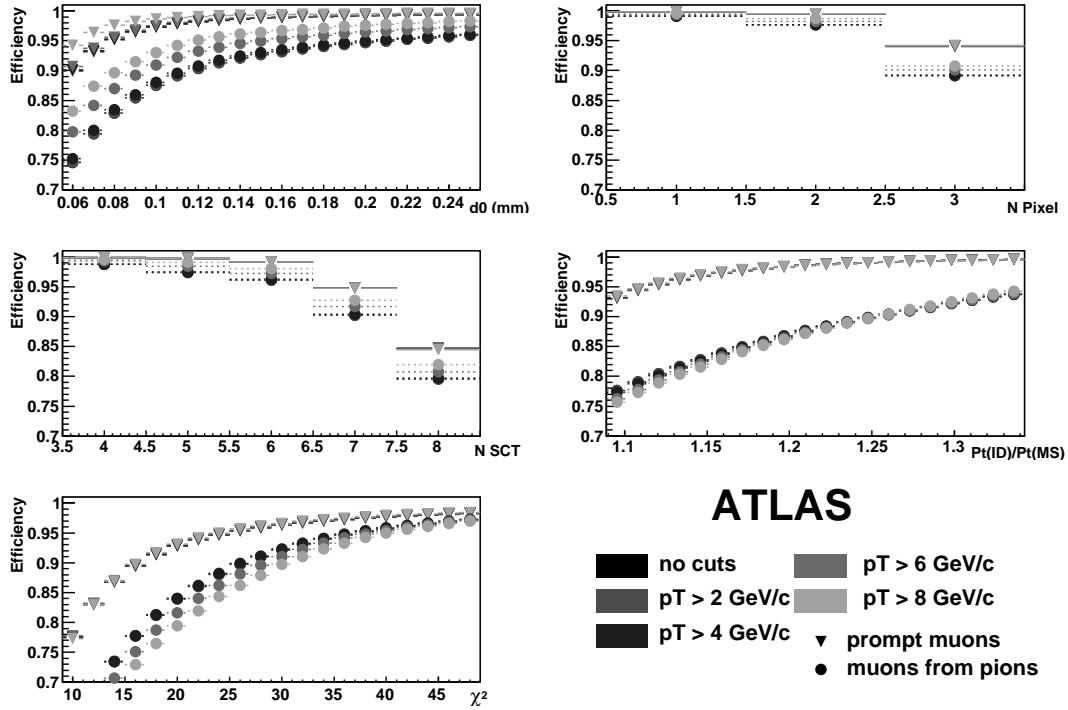

Figure 21: Efficiency for prompt muons and muons from pion decays as a function of the cut on some discriminating variables.

- $|d_0| < 0.15$  mm,  $N_{\text{hits}}(\text{B}_{\text{layer}}) \geq 1$ ,  $N_{\text{hits}}(\text{Pixel}) \geq 3$ ,  $N_{\text{hits}}(\text{SCT}) \geq 6$ ,
- $P_{\text{TID}}/P_{\text{TMS}} < 1.25$ ,  $\chi^2_{\text{matching}} \leq 26$ .

In particular, these values have been chosen by considering efficiency and background rejection at  $p_T = 4$  GeV. It is assumed that cuts will be optimized for each muon item in the trigger menu.

From the application of these cuts on the reference sample of events accepted at the EF, the efficiency for prompt muons and in flight decay muons shown in Fig. 22 have been obtained. A loss of efficiency between 25% at the 4 GeV threshold and 10% at 20 GeV correspond to a reduction in background of 65% and 75%, respectively. The rejection achieved for kaon decays is slightly better than that achieved for  $\pi$  decays, as expected from the different decay kinematics. These results are derived from nominal detector performance and algorithm resolutions. However, they demonstrate that cuts can be adjusted to obtain reasonable trigger rate at the very low  $p_T$  threshold of 4 GeV which is reached mostly by reducing uninteresting events at the cost of some efficiency loss for prompt muons. An optimization of the cuts, with specific tuning for each trigger element, will eventually further improve the signal to background ratio.

## 9 Muon isolation

### 9.1 Optimization procedure

The L2 isolation algorithm is seeded by either muFast or muComb. The algorithm decodes LAr and Tile Calorimeter quantities (i.e. transverse energy deposit or sums of calorimetric cells above a predefined energy threshold) in cones centered around the muon direction. The geometrical definition of these

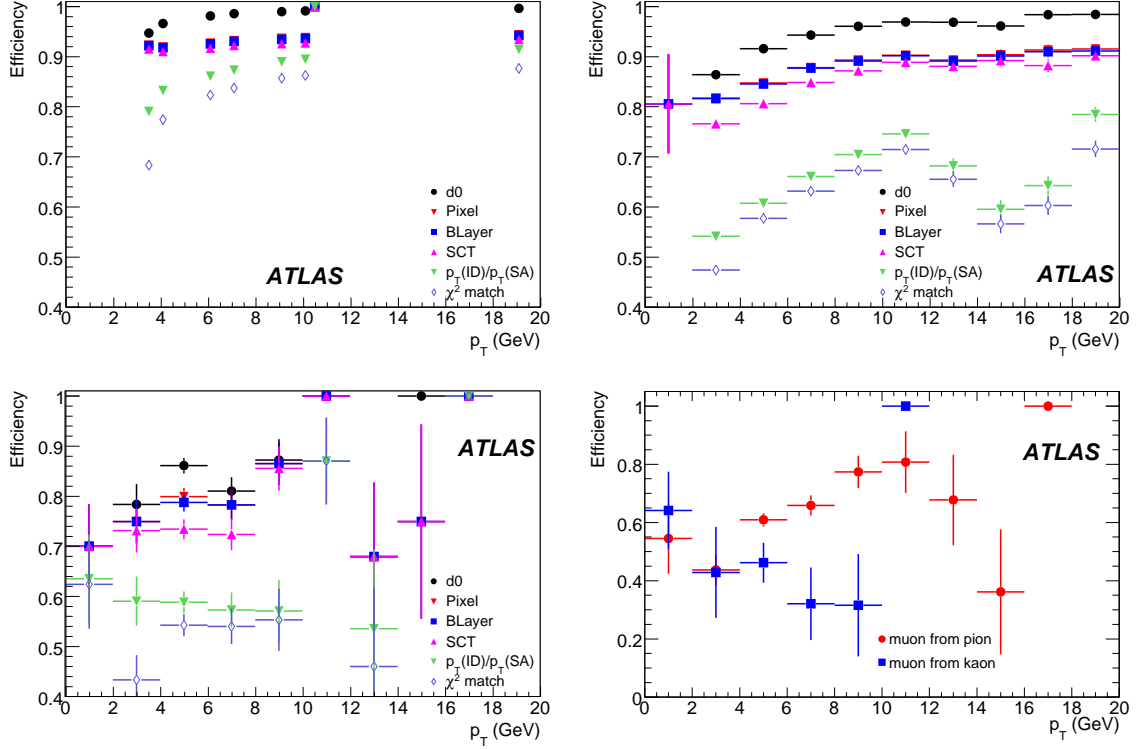

Figure 22: EF efficiency as a function of  $p_T$  for different rejection cuts for prompt muons (a), muons from single pion decays (b), minimum bias events (c and d). In (c)  $\pi/K$  contribution has been separated. Each efficiency curve shows the data reduction obtained by the addition of the corresponding cut to the overall selection procedure. The specific values of the cuts are discussed in the text.

cones is given by the condition  $\Delta R < \Delta R_{MAX}$ , where  $\Delta R = \sqrt{(\Delta\eta)^2 + (\Delta\phi)^2}$ , and  $\Delta\eta$ ,  $\Delta\phi$  are the distances in pseudorapidity and azimuthal angle between the calorimetric cell and the cone axis. Because the muon itself contributes to the energy deposit inside the cone, to improve the discriminating power of the isolation algorithm, two different concentric cones are defined: an internal cone chosen to contain the energy deposit released by the muon itself, and an external one, supposed to include contributions only from detector noise, pile-up and jet particles if present. The optimization of the muon isolation algorithm consists of determining the optimal size of the inner and outer cone radius, the values of the cell energy thresholds, used to compute the transverse energy and number of cells sums, and the isolation requirements.

Table 10 summarizes the samples that have been used to optimize the algorithms and to measure their performance. Half of the events in the samples number 1 and 2 in the Table have been used as signal and background, respectively, in the optimization of the algorithm parameters, the remaining events for sample 1 and 2 and the other samples listed in the Table have instead been used to estimate the algorithm performances.

Only the parameters relative at the muon trigger in the barrel region ( $|\eta| < 1.05$ ) have been studied. Simulation of the electronic readout noise for both LAr and Tile Calorimeters has been also included.

A muon track passing through the calorimetry will deposit energy in the cells which immediately surround it. The deposited energy can be contained within some cone of radius  $R_{Inner}$ , where  $R = \sqrt{\Delta\eta^2 + \Delta\phi^2}$ . If the muon is isolated, there will be little energy deposited in cells which lie in an outer

	Process	Generator	Number of events
1	$Z \rightarrow \mu^+ \mu^-$	Pythia	$1 \cdot 10^4$
2	$b\bar{b} \rightarrow \mu(15)X$	Pythia	$1.5 \cdot 10^4$
3	$b\bar{b} \rightarrow \mu(6)X$	Pythia	$1 \cdot 10^4$
4	$q\bar{q} \rightarrow \mu X$	Pythia	$2.1 \cdot 10^4$
5	Single- $\mu(p_T=100 \text{ GeV})$	Single-Mu gun	$2 \cdot 10^5$
6	Single- $\mu(p_T=38 \text{ GeV})$	Single-Mu gun	$2 \cdot 10^5$
7	Single- $\mu(p_T=19 \text{ GeV})$	Single-Mu gun	$2 \cdot 10^5$

Table 10: Data samples used in the muon isolation algorithm optimization.

annulus around this ( $R \in [R_{Inner}, R_{Outer}]$ ). The radius of the inner cone (i.e. the cone fully containing the muon) has been determined from the distribution of the summed transverse energy contained within a cone of increasing radius around the muon direction from  $Z \rightarrow \mu\mu$ , as shown in Figure 23. The value of  $R$  corresponding to the inner cone radius is visible as a change in the slope of the curve. Once the radius for which all the muon energy is contained in the cone is reached, for each further increase of the cone radius only noise will be summed, resulting in a reduction of the slope of the energy sum curve. The reduction in the slope depends on the level of electronic readout noise per cell, as shown in Fig. 23, where curves for several values of the threshold cut on the calorimetric cell energy is shown, ranging from 40 to 90 MeV. The effect of the electronic noise is only relevant for the LAr calorimeter. From the two figures it can be seen that a cone of radius 0.1 (one readout cell), is sufficient to contain the muon energy deposition in the hadronic calorimeter, while a radius of about 0.07 (one to three readout cells, depending on position), is sufficient for the electromagnetic calorimeter, due to the finer readout granularity. The value of the outer cone radius is instead constrained by timing requirements. Increasing the outer cone radius requires a larger fraction of the calorimeter to be read out and decoded. Because the readout step of the algorithm dominates the execution time ( $> 90\%$  of the overall algorithm time) the requirement to keep the overall timing below  $O(10) \text{ ms}$  constrains the maximum outer cone radius to be below about 0.4. We have verified that optimal background rejection is obtained by keeping the outer cone radius at its maximum value.

An analysis has been performed over all the quantities used in the isolation hypothesis testing, with a goal of minimizing the number of variable used in the optimization step. Each variable used in the optimization is listed in Table 11, together with the respective separation power expressed in term of minimum variance bound [8]. The optimal value of the cell energy cut thresholds, used to compute the transverse energy and number of cell sums, has been obtained by maximizing the background rejection after applying a fixed cut on the isolation variables (*var1* and *var2* in Table 11), giving a 95% efficiency for the  $Z \rightarrow \mu\mu$  signal. A common threshold value of 60 MeV has been obtained with this procedure for both the LAr and Tile calorimeter. Algorithm performances are stable for threshold variations of  $\pm 10$  MeV around the optimal values. The distributions of some of the most powerful variables for signal selection and background rejection are shown in Fig. 24.

Optimal cut values for the isolation variables described above have been obtained in a multivariate optimization procedure by simultaneously varying all the cuts in sensible ranges and by minimizing the  $b\bar{b} \rightarrow \mu X$  background efficiency at fixed  $Z \rightarrow \mu\mu$  signal efficiency. In the optimization procedure, both background and signal efficiencies are calculated with respect to muons satisfying the L2 muFast mu20 requirement. In Fig. 25 the background rejection, defined as  $1/\epsilon_{BG}$  where  $\epsilon_{BG}$  is the efficiency for the  $b\bar{b}$  background sample, and  $(1 - \epsilon_{BG})$  as a function of the  $Z \rightarrow \mu\mu$  signal efficiency, obtained after the optimization procedure, are shown. The chosen working point for the isolation algorithm yields a factor of 10 reduction for the  $b\bar{b}$  background at a 95% signal efficiency for muons with  $p_T > 20 \text{ GeV}$ .

Figure 23: The total transverse energy contained within a cone of increasing radius around the muon candidate track from  $Z \rightarrow \mu\mu$  signal events in the LAr calorimeter (left) and Tile calorimeter (right). The different curves on each figure correspond to different thresholds applied on the cell energy.

Label	variable	Separation
var1	$Iso_{LAr} = \sum E_T^{\Delta R < 0.07} / \sum E_T^{\Delta R < 0.4}$	0.21
var2	$Iso_{Tile} = \sum E_T^{\Delta R < 0.1} / \sum E_T^{\Delta R < 0.4}$	0.29
var3	$E_{LAr}^O = \sum E_T^{\Delta R \in [0.07, 0.4]}$	0.75
var4	$E_{Tile}^O = \sum E_T^{\Delta R \in [0.1, 0.4]}$	0.40
var5	$E_{LAr}^I = \sum E_T^{\Delta R < 0.07}$	0.23
var6	$E_{Tile}^I = \sum E_T^{\Delta R < 0.1}$	0.06
var7	Number of LAr cells above threshold with $\Delta R \in [0.07, 0.4]$	0.72
var8	Number of Tile cells above threshold with $\Delta R \in [0.1, 0.4]$	0.34
var9	Number of LAr cells above threshold with $\Delta R < 0.07$	0.31
var10	Number of Tile cells above threshold with $\Delta R < 0.1$	0.07

Table 11: Variable used in the muon isolation optimization procedure. The separation is zero for identical signal and background shapes, and it is one for shapes with no overlap.

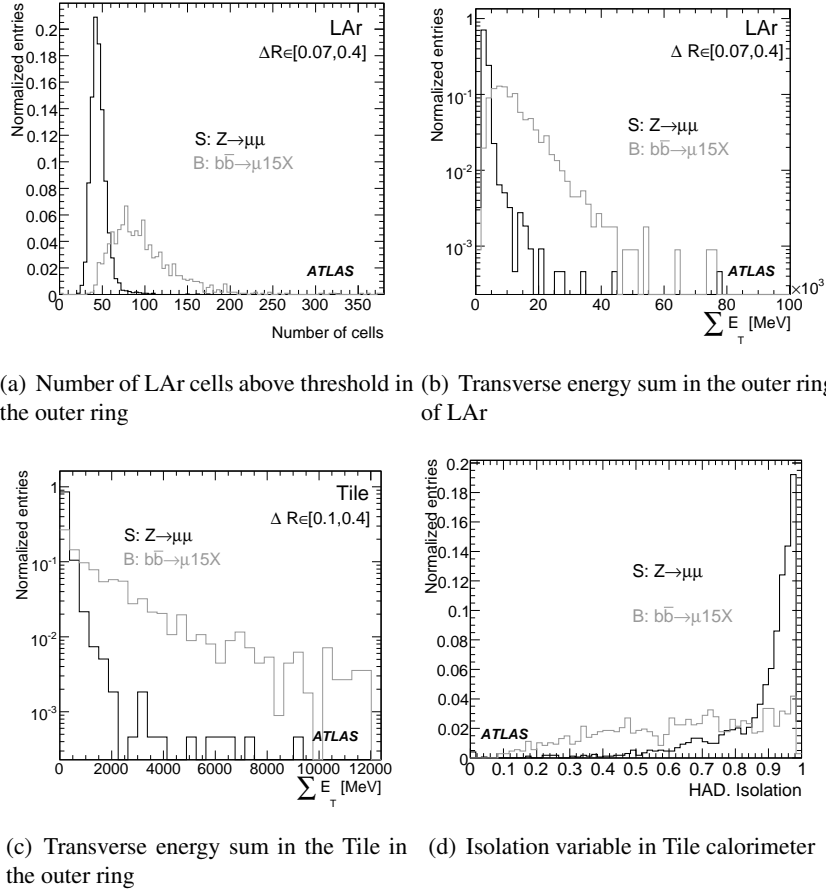

Figure 24: Most powerful variables for calorimetry-based muon isolation.

## 9.2 Performance

The performance of the isolation algorithms in terms of  $b\bar{b}$  and dijet background reduction, efficiency of benchmark signal channels and timing is presented below. The performance of isolation algorithms can be affected by the instantaneous luminosity since the pile-up requires higher thresholds for the same nominal efficiency. This is particularly true for calorimetry-based isolation, while for track-based isolation the effect can be reduced by requiring that the contributing tracks come from the same primary vertex as the muon. For this reason, the results of this study should be taken as preliminary and valid only in the framework of the approximations used in the simulated events production for these studies. Possible changes and further development may occur as soon as real data is available.

The effect of isolation algorithms on various sources of non-isolated muons at L2 is shown in Table 12. The quantity  $1 - \varepsilon_{BG}$  is shown for the isolation requirements corresponding to a working point for the isolation algorithm with a nominal  $Z \rightarrow \mu\mu$  signal efficiency of 95%. Results from dijet decays give an estimate of the rejection power of the isolation algorithm for high- $p_T$  muons from  $K$  and  $\pi$  in flight decays. The rejection power for low- $p_T$  muons from  $b\bar{b}$  decays selected by the level 2 mu6 requirement has also been estimated. The reduction in rejection power, from a factor 10 to a factor of about 2, at the low- $p_T$  limit is expected, given the low energy associated with the jets. As already mentioned, calorimetry based isolation algorithms are not effective against these kind of muons, and the track-based isolation is expected to be much more powerful in reducing this kind of background.

Figure 25: Background rejection ( $1/\epsilon_{BG}$ ) (left), and  $1 - \epsilon_{BG}$  (right), as a function of the signal efficiency as obtained in the muon isolation algorithm optimization procedure.

Process	Trigger item	Average muon $p_T$ (GeV)	$1 - \epsilon_{BG}$ (%)
$b\bar{b} \rightarrow \mu(15)X$	mu20	25.0	$89.4 \pm 0.7$
$b\bar{b} \rightarrow \mu(6)X$	mu6	9.0	$54.6 \pm 0.9$
$q\bar{q} \rightarrow \mu X$	mu20	40.0	$99.6 \pm 0.1$
$q\bar{q} \rightarrow \mu X$	mu6	20.0	$97.3 \pm 0.2$

Table 12: Muon isolation algorithm  $1 - \epsilon_{BG}$  for muons from several background samples. Efficiencies are calculated with respect to muons passing the level 2 mu20 or mu6 requirements, as specified.

The isolation algorithm has been tuned such that the efficiency is 95% at the chosen working point. The efficiency of the isolation requirement has been studied as a function of  $p_T$  using samples of single muons with a  $p_T$  of 11, 39, and 100 GeV. No sizable change in the muon efficiency are visible, indicating that radiation effects are small for  $p_T$  in this range. Evaluation of the effect of the muon radiation for very high  $p_T$  muons (500 to 1000 GeV) is ongoing. The efficiencies for muons from  $Z \rightarrow \mu\mu$  decays and for single muons are reported in Table 13.

Process	Trigger path	$\varepsilon$ (%)
$Z \rightarrow \mu^+ \mu^-$	mu20	$95.5 \pm 0.4$
Single $\mu$ $p_T=100$ GeV	mu20	$98.68 \pm 0.07$
Single $\mu$ $p_T=39$ GeV	mu20	$98.97 \pm 0.07$
Single $\mu$ $p_T=6$ GeV	mu6	$98.54 \pm 0.09$

Table 13: Muon isolation algorithm efficiencies for muons from several processes and thresholds.

The time available for running L2 algorithms in the on-line trigger is limited to approximately 20 ms. The CPU processing time is therefore a relevant parameter for the feasibility of algorithms to be included in the trigger chain. The results obtained indicate a typical overall time of less than 10 ms. Further and more detailed timing studies performed on the actual L2 processors are ongoing.

## 10 Muon identification using the tile calorimeter

The muon signatures in the three radial layers of the Tile Calorimeter are well measured quantities with a typical pattern that can be used to identify the muons efficiently down to very low  $p_T$ . This information can be used to confirm the Muon Spectrometer Triggers (i.e. provide redundancy in noisy/dead regions) or to enhance the selection efficiency for very soft muons typically out of reach for the spectrometer.

The algorithm exploits the radial and transverse calorimeter segmentation. The search starts from the outermost layer, which is the one with the cleanest signal, and once a cell is found with energy compatible with a muon, the algorithm checks the energy deposition in the neighbor cells for the most internal layers. These “candidate patterns” are considered as muons when cells compatible with the typical muon energy deposition are found following a  $\eta$ -projective pattern in all the three TileCal layers. More details can be found in Ref. [9].

### 10.1 Performance

The performance of the TileMuId algorithms has been studied with MonteCarlo single muons and semi-inclusive muon production ( $b\bar{b} \rightarrow \mu(4)X$ ) samples. The effect of minimum-bias pileup at low luminosity ( $\mathcal{L} = 10^{33} \text{cm}^{-2}\text{s}^{-1}$ ) has been investigated as well.

Two algorithms, implementing complementary strategies are described, one (TrigTileLookForMuAlg) is fully executed on the LVL2 Processing Unit (PU) the second (TrigTileRODMuAlg) has a core part executed on the Read Out Driver Digital Signal Processor (ROD-DSP) in order to save time. This allows a very fast processing of the entire detector (full scan) as opposed to the RoI based processing typical of the trigger algorithm running on the LVL2 PUs. Since each ROD-DSP processes a small part of the detector readout the TrigTileRODMuAlg acceptance is lower compared with that of TrigTileLookForMuAlg.

### 10.1.1 Spatial resolution

The spatial resolution of the algorithms can be studied using the distributions of the residuals  $\Delta\eta = \eta(\mu_{\text{Tile}}) - \eta(\mu_{\text{Truth}})$  and  $\Delta\phi = \phi(\mu_{\text{Tile}}) - \phi(\mu_{\text{Truth}})$  in single muon events with  $2 \leq p_T \leq 15$  GeV. The distributions are well described by a Gaussian and resolution can be defined as  $\sigma_\eta = 0.05$  for TrigTileRODMuAlg ( $\sigma_\eta = 0.04$  for TrigTileLookForMu) and  $\sigma_\phi = 0.03$  rad. To characterize the performance of the algorithms with MC physics events a matching region with the MC truth will be used. For this analysis a matching region of  $\Delta\eta \times \Delta\phi = 0.2 \times 0.12$  is used.

### 10.1.2 Efficiency

The muon-tagging efficiency is defined as the ratio of the number of tagged muons which match a truth muon ( $N_{\text{tag}}$ ) to the number of generated truth muons ( $N_{\text{gen}}$ ). Figure 26 shows the efficiency as a function

Figure 26: Efficiency as a function of  $\eta$  (left),  $\phi$  (center) and  $p_T$  (right) for TrigTileLookForMu (filled circles) and TrigTileRODMu (open squares) using single muon events.

Figure 27: Efficiency as a function of  $\eta$  (left) and  $p_T$  (center) for TrigTileLookForMu (filled circles) and TrigTileRODMu (open squares) in  $b\bar{b} \rightarrow \mu(6)X$  events. Right plot show for TrigTileLookforMu the effect of pileup of Minimum Bias events at low luminosity (filled circles) compared with the case without pileup (open squares).

of  $\eta$ ,  $\phi$ , and  $p_T$  of the muon for the two algorithms as obtained using the single muon sample. The efficiency of TileRODMu is lower than that of TileLookForMu. In the region  $0.8 \leq |\eta| \leq 1.1$  the towers

are split between the barrel and the extended barrels, and the cells belonging to different partitions are processed by different ROD DSPs. Similar effects are observed for the boundary at  $\eta \sim 0$ . Except for these two regions of low geometrical acceptance both algorithms show efficiency  $\sim 85\%$  with good agreement. Since TileCal is homogeneous in  $\phi$ , the efficiency is uniform as a function of  $\phi$ , see Fig. 26 (center). The efficiency decreases with the muon  $p_T$  for  $p_T < 3$  GeV and is about 42% at  $p_T = 2$  GeV. Most of the muons with  $p_T < 2$  GeV stop in the Tile calorimeter. For  $p_T > 4$  GeV the efficiency is flat at about 60%. Figure 27 (left) and (center) show the efficiency curves for both algorithms as obtained in  $b\bar{b} \rightarrow \mu(6)X$  events. These results are in good agreement with the performance obtained using single muons, indicating that the algorithms are not too sensitive to the additional hadronic activity in  $b\bar{b}$  events.

To evaluate the performance in a realistic LHC operation scenario a sample of  $b\bar{b} \rightarrow \mu(6)X$  events simulated with pileup of minimum-bias events at a luminosity  $\mathcal{L} = 10^{33} \text{ cm}^{-2}\text{s}^{-1}$  was used. As shown in Fig. 27 (right), the efficiencies as a function of  $p_T$  for two cases are similar for  $p_T > 5$  GeV. The additional muons from minimum-bias events make the efficiency worse in the low  $p_T$  region. The average efficiency in the sample with pileup ( $67.97 \pm 0.81\%$ ) is slightly lower than the one obtained without pileup ( $74.25 \pm 0.79\%$ ). It can be concluded that the efficiency is not substantially affected by minimum-bias pileup.

### 10.1.3 Fraction of fakes

Figure 28: Fraction of fakes as a function of  $\eta$  (left) and  $\phi$  (center) for TrigtileLookForMu (filled circles) and for TrigtileRODMu (open squares) in  $b\bar{b} \rightarrow \mu(6)X$  events. The right plot compare performance of TrigtileLookForMu in samples with (filled circles) and without pileup (open squares).

The muon tags which are not matched with truth muons are considered fake. The same  $\Delta\eta \times \Delta\phi$  matching cuts are used for the efficiency and fake computation. The fraction of fakes in a given data sample is defined as the ratio of the number of misidentified muons to the total number of events.

The left and center plots of Fig. 28 show the fraction of fakes as a function of  $\eta$  and  $\phi$  obtained by the two algorithms. Both algorithms show a very small fake rate in the central region (0.12% for  $|\eta| < 0.7$ ). The main contribution of fakes comes from the extended barrel and gap regions, where the cell segmentation is coarse and the projectivity is the worst. The fraction of fakes in the whole range  $|\eta| < 1.4$  is  $2.7 \pm 0.1\%$  for TrigtileRODMu and  $4.1 \pm 0.1\%$  for TrigtileLookForMu. The fraction of misidentified muons as a function of  $\phi$  is flat as expected.

Figure 28 (right) shows the performance of TrigtileLookForMu in  $b\bar{b} \rightarrow \mu(6)X$  events with and without the pileup of minimum-bias events at low luminosity. The fraction of fakes increase from  $3.7 \pm 0.1\%$  to  $6.0 \pm 0.1\%$  when the minimum bias pileup at  $\mathcal{L} = 10^{33} \text{ cm}^{-2}\text{s}^{-1}$  is taken into account. The

fake rate increases at larger values of  $\eta$  (gap and extended barrel), where the cell granularity is worse and more minimum bias event are expected, compared to the central  $\eta$  region.

## 10.2 Combined performance with the inner detector

In order to measure the  $p_T$  of the identified muon, the secondary RoI produced by the TileMuId algorithm is used to seed the Inner Detector (ID) track reconstruction algorithm. The size of the ID RoI that requires processing is defined by the Tile algorithm resolution and by the bending in the central solenoid. For  $p_T(\mu_{\text{Truth}}) > 2$  GeV,  $\Delta\phi = \phi(\mu_{\text{Tile}}) - \phi(\mu_{\text{Track}}) \approx 0.2$  is required. If at least one track is found within the region  $\Delta\eta \times \Delta\phi = 0.1 \times 0.2$  and with  $p_T > 2$  GeV, the calorimetric tag is confirmed to be a muon and the trigger sequence is successful.

Figure 29: The number of tracks within the given RoI for  $b\bar{b} \rightarrow \mu(4)X$  (left) and with the fixed RoI size of  $\Delta\eta = 0.1$  and  $\Delta\phi = 0.2$  for  $b\bar{b} \rightarrow \mu(6)X$  with/without pileup (center). The right plot shows the efficiency as a function of  $p_T$  for the muons tagged by only TileCal (TileLookForMu) and the muons combined with the associated track.

Figure 29 shows the multiplicity of track in the ID RoI; left plot shows that a region with  $\Delta\phi = 0.1$  misses the low  $p_T$  tracks and results in more events with zero track within the RoI. The RoI with  $\Delta\eta = 0.2$  does not give any advantage. The RoI with a size  $\Delta\eta = 0.1$  and  $\Delta\phi = 0.2$  is a good compromise; the efficiency to reconstruct the muon track is good and the multiplicity of tracks (ambiguity) is acceptable. In the case of reconstruction of multiple tracks, the closest is chosen as the best-matched for the  $\mu$  tagged by TileCal, and all tracks are saved since the ambiguity cannot be further resolved at this level. As shown in Figure 29 (center), the multiplicity of tracks within the RoI is not significantly affected by the pileup.

Figure 29 (right) shows the overall combined (TileCal+ID) efficiency for  $\Delta\phi = 0.1$  and  $\Delta\phi = 0.2$  as a function of muon  $p_T$ . The combined efficiency obtained with  $\Delta\phi = 0.2$  is approximately equal to that of the TileCal stand-alone except for  $p_T < 3.5$  GeV. The efficiency from the matched track shows no dependence on  $\eta$  or  $\phi$ . The efficiency, purity and acceptance using the different sizes of RoI are summarized in Table 14. The efficiency and acceptance are significantly improved from  $\Delta\phi = 0.1$  to  $\Delta\phi = 0.2$ . For  $\Delta\phi = 0.2$ , 97% of tagged muons by TileCal match the associated track. The purity and acceptance of  $\Delta\phi = 0.3$  are similar to those of  $\Delta\phi = 0.2$ . However, the size of  $\Delta\eta$  does not affect the efficiency of the matched track with  $\mu$  significantly. The differences due to the minimum-bias pileup are observed to be about 2 to 3% due to the small number of events from pileup samples.

	TileLookForMu	RoI size with $(\Delta\eta, \Delta\phi)$ for matching tracks		
		(0.1, 0.1)	(0.1, 0.2)	(0.1, 0.3)
Efficiency (%)	$73.08 \pm 0.17$	$42.02 \pm 0.19$	$70.91 \pm 0.18$	$72.06 \pm 0.18$
Unmatched $\mu_{\text{Tile}}$ (%)		$42.50 \pm 0.36$	$2.98 \pm 0.08$	$1.40 \pm 0.05$
Efficiency ( $p_T > 4$ GeV)		$44.09 \pm 0.20$	$72.94 \pm 0.18$	$73.06 \pm 0.18$
Purity ( $p_T > 4$ GeV)		$98.51 \pm 0.88$	$98.79 \pm 0.67$	$98.69 \pm 0.67$
Acceptance ( $p_T > 4$ GeV)		$40.78 \pm 0.31$	$71.93 \pm 0.45$	$72.01 \pm 0.45$

 Table 14: Performance with the matched track for  $b\bar{b} \rightarrow \mu(4)X$ .

## 11 Muon trigger performance for $Z \rightarrow \mu^+\mu^-$

### 11.1 The “tag and probe” method

The trigger efficiency is a fundamental parameter in physics analyses and therefore it is important to have several independent methods for estimating it. The “Tag and Probe” method is a concrete application of a data-driven technique for performance analysis. This method is based on the definition of a “probe-like” object, used to make the performance measurement, within a properly “tagged” sample of events. Physics processes suitable for this method are generally those characterized by a double-object final state signature. The decay of the Z provides two high- $p_T$  muons that can lead to two trigger tracks in the Inner Detector and Muon Spectrometer and to a combined object. These two measurements are in principle independent, though not necessarily uncorrelated.

“Tagged” events require one triggered track with  $p_T > 20$  GeV and “Probe” objects can be defined as *Inner Detector offline reconstructed tracks (ID-Probe)*, where measurements are referred to the offline Inner Detector reconstruction efficiency ( $\sim 100\%$ ), or as *Muon Spectrometer offline reconstructed tracks (MS-Probe)*, where values are normalized to the offline Muon Spectrometer reconstruction efficiency (standalone or combined with the Inner Detector).

The trigger performance is measured by checking for L1, L2, and EF trigger tracks associated with each probe object. A schematic illustration of the method is shown in Fig. 30. It must be verified that selected tracks come from a Z decay. A background process with two isolated tracks in the Inner Detector, of which only one is a real muon, would introduce a systematic error in the efficiency evaluation. For this reason, cuts have to be applied in order to select a clean signal sample.

A significant background contribution is expected from QCD processes, which have large cross-sections.

Process	Generation cuts	$\sigma$ [pb]
$Z \rightarrow \mu^+\mu^-$	$M_{\mu\mu} > 60 \text{ GeV}/c^2$ $1\mu:  \eta  < 2.8, p_T > 5 \text{ GeV}$	1497
$W \rightarrow \mu\nu$	$1\mu:  \eta  < 2.8, p_T > 5 \text{ GeV}$	11946
$B\bar{B} \rightarrow \mu\mu X$	$1\mu:  \eta  < 2.5, p_T > 15 \text{ GeV}$ $1\mu:  \eta  < 2.5, p_T > 5 \text{ GeV}$	4000
$t\bar{t} \rightarrow W^+bW^-b$	only leptonic decay	461
$Z \rightarrow \tau^+\tau^-$	$\tau\tau \rightarrow l\bar{l}, M_{\mu\mu} > 60 \text{ GeV}/c^2$ $1\mu:  \eta  < 2.8, p_T > 5 \text{ GeV}$	77

Figure 30: Illustration of the Tag and Probe method (left) and cross-sections with generation cuts for signal and background processes (right).

This background has been studied by considering the dominant contribution of muons from decays of  $B$ -meson pairs. Also the muonic  $W$  boson decay, which can give a higher energetic muon plus an additional muon from a QCD jet and the  $Z \rightarrow \tau^+ \tau^- \rightarrow \mu^+ \nu_\mu \bar{\nu}_\tau \mu^- \bar{\nu}_\mu \nu_\tau$  process have been considered.

Moreover the top-pair production cross-section at LHC is of the same order of magnitude as  $Z$  boson cross-section. Top quarks decay with a 99.9% probability into a  $W$  boson and a  $b$  quark. Therefore muons originating from  $W$  boson and  $b$ -quark decays can also give a signal-like signature. Cross-sections and generation cuts of the processes considered are reported in Fig. 30. PYTHIA [5] is used to generate the processes.

Another possible source of background is muons from cosmic-rays. An estimation of cosmic rates in the trigger system has been done in Ref. [10] and shows a negligible effect on trigger performance.

The isolation variables chosen for this analysis are the number of reconstructed tracks in the Inner Detector ( $N_{cone}^{ID}$ ), the sum of  $p_T$  of the Inner Detector tracks ( $\sum p_{T,cone}^{ID}$ ), the energy of a jet candidate ( $E_{cone}^{jet}$ ) and the sum of reconstructed energy in the cells of the Calorimeter ( $\sum E_{cone}^{EM}$ ). Muons from QCD processes tend to be produced within a large cascade of other particles and therefore should not appear isolated in the detector. In the case of the decay of top pairs, one highly energetic and isolated muon can come from one  $W$  boson decay while the second  $W$  boson can decay leptonically into a high- $p_T$  electron which appears as an isolated track in the Inner Detector. In order to not count this as a false probe, electrons are vetoed. The values of the selection cuts applied in this analysis have been defined in [11]. The isolation cuts allow for background rejection of approximately 99% while retaining a signal efficiency of about 76%. After applying the probe selection cuts the signal to background ratio is more than  $10^3$ . In addition, probe muons selected from background processes can be associated to trigger tracks and hence have no negative impact on trigger efficiency measurements.

## 11.2 Determination of trigger efficiencies

Two measurement scenarios have been studied:

- *Low luminosity* ( $\int \mathcal{L} dt \simeq 50 \text{ pb}^{-1}$ ): in order to not rely on the combined reconstruction based on Inner Detector and Muon Spectrometer matching, only the tracks from the Muon Spectrometer are used. The isolation cuts are also based only on Inner Detector quantities;
- *High luminosity* ( $\int \mathcal{L} dt \simeq 1000 \text{ pb}^{-1}$ ): full combined information from Inner Detector and Muon Spectrometer is used and also Calorimeter based cuts are applied to select isolated tracks.

In each scenario both the ID- and MS-Probe methods have been studied. The efficiency dependence on  $\phi$  and  $\eta$  is determined by the Muon Spectrometer layout. A  $p_T$  cut of 20 GeV has been applied on the probe tracks to test the system in its plateau region. The efficiency as a function of  $p_T$  has been also estimated from data in the *high luminosity* scenario.

### 11.2.1 Low luminosity measurements

The relative efficiency as a function of  $\eta$ , measured at each trigger level, is shown in Fig. 31 using the ID-probe. L1 acceptance losses are related to an incomplete coverage of the trigger detectors due to the presence of support and access structures. The L2 efficiency, with respect to the L1 selection, is about 96% in the barrel region with a small decrease in the endcap, an improvement is expected due to optimization of the TGC cabling in next software releases. The EF shows an  $\eta$  efficiency distribution, with respect to L2, close to 99% in the barrel region and a very small decrease from  $|\eta| > 2.0$ . In the region  $1.05 < |\eta| < 1.3$  the absence of the some MDT chambers in the ATLAS initial layout resulted in an efficiency loss of about 10%.<sup>2</sup>

<sup>2</sup>The missing chambers are scheduled to be installed by the end of 2009.

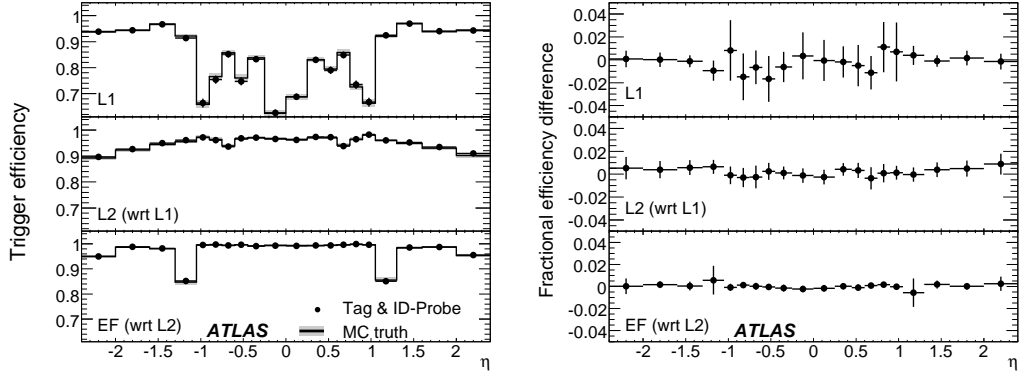

Figure 31: The muon trigger efficiency for each trigger level (left) and fractional efficiency difference (right) as a function of  $\eta$  in the *low luminosity* scenario using the ID-Probe. The efficiencies determined with the Tag and Probe method are compared to those calculated in a Monte Carlo truth-based analysis.

Figure 32: The muon trigger efficiency for each trigger level (left) and fractional efficiency difference (right) as a function of  $\eta$  in the *low luminosity* scenario using the MS-Probe. The efficiencies determined with the Tag and Probe method are compared to those calculated in a Monte Carlo truth-based analysis.

The observed agreement with the Monte Carlo truth-based analysis is very good. In order to quantitatively estimate the bin-by-bin differences the “fractional efficiency difference”

$$\frac{\mathcal{E}_{\text{Tag\&Probe}} - \mathcal{E}_{\text{MC}}}{\mathcal{E}_{\text{MC}}} \quad (5)$$

has been computed. This quantity is shown for each trigger level in Fig. 31 as a function of  $\eta$ .

The agreement between Tag and Probe method and Monte Carlo analysis is very high, more than 99% over all the trigger coverage. The only observed deviations, at the level of 2%, are found in the central crack at  $\eta = 0$  and in the transitions from barrel to endcap at  $|\eta| = 1.05$ . The results obtained by the application of the Tag and Probe method using the standalone MS-Probe are reported in Fig. 32 as functions of  $\eta$ . With respect to the values shown in Fig. 31 inefficiencies due to L1 acceptance cracks are partially factorized in the offline muon reconstruction efficiency of the MS-Probe (e.g. the  $\eta = 0$  region.). The same effect is clearly evident at the EF level for the efficiency loss at  $1.05 < |\eta| < 1.3$  visible in Fig. 31.

Table 15 shows the uncertainties on the overall trigger efficiency in each case, calculated also only in barrel and endcap regions. The statistical uncertainty is reported together with expected systematic

Detector region	Barrel ( $ \eta  < 1.05$ )	Endcap ( $1.05 <  \eta  < 2.4$ )	Overall ( $0 <  \eta  < 2.4$ )
<b>Low luminosity - ID probe (<math>\int \mathcal{L} dt = 50 \text{ pb}^{-1}</math>)</b>			
Trigger Efficiency	71.65	83.59	77.38
Statistical Uncertainty	0.42	0.36	0.28
$ \epsilon_{TRUTH} - \epsilon_{TP} $	0.23	0.40	0.10
Expected Background Contribution	0.57	0.17	0.40
Overall Systematic Uncertainty	0.61	0.43	0.41
<b>Low luminosity - MS probe (<math>\int \mathcal{L} dt = 50 \text{ pb}^{-1}</math>)</b>			
Trigger Efficiency	76.94	87.83	82.13
Statistical Uncertainty	0.41	0.34	0.27
$ \epsilon_{TRUTH} - \epsilon_{TP} $	0.17	0.64	0.33
Expected Background Contribution	0.01	0.00	0.01
Overall Systematic Uncertainty	0.17	0.64	0.33

Table 15: Estimated uncertainties of in-situ determined muon overall trigger efficiency for the *low luminosity* scenario, using an ID- and an MS-Probe track. Systematic uncertainties are reported for background contribution and absolute difference with Monte Carlo truth-based analysis.

Detector region	Barrel ( $ \eta  < 1.05$ )	Endcap ( $1.05 <  \eta  < 2.4$ )	Overall ( $0 <  \eta  < 2.4$ )
<b>High luminosity - ID probe (<math>\int \mathcal{L} dt = 1000 \text{ pb}^{-1}</math>)</b>			
Trigger Efficiency	73.24	86.31	79.73
Statistical Uncertainty	0.10	0.08	0.06
$ \epsilon_{TRUTH} - \epsilon_{TP} $	0.02	0.72	0.58
Expected Background Contribution	0.05	0.01	0.03
Overall Systematic Uncertainty	0.05	0.72	0.58

Table 16: Estimated uncertainties of in-situ determined muon overall trigger efficiency for the *high luminosity* scenario using the ID-Probe. Systematic uncertainties are reported for background contribution and absolute difference with Monte Carlo truth-based analysis.

errors. Two sources of systematic uncertainties are considered: the absolute difference with respect to the value measured in a Monte Carlo truth-based analysis and the background contribution, evaluated by comparing the efficiency calculated with Tag and Probe method using only the signal sample and using a cross-section weighted sum of all processes. Both systematics are less than 0.5%. A greater background contribution is observed when using ID-Probe, since the isolation is based only on Inner Detector quantities.

### 11.2.2 High luminosity measurements

After early data is collected and analyzed, a better understanding of the detector, in terms of calibration and alignment, will allow to use all the available information such as Calorimeter quantities for track isolation and combination of Inner Detector and Muon Spectrometer tracks. The trigger efficiency measurements from data in this scenario are reported using the *high luminosity* dataset of  $\int \mathcal{L} dt = 1000 \text{ pb}^{-1}$ .

As in the *low luminosity* case the measured differences between the Tag and Probe and Monte Carlo analysis are compatible with zero. Small deviations at the level of 1 to 2% are observed in the endcap for the L2 trigger efficiency in the  $|\eta| > 1.5$  region. These effects are expected to be reduced by the L2 algorithm optimization. Results are shown in Table 16. With the addition of the calorimeter-based isolation, the background systematic contribution is reduced by a factor of 10 with respect to the low luminosity scenario. The dependence of the trigger efficiency on the  $p_T$  shows the typical shape of a turn-on curve. The sharpness of the curve is related to the finite  $p_T$  resolution,  $\sim 30\%$  at L1,  $\sim 5\%$  at

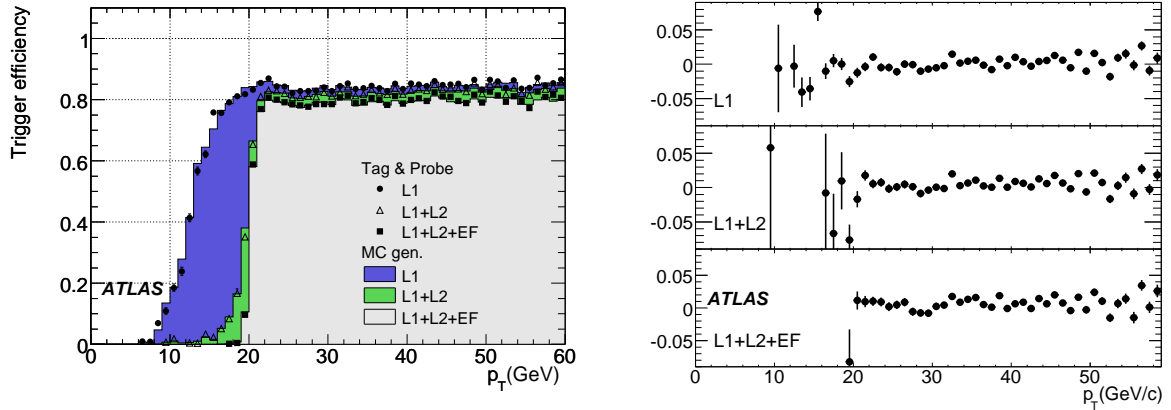

Figure 33: Muon trigger efficiency turn-on curve after each trigger level determined by the Tag and Probe method and by the Monte Carlo truth-based analysis in the *high luminosity* scenario using the ID-Probe (left). In the right plot the fractional efficiency difference is shown.

L2, and  $\sim 3\%$  at the EF. Turn-on curves are shown in Fig. 33 using the ID-probe and similar results are obtained with the MS-probe. The turn-on point and the plateau values are correctly reproduced from data. The fractional efficiency difference is shown for each trigger level. The disagreement near the threshold is within 5%, due mainly to resolution effects, while in the plateau region the observed difference is less than 1%.

## 12 High $p_T$ Dimuon final states

In principle, the high mass dilepton/diphoton resonance search should have a fairly straightforward trigger strategy as there are very high energy leptons in the event. However, there are several questions that remain: what trigger requirements are optimal for the analysis? What  $p_T$  thresholds and object quality selection should be applied? How can one estimate the trigger efficiency from data for such rare (or non-existent) events? Are the same object quality requirements that are appropriate for lower  $p_T$  objects appropriate for very high energy objects?

This Section addresses these questions, evaluates the trigger efficiency for the signal samples of interest, and discusses the trigger strategy for the earliest data taking periods. It is expected that during both low and high luminosity periods there will be an unrescaled single muon trigger without an isolation requirement. The 20 or 40 GeV threshold are expected to be highly efficient for a high mass resonance decaying into two muons.

### 12.1 Efficiency estimate

The muon trigger efficiency is estimated using several methods. The first method is to rely on simulation; while this is the simplest and most direct method it is believed to be somewhat more optimistic (better resolution, higher efficiency). Therefore, the trigger efficiency is also estimated using methods which can be applied to real data.

The trigger efficiencies are calculated with respect to the offline event selection. Two combined muons are required to satisfy the cuts:  $|\eta| < 2.7$ ,  $p_T > 30$  GeV, track fit  $\frac{\chi^2}{\text{D.O.F}} < 10$  and Inner Detector and Muon Spectrometer track match  $\frac{\chi^2}{\text{D.O.F}} < 10$ . The trigger efficiencies for the dimuon heavy resonance Monte Carlo samples are shown in Table 17. The efficiency as a function of  $p_T$  has been fit to

Sample	L1 %	L2 %	EF %	Total Trigger Efficiency %
400 GeV $\rho_T/\omega_T$	$97.6 \pm 0.10$	$98.8 \pm 0.07$	$99.5 \pm 0.05$	$96.0 \pm 0.13$
600 GeV $\rho_T/\omega_T$	$98.1 \pm 0.08$	$98.5 \pm 0.08$	$99.2 \pm 0.06$	$95.9 \pm 0.13$
800 GeV $\rho_T/\omega_T$	$97.6 \pm 0.10$	$98.7 \pm 0.07$	$99.2 \pm 0.05$	$95.6 \pm 0.13$
1 TeV $\rho_T/\omega_T$	$97.6 \pm 0.09$	$98.7 \pm 0.07$	$99.2 \pm 0.05$	$95.6 \pm 0.12$
1 TeV Z' (E6)	$97.8 \pm 0.09$	$98.9 \pm 0.06$	$99.5 \pm 0.04$	$96.3 \pm 0.1$
2 TeV Z' (SSM)	$97.6 \pm 0.14$	$98.7 \pm 0.11$	$98.9 \pm 0.10$	$95.3 \pm 0.2$

Table 17: Trigger efficiencies of dimuon resonance samples. For the meaning of E6 and SSM see [12].

Trigger Level	$A_0$	$A_1$	$A_2$
L1	$12.5 \pm 0.3$	$3.7 \pm 0.4$	$0.845 \pm 0.02$
L2	$19.6 \pm 0.2$	$1.59 \pm 0.19$	$0.976 \pm 0.02$
EF	$19.5 \pm 0.4$	$1.56 \pm 0.3$	$0.931 \pm 0.01$

 Table 18: Fitted parameter for the L1, L2, and EF of the trigger  $p_T$  turn on curves

$$f(p_T) = 0.5 \cdot A_2 \cdot (1.0 + \operatorname{erf}(\frac{p_T - A_0}{\sqrt{2} \cdot A_1})) \quad (6)$$

where  $\operatorname{erf}$  is the error function,  $A_0$ ,  $A_1$ , and  $A_2$  are the fit parameters which represent the  $p_T$  value at which the efficiency reaches half its maximum value, the slope of the turn-on curve, and the maximum efficiency in the plateau region, respectively.

There are several methods to evaluate the trigger efficiency from the data itself. A possible one is to look at the trigger efficiency for a known experimentally clean signature that is similar to the final state of interest;  $Z \rightarrow \mu^+ \mu^-$  is one of such signatures. Since the Z is light compared to the total center of mass energy, it can be produced with a significant  $p_T$  distribution. The trigger efficiency on the Z can be measured and extrapolated to high  $p_T$ . The advantage of this method is that it uses data to measure the trigger efficiency which is the most accurate method of measuring the Z trigger efficiency. A disadvantage is that the muon trigger efficiency is being extrapolated to a  $p_T$  by a factor of 10 higher than the mean  $p_T$  of the muons from the Z decay.

The strategy of evaluating the trigger efficiency from data is as follows. It is first necessary to use one of several methods to estimate the muon trigger efficiency as a function of the muon  $p_T$  and its uncertainty. The single object trigger efficiency allow the construction of the probability for an event with N objects to pass the trigger. This probability can be written as:

$$P = 1 - \prod_{i=1}^N (1 - P_i) \quad (7)$$

where  $P_i$  is the probability for the  $i$ -th object to pass the trigger.

Two common methods that have been used extensively at the Tevatron are the selection by orthogonal triggers and the 'Tag and Probe' method using  $Z \rightarrow \mu\mu$  decay. The 'Tag and Probe' requires two offline muons to have an invariant mass within 12 GeV<sup>2</sup> of 91.1 GeV<sup>2</sup>. The turn on curves as a function of the offline muon  $p_T$ , obtained using this method, is fit to equation 6. This procedure was repeated for all three trigger levels and the results are summarized in Table 18.

A second possible method of evaluating the trigger efficiency with data is by the method of orthogonal triggers. To obtain a sample of unbiased events we select events that pass one of the calorimeter based triggers, the single 20 GeV jet trigger. We then perform the offline analysis and require that we have a dimuon pair using identical event selection to the 'Tag and Probe' analysis. From this sample we

<i>Sample</i>	L1Mu20 Efficiency %	L2Mu20 Efficiency %	EFMu20 Efficiency	Total Efficiency
$Z' \ 1 \text{ TeV (SSM)}$	$97.7 \pm 0.11$	$99.0 \pm 0.07$	$99.6 \pm 0.04$	$96.3 \pm 0.01$
$Z \rightarrow \mu^+ \mu^-$	$97.83 \pm 0.04$	$98.86 \pm 0.03$	$99.52 \pm 0.02$	$96.26 \pm 0.05$

Table 19: L1Mu20 trigger efficiencies at L1, L2, and Event Filter w.r.t offline reconstruction using orthogonal trigger selection to record events

simply check the fraction of events that pass the L1, L2, and EF trigger conditions for the 20 GeV muon trigger. The results are shown in Table 19 and are in good agreement with the 'Tag and Probe' method and direct emulation of the trigger on the Monte Carlo sample. Unfortunately, in the real experiment a single jet trigger with a threshold of 20 GeV would be very highly prescaled and hence will suffer from poor statistics. Events that passed any calorimeter trigger could be used for this study if biases in the event topology were taken into account, however, such a study is beyond the scope of this note.

We have developed two methods that could be used to evaluate the trigger efficiency from data. Extraction of the muon trigger efficiency as a function of the reconstructed muon kinematics via a tag and probe method and an orthogonal trigger method agree well with the simulated trigger efficiency. These methods will allow us to more accurately estimate the trigger efficiency for LHC data.

### 13 Summary

In this paper Muon trigger baseline performance and rates for initial and standard LHC operation have been presented. Trigger efficiency has been studied in detail in a wide energy range using single muon simulated samples. From efficiencies the muon rates have been evaluated. It should be noted that due to the uncertainties of the inclusive muons cross-sections, rates could vary significantly and different threshold cuts could be adopted. A further rate reduction should come from dedicated strategies to reject muon from in-flight decays of  $K$  and  $\pi$ ; in this paper a preliminary analysis is presented at Event Filter. It is demonstrated that a good rejection can be achieved with contained losses of prompt muons.

The possibility to select at the ATLAS second level trigger with high efficiency isolated muons from  $W$  and  $Z$  decays reducing the ones from heavy quark decays has been studied in depth. Although electronic readout and pileup noise have been simulated, no cavern background has been yet included. A factor of ten reduction on high- $p_T$  muons from heavy-quark decays has been obtained while maintaining a 95% efficiency on  $Z \rightarrow \mu^+ \mu^-$  final state. Next step will be to investigate how much the use of the longitudinal granularity of the calorimeters and inner tracker detector will increase the muon isolation rejection power.

The overall performance of the TileCal muon tagging algorithm has been presented, using MC samples of single muons and inclusive B-Physics processes, including minimum-bias pileup at low luminosity.

We finally addressed the question of how the muon trigger efficiency can be measured with  $Z \rightarrow \mu^+ \mu^-$  and  $Z' \rightarrow \mu \mu$  using the tag and probe method. This technique shows a very good agreement with results based on Monte Carlo studies.

# HLT $b$ -Tagging Performance and Strategies

## Abstract

The ability to trigger on  $b$ -jets improves the flexibility and physics performance of the High Level Trigger (HLT), especially for topologies containing more than one  $b$ -jet. It will be shown that the acceptance for  $b$ -jets can be increased and background reduced by lowering jet transverse energy thresholds and applying  $b$ -tagging selections based on the impact parameter of tracks in jets. This note reviews the  $b$ -jet selection in the HLT and discusses its integration into the ATLAS trigger menu.

## 1 Introduction

Final states containing  $b$ -jets have been proposed as signatures with substantial discovery potential in a variety of physics channels. The ability to separate  $b$ -jets from light-quark and gluon jets is thus an important ingredient of the online selection strategy in ATLAS.

One of the most interesting physics cases addressed by such a  $b$ -jet trigger selection involves events with final states containing four  $b$ -jets. This event class is relevant for Higgs bosons search in the low mass range,  $m_H < 130$  GeV. The most promising channels are the  $H \rightarrow b\bar{b}$  decay, where the Standard Model Higgs boson is produced by way of the associated production channel  $t\bar{t}H$  and, in supersymmetric theories, the channels  $b\bar{b}H$ ,  $b\bar{b}A$  with  $H/A \rightarrow b\bar{b}$  or  $H \rightarrow hh \rightarrow b\bar{b}b\bar{b}$ .

The selection of  $b$ -jets at the trigger level is mainly meant to improve the flexibility of the HLT, extending its physics performance for the topologies described above. This is achieved by increasing the acceptance for signal events, while concurrently reducing the background.

The  $b$ -jet selection relies on tracking information which is only available starting with the Second Level Trigger (L2). Therefore, the acceptance for signal can only be increased by simultaneously lowering L1 jet thresholds and applying a more discriminating  $b$ -jet selection in the High Level Trigger (L2 and EF). High rejection power from the  $b$ -jet trigger is required to compensate for less rejection due to lower L1 thresholds and thereby to comply with L2 and EF output rate limitations.

## 2 Monte Carlo samples

The  $b$ -tagging performance on single jets, presented in this note, is evaluated on  $b$ -jets from  $H \rightarrow b\bar{b}$  decays, where the Higgs boson has a mass of 120 GeV and is produced in association with a  $W$  decaying leptonically. The standard background for single-jet studies are the corresponding  $u$ -jets, obtained by artificially replacing the  $b$ -quarks from the Higgs decay with  $u$ -quarks. While these events imprecisely model the real background from light-flavour jets they can be seen as a worst case scenario since the kinematical properties of signal and background are very similar.

Even in this very simple situation, the association between Regions of Interest (RoI), identified by the L1 trigger, and jets is not uniquely defined: a generic  $x$ -quark in the final state of an interaction or a decay can radiate gluons and, therefore, change its direction. An RoI from  $H \rightarrow b\bar{b}$  or  $H \rightarrow u\bar{u}$  is labeled as  $x$ -jet ( $x = b, u$ ) if an  $x$ -quark from the original hard process points, after final state radiation, along the RoI direction within an angular distance of  $\Delta R = \sqrt{\Delta\eta^2 + \Delta\phi^2} < 0.1$ .

In order to evaluate the rate of the  $b$ -jet trigger menu, the rejection power must be evaluated on a more representative background sample. As for many of the trigger studies in ATLAS, dijet samples are chosen for this purpose since they correctly include all contributions to the  $b$ -tagging background, including  $c$ -quarks and taus.

All data samples studied in this note have been generated without pile-up, leaving the influence of pile-up for further studies. The activity due to underlying event is taken into account since it is automatically included in the PYTHIA [1] event generation.

### 3 HLT $b$ -jet selection

#### 3.1 L1 configuration

The HLT reconstruction starts from the RoIs selected by the L1 trigger [2]. In particular, the  $b$ -jet trigger starts from a L1 jet-RoI  $\Delta\eta \times \Delta\phi = 0.8 \times 0.8$  and performs track and vertex reconstruction in a smaller RoI  $\Delta\eta \times \Delta\phi = 0.4 \times 0.4$  in order to reduce data access and consequently processing time.

#### 3.2 $b$ -jet trigger feature extraction algorithms

The first step in the  $b$ -jet trigger chain, both at L2 and EF, is the reconstruction of the relevant quantities needed to perform the selection. The  $b$ -jet RoIs can be separated from light jet RoIs using the impact parameters of the charged tracks, the properties of reconstructed secondary vertices, or soft leptons; all these quantities are related to the  $b$ -quark lifetime and to its decay properties.

The present  $b$ -jet trigger implementation relies only on the impact parameters of charged tracks. Primary vertex reconstruction is performed only in the  $z$  direction while its coordinates in the transverse plane are assumed to be compatible with the origin.

Track reconstruction algorithms are described, together with their performance, in [3]. The two Inner Detector tracking algorithms available at L2 show equivalent performance when operating on jet samples [3]. Thus to avoid unnecessary comparisons, the results obtained with the SiTrack algorithm are presented. For EF track reconstruction, the algorithm corresponding to that used for offline reconstruction has been adopted (NewTracking).

##### 3.2.1 Primary vertex reconstruction

Along the  $z$  direction no *a priori* knowledge of primary vertex  $z_{vtx}$  is available; consequently, this has to be reconstructed, starting from the tracks available in the RoI. This information is needed for the correct evaluation of the longitudinal parameter of each track with respect to the primary interaction position.

The adopted algorithm, a simple histogramming method based on a sliding window, yields an efficiency of 98(99)% and a resolution on  $z_{vtx}$  of about 120(100) $\mu\text{m}$  at L2(EF) as illustrated in Fig. 1.

#### 3.3 Tagging variables

The HLT  $b$ -jet tagging methods are based on the transverse and longitudinal impact parameters of the reconstructed tracks. Since the methods are the same for L2 and EF they will be described using L2 variables only.

##### 3.3.1 Transverse impact parameter

The most natural choice is to build the  $b$ -tagging discriminant variable from the transverse impact parameter  $d_0$  of the reconstructed tracks. Since the hadrons containing  $b$ -quarks have a finite lifetime ( $\tau \sim 1.6$  ps), tracks from their decays are characterized by large  $d_0$  values, while tracks from  $u$ -jets come dominantly from the primary vertex ( $d_{vtx} = 0$ ).

In particular, the significance of the transverse impact parameter  $S = d_0/\sigma(d_0)$  is used, where  $\sigma(d_0)$  is the error on the impact parameter. The error on the transverse impact parameter at L2 is parametrized

Figure 1: The distribution of the difference between the true and the reconstructed  $z$  primary vertex coordinates at L2 (full line) and EF (dashed line). The widths as determined by a fit to the distributions are  $120 \mu\text{m}$  and  $100 \mu\text{m}$ , respectively.

as a function of reconstructed  $p_T$  as:

$$\sigma(d_0) = \sqrt{p_0^2 + \left(\frac{p_1}{p_T}\right)^{p_2}}$$

where  $p_0$  is the asymptotic term,  $p_1$  is the term due to multiple scattering, and  $p_2$  is the exponent of the multiple scattering contribution (close to two). Although L2 tracking algorithms have recently reached a good level of precision, the above error parametrization is still applicable at L2 during early data, while for the EF the reconstructed error is used.

Figure 2 shows the distributions of the impact parameter significance  $d_0/\sigma(d_0)$  for  $b$ -jets and light jets at L2. The significance has been rescaled according to the function  $f(x) = \log(1 + |x|)$  in order to have a reasonably uniform bin population along the  $x$  axis. From these plots it can be guessed that the impact parameter significance is a promising choice for the discriminant variable, since the two distribution are very well separated.

### 3.3.2 Longitudinal impact parameter

The longitudinal impact parameter ( $z_0$ ), i.e. the track's  $z$ -intercept, can be adopted, as well as the transverse impact parameter, to discriminate between  $b$ -jets and light jets. After the primary vertex position has been reconstructed, the  $\delta z_0 = z_0 - z_{vtx}$  variable can be used to form a discriminant which can then be used for  $b$ -jet selection. Figure 3 shows the distributions of the longitudinal impact parameter significance ( $\delta z_0/\sigma(z_0)$ ) of  $b$ -jets and light jets at L2. The significance has been rescaled as described above for the transverse impact parameter.

As for Fig. 2, the signal and background distributions are different although much less so than for the transverse impact parameter significance. From this comparison, it is clear that most of the discrimination will be provided by the measured transverse impact parameter significance. The resolution of the longitudinal impact parameter significance is not as good due to the coarser resolution of the silicon

Figure 2: Distribution of the rescaled function (described in the text) of the transverse impact parameter significance for tracks coming from  $b$ -jets (solid line) and light jets (dashed line) at L2.

Figure 3: Distribution of the rescaled function (described in the text) of the longitudinal impact parameter significance for tracks coming from  $b$ -jets (solid line) and light jets (dashed line) at L2.

tracking detectors along the  $z$ -direction, bigger extrapolation distance from innermost silicon layer hit to primary vertex at high  $\eta$ , and to the resolution of the reconstructed primary vertex.

### 3.4 HLT $b$ -jet tagging methods

In this Section, HLT  $b$ -tagging methods are described. The likelihood ratio method is quite general and can be applied to different variables while the  $\chi^2$  method is essentially designed to test the compatibility of the tracks with respect to the primary vertex using the transverse impact parameter.
