The likelihood ratio, using information on the signal and background shape that have to be estimated on real data, is both more powerful and more difficult to tune than the  $\chi^2$  method.

#### 3.4.1 The likelihood-ratio method

The likelihood-ratio method is a statistical tool used to separate two or more event classes, and is based on a set of characteristic variables. The likelihood-ratio variable  $W$  is evaluated, for a given event, as the ratio between the probability distributions for two alternative hypotheses. In its application to  $b$ -jet selection, the likelihood-ratio variable is defined as

$$W = S(s)/S(b),$$

where  $S(s)$  and  $S(b)$  are the probability densities for the signal, the  $b$ -jets, and the background, represented in this case by the  $u$ -jets. This variable is widely used to obtain the best possible separation between signal and background, in terms of a single variable, in fits aimed at extracting the fraction of signal events in a given sample. The same variable can be also directly used, as in the  $b$ -jet selection case, to select signal events, for example by applying a cut on the likelihood-ratio variable itself.

The probability density distributions used in the  $b$ -tagging application can be functions of some parameter of each track (e.g. the transverse impact parameter  $d_0$ ) or of some collective property of the jet (e.g. its track multiplicity). In the first case, these distributions take the form

$$\begin{aligned} s(par_1, par_2, par_3, \dots, par_n), \\ b(par_1, par_2, par_3, \dots, par_n), \end{aligned}$$

where the  $1, \dots, n$  indices identify each track belonging to the jet. The corresponding likelihood-ratio variable is thus defined as

$$W = \frac{s(par_1, par_2, par_3, \dots, par_n)}{b(par_1, par_2, par_3, \dots, par_n)}$$

Exact evaluation of the  $s$  and  $b$  functions is very difficult, since it would require an almost infinite amount of simulated data; for example, in order to reasonably populate an  $n$ -dimensional cube, about 100 entries are needed for each dimension, corresponding to  $n^{100}$  tracks; even worse, the number of tracks in a jet is not fixed. However, if we assume that the variables corresponding to different tracks are independent, the ratio between the overall probability densities reduces to the product of the ratios of the single probability densities:

$$W = \prod_{i=1}^n \frac{s(par_i)}{b(par_i)},$$

which is much easier to evaluate. In the  $b$ -tagging case, track parameters have complex correlations which depend on the proper time for the  $B$  hadron and on its decay kinematics. Nevertheless, it can be proven that, neglecting these correlations does not invalidate this variable, but results only in a slight reduction of its discriminating power.

The  $W$  variable, can take any value between 0 (for the background) and  $+\infty$  (for the signal). For practical reasons, it is useful to handle a variable defined on a finite interval; to achieve this,  $W$  is usually replaced by another variable

$$X = \frac{W}{1 + W},$$

which can only range between 0 and 1.

As an illustration of the method, Fig. 4 and Fig. 5 show the distributions of the discriminant variable  $X$  which is based on the combination of the transverse and longitudinal impact parameter for  $b$ -jets and light jets respectively at L2 and EF. It can be seen that signal events ( $b$ -jets) accumulate near  $X = 1$ , while the background (light jets) tends to have  $X$  close to 0.

Figure 4: Distribution of the discriminant variable  $X$  based on the combination of the transverse and longitudinal impact parameter significances for  $b$ -jets and  $u$ -jets (dark area) at L2.

Figure 5: Distribution of the discriminant variable  $X$  based on the combination of the transverse and longitudinal impact parameter significances for  $b$ -jets and  $u$ -jets (dark area) at EF.

Contrary to the offline  $b$ -tagging methods based on likelihood ratio, the sign of the impact parameters is currently not used at HLT since the RoI direction does not give a precise estimation of the  $b$ -jet direction. Future studies will use the impact parameter sign determination respect to a track based cone jet described in the next Section.

### 3.4.2 $\chi^2$ method

The  $\chi^2$  method offers an alternative tagging approach that is more robust since it is less dependent on the details of the impact parameter distributions. This method has been studied and characterized only at L2.

The  $\chi^2$  method computes the probability for a jet to originate from the primary vertex, based on the *signed* transverse impact parameter significance of tracks pointing to the jet. This technique was originally developed by the ALEPH collaboration and extensively used at LEP and Tevatron experiments [6] [7] [8]. One of the main advantages of this method is that it only relies on the transverse impact parameter significance distribution of prompt tracks in multi-jet events, which can be easily derived completely from real data. On the other hand the performance of this method is limited due to the fact that tracks from beauty and charm particles produce significant tails with negative impact parameters. These negative tails originate from the differences of the direction of the estimated jet and  $B$ -hadrons and also in the differences of the direction of  $B$ -hadrons and charmed hadrons in the cascade decays.

The definition of the sign of the transverse impact parameter is based on the angle between the jet axis and the line between the primary vertex and the point of closest approach of the track, such that it is negative when the track appears to originate behind the primary vertex (i.e. when the angle is greater than  $\pi/2$ ) as illustrated in Fig. 6.

Figure 6: Definition of the sign of the transverse impact parameter. When the angle between the jet axis and the line between the primary vertex and the point of closest approach of the track is lower (greater) than  $\pi/2$  the sign is positive (negative).

Tracks from light-quark jets have equal probability to have positive or negative transverse impact parameters, and the width of the signed transverse impact parameter distribution depends on the tracking detector resolution and multiple-scattering effects. The signed transverse impact parameter distribution of tracks from displaced  $b$ -jets, on the other hand, has a large positive asymmetry due to the fact all that most of the long-lived particles from  $b$ -hadron decays are produced with positive impact parameters.

Good jet angular resolution is a key to achieving a good  $b$ /light-quark jet discrimination since the direction of the jet axis enters into the calculation of the sign of the impact parameter. Poor jet angular resolution results in frequent mis-assignment, particularly for tracks with small angle with respect to the jet direction.

In order to improve the resolution of the azimuthal angle ( $\phi$ ) of the jet, a track-based simple cone jet reconstruction algorithm is used instead of the jet-RoI  $\phi$  direction. Figure 7 shows that the  $\phi$  resolution improves by more than a factor of two when tracks are used to compute the jet direction. The effect of jet  $\phi$  resolution on  $b$ /light quark jet discrimination can be seen in Fig. 8, which shows the distribution of signed transverse impact parameter significance for  $b$ -jet tracks when  $\phi$  is computed using truth, RoI, and track-jet  $\phi$  directions.

The negative transverse impact parameter significance is computed using a parameterization for the

Figure 7:  $\Delta\phi$  between the true  $b$ -quark direction and its estimate using RoIs (solid line) and track-based jets (dashed line), as a function of the track-jet multiplicity.

Figure 8: Distribution of the signed impact parameter significance for  $b$ -jets when the jet  $\phi$  direction is computed using truth, track-jet, and RoI information.

Figure 9: Negative transverse impact parameter significance and the resolution function  $R(S)$  for tracks with less than 7 hits in the Silicon detectors.

Figure 10: Negative transverse impact parameter significance and the resolution function  $R(S)$  for tracks with at least 7 hits in the Silicon detectors.

transverse impact parameter error as a function of  $p_{scat} = p \sin \theta^{3/2}$  and the number of hits in the pixel detector. A double-Gaussian fit to the distribution of negative transverse impact parameter significance ( $R(S)$ ) is used to define  $p_{trk}(S)$ , the probability for a track to originate from a primary vertex:

$$p_{trk}(S) = \frac{\int_{-15}^{-|S|} R(S) dS}{\int_{-15}^0 R(S) dS} \quad (1)$$

where only tracks with positive impact parameter are used in the calculation. The distribution of negative transverse impact parameter significance and the resolution function  $R(S)$  is shown in Fig. 9 and Fig. 10 for tracks with less and more than 7 Silicon detectors hits.

The definition of  $p_{trk}$  ensures a uniform distribution between 0 and 1 for tracks originating from the primary vertex. Tracks from displaced  $B$  decays result in  $p_{trk} \sim 0$ .

A  $\chi^2$  jet probability is defined by considering the probabilities of all tracks with positive transverse

impact parameter in a jet [6]:

$$p_{jet} = \Pi \sum_{j=0}^{N-1} \frac{(-\log \Pi)^j}{j!} \quad (2)$$

where  $\Pi = \prod_1^N p_{trk}(S)$ .

Figure 11 shows the  $p_{trk}$  distribution for light and  $b$ -quark jets. The spike at small probability for light quarks tracks is due to tracks from  $V^0$  decays, which have positive transverse impact parameter.

Figure 12 shows the  $p_{jet}$  distribution for light and  $b$ -quark jets. Jets are tagged as  $b$ , if the  $p_{jet}$  is below some value, typically between 0.5% and 5%.

Figure 11: Track  $\chi^2$  probability ( $p_{trk}$ ) for  $b$ -jets (full histogram) and light jets (shaded histogram).

Figure 12: Jet  $\chi^2$  probability ( $p_{jet}$ ) for  $b$ -jets (full histogram) and light jets (shaded histogram).

## 4 HLT $b$ -jet selection performance on single jet-RoIs

Every tagging method will be characterized by the curve showing the light-jet rejection versus the efficiency to select  $b$ -jets ( $\epsilon_b$ ). The light-jet rejection is defined as the inverse of the efficiency of selecting  $u$ -jets ( $R_u = 1/\epsilon_u$ ) where we have assumed that  $u$ -jets are representative of light jets in general.

### 4.1 Likelihood ratio method using impact parameters

Figures 13 and 14 show, respectively, the  $b$ -tagging performance for L2 and EF when the transverse impact parameter significance is used in defining the discriminant variable  $X$ , while figures 15 and 16 show the  $b$ -tagging performance curves for L2 and EF, when the significance of the longitudinal impact parameter with respect to the primary vertex is used instead.

Figures 17 and 18 show the  $b$ -tagging performance curves for L2 and EF when the likelihood ratio method is built on the combination of the transverse and longitudinal impact parameter significances.

### 4.2 $\chi^2$ method

The performance of the  $\chi^2$   $b$ -tagging algorithm, evaluated as a function of the  $\chi^2$  cut is shown in Fig. 19. The limited efficiency of the method is due to the request of at least two reconstructed tracks to define the track-jet. Clearly, an effort should be made to include RoIs having only a single track. Nonetheless,

Figure 13: Performance of the  $b$ -jet selection based on the  $d_0$  significance discriminant variable at L2.

Figure 14: Performance of the  $b$ -jet selection based on the  $d_0$  significance discriminant variable at EF.

Figure 15: Performance of the  $b$ -jet selection based on the  $\delta z_0$  significance discriminant variable at L2.

Figure 16: Performance of the  $b$ -jet selection based on the  $\delta z_0$  significance discriminant variable at EF.

Figure 17: Performance of the  $b$ -jet selection based on the combination of the transverse and longitudinal impact parameter significances at L2.

Figure 18: Performance of the  $b$ -jet selection based on the combination of the transverse and longitudinal impact parameter significances.

we note that the strength of the method lies in its impact intrinsic robustness and this advantage must also be considered when comparing its performance with that of the likelihood method.

Figure 19: Performance of the  $b$ -tagging selection based on the jet  $\chi^2$  probability variable.

### 4.3 Comparison with the offline selection

To tune the online working points so as to ensure the attainment of the overall (i.e. including offline cuts) efficiency goal of 60% for  $b$ -jet tagging and avoid biases, it is crucial to evaluate the correlation between the online and offline algorithms.

The performance of the L2 and EF trigger algorithms based on impact parameters in the transverse plane has been compared to that obtained with the corresponding offline algorithm. This choice is motivated by the wish to perform a coherent comparison; more exhaustive comparison studies will be performed on specific physics selections.

Figure 20 demonstrates that the L2, EF and Offline selections are well correlated. In particular it is always possible to recover the full offline performance at a given  $b$ -jet efficiency if the L2 and EF working points are set at an appropriate higher efficiency. In particular for the trigger menu studies shown in the following, a working point of about 80% efficiency at L2 and about 70% at EF have been chosen in order to ensure full acceptance for the standard offline working point (60%).

Future studies will address remaining differences between EF and offline algorithms.

### 4.4 Execution time at L2 and EF

The execution time needed to reconstruct relevant quantities described in this note and to perform  $b$ -jet selection was evaluated both at L2 and EF. Results highlight that the timing performance fits design requirements and that the overall time spent is dominated by data preparation and track reconstruction algorithms. Further details are given in [3].

## 5 $b$ -tagging trigger strategy

After having defined and characterized the  $b$ -jet selection algorithm on single  $b$ -jet RoIs the  $b$ -jet trigger menu has to be built. Figure 21 illustrates the online  $b$ -jet selection algorithm's performance as evaluated using high statistics samples. The performance of the L2 algorithm is indicated along with the performance of the EF algorithm on events which are selected by L2 (at the nominal working point of 80% efficiency). Since the  $b$ -tagging cut is fixed, the  $b$ -tagging efficiencies vary with  $E_T$  threshold. Typical

Figure 20: The correlation between L2, EF and offline taggers

L2(EF)  $b$ -jet tagging efficiencies are  $\epsilon_b = 76(67)\%$  at  $E_T = 18 \text{ GeV}$  and  $\epsilon_b = 80(73)\%$  at  $E_T = 70 \text{ GeV}$ . This variation of the working point as a function of  $E_T$  compensates for the effect of the worsening of the  $b$ -jet tagging performance at low  $E_T$ , so the rate reduction does not change significantly with  $E_T$ .

It is clear that  $b$ -jet selection can play an important role especially for events with multiple  $b$ -jets because the selective filtering of  $b$ -jets can produce very high rejection and thereby allow a significant decrease of the L1 thresholds while keeping the jet-RoI output rate of L2 and EF almost constant.

### 5.1 $b$ -jet trigger menu

The possible  $b$ -jet signatures initiated by multi-jet L1 signatures with given  $E_T$  thresholds can be represented in general as  $\mathbf{nb}E_T\text{-}\mathbf{mL1J}E_T$ , where  $n$  indicates the number of  $b$ -tagged jets required out of  $m$  L1 jets with transverse energy greater than  $E_T$ . The HLT  $b$ -tagging working point is the one describe in section 4.3. The rate reduction as a function of the available L1 thresholds is shown in Fig. 22. The EF output rates of different multi  $b$ -jet signatures at the luminosity of  $10^{31} \text{ cm}^{-2}\text{s}^{-1}$  are given in Table 1. The rates and uncertainties of these rates have been computed for dijet samples using the relations

$$\begin{aligned}
 p_i &= N_{EF}^i / N_{Total}^i \\
 R &= \mathcal{L} \sum p_i \sigma_i \\
 \sigma(R) &= \mathcal{L} \sqrt{\sum \frac{p_i(1-p_i)}{N_{Total}^i} \sigma_i^2}
 \end{aligned} \tag{3}$$

Figure 21:  $b$ -jet performance based on the combination of the transverse and longitudinal impact parameter (EF selection starts from the chosen L2 working point).

Figure 22: Rate reduction achieved with HLT  $b$ -jet as a function of the L1  $E_T$  threshold.

where  $N_{EF}^i$  and  $N_{Total}^i$  are respectively the number of events selected at the end of the trigger chain and the total number of events in the sample  $J_i$ ,  $\sigma_i$  is the cross-section of the sample  $J_i$  and  $\mathcal{L}$  is the luminosity.

The uncertainties in the tables indicate that at high transverse energy, the rate computation is not very

precise. Nevertheless, with the requirement of keeping the EF output rate at a few Hz for each multi  $b$ -jet signature, trigger menus for different luminosities can be chosen as:

- luminosity  $10^{31} \text{ cm}^{-2}\text{s}^{-1}$ : **3b23\_3L1J23, 3b18\_4L1J18**
- luminosity  $10^{32} \text{ cm}^{-2}\text{s}^{-1}$ : **2b42\_3L1J42, 3b35\_3L1J35, 3b23\_4L1J23, 4b18\_4L1J18**
- luminosity  $10^{33} \text{ cm}^{-2}\text{s}^{-1}$ : **2b70\_3L1J70, 3b42\_3L1J42, 3b35\_4L1J35, 4b23\_4L1J23**

It can be noticed that as the luminosity increases, requiring more  $b$ -tagged jets is a viable alternative to increasing  $E_T$  thresholds.

Transverse energy $E_T[\text{GeV}]$	Signature rate [Hz]			
	$2bE_T\_3L1JE_T$	$3bE_T\_3L1JE_T$	$3bE_T\_4L1JE_T$	$4bE_T\_4L1JE_T$
18	$47 \pm 11$	$1.5 \pm 0.4$	$1.0 \pm 0.3$	$0.2 \pm 0.1$
23	$18 \pm 7$	$0.5 \pm 0.2$	$0.4 \pm 0.2$	$0.004 \pm 0.002$
35	$1.0 \pm 0.2$	$0.04 \pm 0.01$	$0.02 \pm 0.01$	$0.0007 \pm 0.00006$
42	$0.4 \pm 0.1$	$0.02 \pm 0.01$	$0.01 \pm 0.01$	$0.0007 \pm 0.00006$
70	$0.01 \pm 0.02$	$0.0008 \pm 0.0006$	$0.0007 \pm 0.0006$	$0.0007 \pm 0.00006$

Table 1: EF output rates for the different multiple  $b$ -jet signatures at  $10^{31} \text{ cm}^{-2}\text{s}^{-1}$ .

The strategy behind the evolution of the  $b$ -jet signatures is to select more aggressively as luminosity increases and HLT tracking becomes better understood. Before the  $b$ -jet trigger achieves full performance, a good online resolution of track impact parameters must be achieved. In turn, this requires adequate knowledge of the inner detector alignment and sufficient understanding of the overall detector performance.

## 5.2 Prospects for measuring efficiency and correlation with offline on real data

The HLT  $b$ -tagging group is working closely with the offline  $b$ -tagging group to develop a method to measure the  $b$ -jet efficiency with real data. For an explanation of the method and a discussion of its performance we refer to the  $b$ -tagging note on dijets [5].

In addition to the “physics” triggers listed in the previous Section, the  $b$ -jet group has introduced several “technical” triggers in order to study rate and correlation of the online and offline algorithms:

- single  $b$ -jet signatures:  $b18, b23, b35, b42, b70$ : prescaled to limit their contribution to the EF output to few Hz;
- each multi jet item is duplicated with an identical signature which selects, independently of the HLT  $b$ -jet result, one over  $n$  events (where  $n$  is presently set at 1000 but will be tuned according to the rate allocated to  $b$ -jet triggers).

## 6 Summary and conclusions

The  $b$ -jet selection at the L2 and EF stages of the ATLAS High Level Trigger has been described and characterized. An HLT  $b$ -tagging trigger menu has been implemented which demonstrates the feasibility of increasing the acceptance of events with more than one  $b$ -jet by decreasing L1 jet  $E_T$  thresholds while controlling the output rate by introducing a  $b$ -jet selection at the HLT.

# Overview and Performance Studies of Jet Identification in the Trigger System

## Abstract

This note describes in detail the algorithms used to identify jets in the ATLAS trigger system. Results from performance studies of these jet algorithms are presented. An initial trigger menu using jets and proposed strategy to adapt to increases in luminosity are also discussed.

## 1 Introduction

A critical component of the ATLAS trigger system is the ability to efficiently identify hadronic jets in an event. The performance of the jet reconstruction depends on the trigger jet energy resolution and scale. In this note we discuss the algorithms at the different trigger levels and evaluate their performance.

## 2 L1 jet trigger algorithm

A detailed description of the L1 jet trigger algorithm can be found in [1]; however, for completeness, a summary of the relevant features of this algorithm is presented below.

The ATLAS electromagnetic and hadronic calorimeters are segmented into approximately 7200 trigger towers, with granularity of approximately  $0.1 \times 0.1$  in  $\eta \times \phi$  space. The granularity varies slightly in different sub-detector systems, for further details see [1]. Analog signals from these trigger towers are transmitted directly to the L1 system. The L1 hardware digitises the trigger tower signals, associates them with a bunch crossing and performs pedestal subtraction. The L1 system also applies a noise suppression threshold and transverse energy calibration. The electromagnetic tower  $E_T$  response is calibrated at the EM scale and the hadronic tower  $E_T$  response is calibrated for jets.

The L1 trigger constructs “jet elements” made of the sum of  $2 \times 2$  trigger towers in the electromagnetic (EM) calorimeter added to  $2 \times 2$  trigger towers in the hadronic calorimeter which gives a granularity of  $0.2 \times 0.2$  in  $\eta \times \phi$  space. The jet reconstruction algorithm consists of a sliding window of programmable size that could be either  $2 \times 2$ ,  $3 \times 3$  or  $4 \times 4$  jet elements. A jet is reconstructed if the total transverse (EM+Hadronic) energy within the window is above a given threshold. The step size for the sliding window is 0.2 in both  $\eta$  and  $\phi$  which implies significant overlap of the window in neighbouring positions. To prevent the L1 algorithm from identifying overlapping jets, the transverse energy of a cluster, defined as a region spanned by  $2 \times 2$  jet elements, is required to be a local maximum within  $\pm 0.4$  units in  $\eta$  and in  $\phi$ . The L1 jet algorithm identifies jets within the region of  $|\eta| < 3.2$ . Figure 1 shows a schematic diagram of the jet reconstruction algorithm at L1.

In contrast to the other calorimeters, the L1 forward calorimeter (FCAL) trigger towers have a granularity of approximately  $0.4 \times 0.4$  in  $\eta$  and  $\phi$ . The forward jet trigger electronics was originally designed to only be used for the calculation of missing  $E_T$  at L1, and not to identify in addition jets in the forward regions of the detector. As a consequence, limited granularity of the FCAL data is available at L1. A jet element in the FCAL is formed by summing calorimeter towers in  $\eta$ . Therefore, the FCAL jet elements have a  $\phi$  granularity of 0.4 with only a single  $\eta$  bin at each end. This has an impact on how the HLT forward jet reconstruction algorithm is implemented, as discussed in Section 5.

In the tentative menu proposed for early data taking, a sliding window size of  $4 \times 4$  jet elements has been chosen for almost all thresholds; the exception is the algorithm used to reconstruct b-jets which has a proposed transverse energy threshold of 5 GeV and uses a window size of  $2 \times 2$  to minimise the identification of fake jets associated with possible calorimeter noise.

Figure 1: Schematic diagram of the L1 jet algorithm showing a window of  $4 \times 4$  jet elements spanning the electromagnetic and hadronic calorimeter in depth, and a local maximum transverse energy cluster of  $2 \times 2$  jet elements.

Table 1: Simulated dijet event samples used to study the performance of the jet trigger algorithms. The last row gives a summary of the cuts applied on the hard scatter parton in the event.

Event Sample	J0	J1	J2	J3	J4	J5	J6	J7	J8
Cross-section (mb)	17.6	1.4	9.3E-2	5.9E-3	3.14E-4	1.3E-5	3.6E-7	5.3E-9	2.22E-11
$E_T$ Range (GeV)	8-17	17-35	35-70	70-140	140-280	280-560	560-1120	1120-2240	> 2240

### 3 L1 performance

Dijet events were used to study the performance of the L1 jet trigger algorithm. Table 1 provides a summary of the simulated data samples used along with their respective cuts on the hard scatter parton and cross-section. These simulated dijet event samples, together, span the whole  $E_T$  jet spectrum relevant for jet identification in the trigger.

The transverse energy scale of L1 jets is defined as the ratio between the transverse energy measured in L1 divided by the truth jet  $E_T$ . Each jet identified by the L1 trigger was matched to a truth jet found using the cone algorithm with  $R = 0.4$ . The matching criterion consists in searching for the closest truth jet in the  $\eta - \phi$  plane, where the distance is defined as  $\Delta R = \sqrt{(\eta_{L1} - \eta_{Reco})^2 + (\phi_{L1} - \phi_{Reco})^2}$ . The L1 jet transverse energy scale as function of truth jet  $E_T$  is shown in Fig. 2(a). The transverse energy scale at L1 varies from about 70% to 90%, increasing with the transverse energy of the jet. There are several effects that contribute to this behaviour. The first one is the noise suppression mentioned in Section 2. The lower the transverse energy of the jet, the larger is the number of trigger towers that do not satisfy this noise suppression threshold leading to an underestimation of the jet transverse energy. In addition, each L1 trigger tower signal must be associated with a particular Bunch Crossing Identification number. The efficiency of this requirement is approximately 50% for 1 GeV trigger tower signals, reaching nearly 100% for 3 GeV trigger tower signals. Again, this inefficiency particularly affects lower transverse energy jets that will tend to contain a larger fraction of trigger towers with low energy signals. The most important reason for the lower jet transverse energy scale with respect to truth jets comes from the different  $e/\pi$  response of EM and hadronic towers. For presentation purposes, a common conversion factor is used to translate the number of counts measured in an EM or hadronic tower into units of transverse energy. This results in an apparent lower jet transverse energy scale compared to truth jets. It is important to note that thresholds in the L1 are applied in terms of the internal L1 quantity “counts” and not in units of transverse energy. In Fig. 2(b), the L1 jet transverse energy scale is also shown as

Figure 2: The L1 jet transverse energy scale as function of truth jet transverse energy (a) and pseudo-rapidity (b).

Figure 3: L1 jet transverse energy resolution as a function of truth jet transverse energy (a) and the L1 jet trigger efficiency as function of the offline reconstructed jet  $E_T$  for different L1 energy thresholds (b).

a function of the pseudo-rapidity ( $\eta$ ) of the truth jet. The response of the different calorimeter sub-detectors can be identified. Figure 3(a) shows the L1 transverse energy resolution as function of truth jet  $E_T$ . The transverse energy resolution is defined as the width of the  $E_T^{L1} - E_T^{truth}$  distribution in each  $E_T^{truth}$  bin, divided by the  $E_T^{truth}$  of that bin.

Figure 3(b) shows the L1 jet trigger efficiency as function of offline reconstructed jet  $E_T$  for different L1 jet trigger thresholds. The limited jet transverse energy resolution of the L1 system particularly affects the higher L1 energy thresholds.

The effect of pile-up on the performance of the L1 jet trigger reconstruction was also studied. At a luminosity of  $10^{33} \text{ s}^{-1} \text{ cm}^{-2}$ , an average of approximately 2 inelastic collisions are expected per bunch crossing. Simulated dijet events including this level of pile-up were generated. The effect of increased occupancy in the calorimeters will have some impact on the reconstructed transverse energy of the jet. Figure 4 shows the impact of this pile-up on the L1 jet transverse energy scale and jet trigger efficiency. The transverse energy scale increases due to the additional energy deposited in the calorimeter from pile-up events. The L1 transverse energy resolution also worsens as seen on Fig. 4(b). The effect is clearly more important for low energy jets where the contribution of pile-up energy can be of the same order of magnitude as the jet energy itself.

Figure 4: The L1 jet transverse energy scale as function of truth jet transverse energy (a) for simulated dijet events with pile-up. The L1 jet trigger efficiency as function of offline reconstructed jets (b) for a 35 GeV L1 trigger threshold, with and without taking into account pile-up.

## 4 HLT jet algorithms

The HLT object reconstruction is guided by the result of the L1 system. HLT algorithms typically only access data from a limited region of the detector in the vicinity of an RoI provided by L1. The position of this RoI is successively updated and refined by the HLT algorithms.

HLT algorithms are classified in two types:

- “Feature Extraction algorithms”: Algorithms that retrieve and unpack detector data and create simple classes composed of useful physics observables. These algorithms consume most of the available time.
- “Hypothesis algorithms”: Algorithms that retrieve the physics information produced in the preceding Feature Extraction algorithms, and validate a specific hypothesis (e.g.  $E_T$  threshold). These algorithms have a very fast execution time.

This separation between Feature Extraction and Hypothesis algorithms optimises the overall execution time since the data retrieved by a single Feature Extraction algorithm can be used to provide input to several fast Hypothesis algorithms to test various physics signatures, and hence avoids multiple data access and unpacking.

Figure 5 shows a schematic diagram of the sequence of algorithms used to reconstruct jets in the HLT. The Hypothesis algorithms for jets reconstructed at L2 and EF compare the energy of the jet candidates to some predefined  $E_T$  thresholds. The next few sections describe in detail each Feature Extraction algorithm appearing in Fig. 5.

## 5 L2 jet algorithm

Standard L2 jets are defined within the  $|\eta| < 3.2$  region and are reconstructed using the electromagnetic and hadronic calorimeter data. Forward jets are defined within the range  $3.2 < |\eta| < 5$  and are reconstructed using data from the forward calorimeters. As described below, the forward jet reconstruction is different than the standard jet algorithm due to the limited  $\eta$  position resolution of L1 jets.

The output of the L2 Feature Extraction algorithm is a reconstructed jet with a given energy and position in  $\eta$  and  $\phi$ . The algorithm contains three distinct parts described below: data preparation, jet finding and calibration.

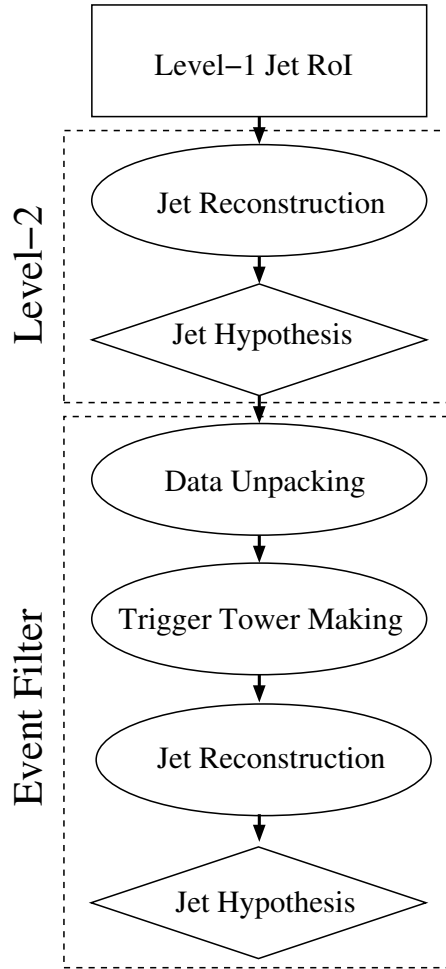

Figure 5: Schematic diagram of the sequence of algorithms used to reconstruct jets in the HLT. The ovals and diamonds represent Feature Extraction algorithms and Hypothesis algorithms, respectively.

### 5.1 L2 jet data preparation

The data preparation for the L2 jet trigger is a critical part of the algorithm chain. It provides the collection of data from the detector readout drivers (ROD) to the L2 processing units and the conversion from the raw data into bytestream files readable by the HLT algorithms. The RODs receive data from the calorimeters front-end boards (FEB) via optical fibres. The FEBs are installed on the detector and contain the electronics for amplifying, shaping, sampling, pipelining, and digitising the signals [2, 3].

The ATLAS calorimeters consist of more than  $10^5$  individual readout channels; therefore, in order to meet the L2 timing performance goals of 40 ms total processing time per event, the amount of data unpacked must be kept to a minimum while simultaneously maximising the physics performance of the algorithm.

The L2 jet trigger algorithm accesses calorimeter data that lies in a rectangular region centred around the L1 jet RoI position with a width  $\Delta\eta$  and  $\Delta\phi$  that can be defined to have any size. The widths  $\Delta\eta$  and  $\Delta\phi$  are parameters that are specified at trigger configuration time. Figure 6 shows a schematic diagram of the L2 jet reconstruction algorithm.

The position and transverse energy of each detector element that falls into the chosen  $(\Delta\eta, \Delta\phi)$  window is read out by the algorithm. As a result the calorimeter read out region can be regarded as

Figure 6: Schematic diagram summarising the L2 jet algorithm. The data unpacking step reads in the necessary calorimeter data within a predefined window size and defines a grid of calorimeter elements each with an associated energy and position. The size of grid elements depends on the calorimeter data unpacking method used. The dark (red) boxes in the diagram represent grid elements with substantial energy deposition. The algorithm is seeded by the L1 position as shown on the left. The final jet is found after a given number of iterations. The position of the jet is calculated as the energy weighted average of the grid elements position within a given cone size. The energy of the jet is calculated as the sum of the energy of each grid elements falling within the given cone size.

partitioned into a grid of elements with associated energies and  $(\eta, \phi)$ -coordinates as shown in Fig. 6. Therefore, the amount of data accessed is equivalent to the number of grid elements.

Two different data unpacking approaches are implemented and described below. One of the methods, the cell-based approach, has finer granularity and hence produces more accurate energy and transverse energy reconstruction, but is more time consuming. The other method, the front-end board approach, is faster but the coarser granularity produces a less precise reconstruction. Both methods are, as we will see in section 6, reasonably within the L2 time budget limits. The final decision of what approach should be used will be made depending on the final High Level Trigger setup.

### 5.1.1 The cell-based approach

This method uses the full granularity of the calorimeters [1]. Each grid element in Fig. 6 corresponds to a calorimeter cell with a given transverse energy and  $(\eta, \phi)$ -coordinate provided by the ROD. In the following discussions, jets reconstructed using this data unpacking approach are referred to as “cell-based jets”.

### 5.1.2 The front-end board approach

This method uses a coarser granularity than the cell-based data unpacking. Instead of reading out every cell over a specified region of the liquid argon (LAr) calorimeters, only information from the LAr calorimeters front-end boards is used. There are 128 readout channels per FEB and two FEBs are connected to one ROD. For the tile calorimeter, the full cell granularity is still used.

In the RODs, the sums of the Cartesian components of the cell energies are calculated for each FEB:

$$E_x = \sum_{i=1}^{128} E_i \frac{\cos \phi_i}{\cosh \eta_i} \quad (1)$$

$$E_y = \sum_{i=1}^{128} E_i \frac{\sin \phi_i}{\cosh \eta_i} \quad (2)$$

$$E_z = \sum_{i=1}^{128} E_i \tanh \eta_i \quad (3)$$

where  $E_i$  is the energy and  $\phi_i$ ,  $\eta_i$  the position of each cell. This sum is computed per FEB and runs over all channels with an energy  $E_i > 2 \cdot \sigma_{\text{noise}}$ . The noise cut value, which is a configuration parameter, has been determined from performance studies with QCD dijet events, such as to give the similar jet energy scale as obtained with the cell-based approach, which will be presented in the next section. The total energy of the cells connected to a FEB is then obtained from the quadratic sum of the three components,  $E_{\text{tot}} = \sqrt{E_x^2 + E_y^2 + E_z^2}$ . The corresponding  $\eta$  and  $\phi$  coordinates are calculated as

$$\eta = \text{atanh}(E_z/E_{\text{tot}}),$$

$$\phi = \text{atan2}(E_y/E_x),$$

where the function  $\text{atan2}$  returns the angle  $\phi \in [-\pi, \pi]$ . The resulting values for the energy and the  $(\eta, \phi)$ -coordinate are then used to define the grid of elements in a region around the L1 RoI position, as is illustrated in Fig. 6. In the following text, jets reconstructed using this data unpacking method are referred to as “FEB-based jets”.

## 5.2 L2 jet finding algorithm

Jets are defined as a cone-shaped object in the  $(\eta, \phi)$ -space with a given radius  $\Delta R = \sqrt{\Delta\eta^2 + \Delta\phi^2}$ . The value  $\Delta R$  is a parameter of the algorithm that is defined at trigger configuration time. The jet energy and position are found through an iterative procedure with the following steps:

- The L1 jet RoI is used as a seed for the algorithm. A reference jet is created, labeled  $j_0$ , defined by the L1 jet RoI position with the pre-defined cone radius  $\Delta R$  (see left-hand side of Fig. 6). Note that the possible positions of the reference jet  $j_0$  are discrete due to the L1 granularity.
- Grid elements that fall within the  $(\eta, \phi)$ -region encompassed by the reference jet  $j_0$  are used to recalculate the jet energy and position according to:

$$\eta_{j_1} = \frac{\sum_{i=1}^k E_i \eta_i}{\sum_{i=1}^k E_i}, \quad (4)$$

$$\phi_{j_1} = \frac{\sum_{i=1}^k E_i \phi_i}{\sum_{i=1}^k E_i}. \quad (5)$$

The sum runs over the  $k$  grid elements that are contained in the cone defined by the reference jet  $j_0$ . A grid element is included in the sum if its centre falls within the region spanned by the cone radius  $\Delta R$ . The total energy and coordinates  $(\eta_{j_1}, \phi_{j_1})$ , computed in Equations (4) and (5), are used to define the new reference jet  $j_1$ .

- The previous step is repeated with  $j_0$  replaced by  $j_1$  in Equations (4) and (5), which results in updated coordinates  $\eta_{j_2}$  and  $\phi_{j_2}$  to define the updated jet  $j_2$ . This algorithm can be repeated  $N$  times to create jet  $j_N$ .

- A predetermined fixed number of iterations are executed. The energy of the final jet is calculated as the sum of the energy of all the grid elements falling within the cone radius. The position of the jet is obtained as the energy weighted average of the position of each grid elements within the cone, as shown in Fig. 6.

The outcome of this algorithm is a jet defined by its  $(\eta, \phi)$  position and total energy. The calorimeter energy scale, at this point, is set at the electromagnetic scale which does not provide an accurate measure of the jet energy. The next Section describes the calibration weights applied to correct the total jet energy for non-electromagnetic shower components.

### 5.3 L2 jet calibration

The ATLAS calorimeter response to the electromagnetic component of a hadron shower is not equal to the response to the non-electromagnetic component. In general, the hadronic response ( $h$ ) is smaller than the electromagnetic response ( $e$ ),

$$e/h > 1.$$

This effect is mainly due to the energy lost in the breakup of nuclei or in nuclear excitation. In order to correct for it, a weight is applied to each element that makes up a jet. Depending on the calibration method used, a jet can be regarded as composed, for example, of individual calorimeter cells or of energy deposits in calorimeter samplings. The calibrated jet energy can then be written as:

$$E_{\text{jet}}^{\text{rec}} = \sum_{i=1}^n w_i E_i \quad (6)$$

where the sum runs over the  $n$  constituents of the jet.

The weights  $w_i$  in Equation (6) are extracted using simulated event samples by minimising the function:

$$S = \sum_{m=1}^{N_{\text{jets}}} \left[ \frac{(E_m^{\text{truth}} - E_m^{\text{rec}})}{\sigma_m} \right]^2 \quad (7)$$

The sum runs over all the jets in the events. The true energy of the  $m$ -th jet in the event is labeled  $E_m^{\text{truth}}$  and is obtained from the Monte Carlo (MC) truth information, running a cone jet algorithm with radius  $\Delta R = 0.4$  over the MC truth particles and finding the truth jet that is closest to the  $m$ -th jet. A truth jet is made up of all particles generated, excluding neutrinos and muons which have their own observables, missing transverse energy for neutrinos and reconstructed tracks for muons. By minimising  $S$  with respect to the true jet energy, an improvement of the jet energy scale and resolution is obtained.

Different calibration methods can be applied, which differ in the partitioning of the jet energy into calorimeter components (e.g. cells, layers). The calibration method used here is the so-called sampling technique [4]. In this method, individual weights can be applied to the energy deposited in each of the electromagnetic (EM) and hadronic (HAD) calorimeter sampling layers. The energy dependence of the weights is chosen to be:

$$w_i = a + b \log(E). \quad (8)$$

In the implementation used for L2 jets, only two weights are calculated and applied to calibrate the reconstructed jet energy; one weight for the total energy deposited in the EM calorimeter, and one weight for the total energy deposited in the hadronic calorimeter. Furthermore, the  $\eta$  range is split in 32 bins with a size of 0.1 in the region  $0 < |\eta| < 3.2$ . This procedure assumes an azimuthally symmetric response. This assumption will need to be validated with real data. A fit to Equation (8) is performed

Table 2: Parameters used in the L2 jets reconstruction. The value of the cone size radius is defined for each iteration.

Parameter	Standard Jets	Forward Jets
Number of iterations	3	3
Cone radius	0.4/0.4/0.4	1/0.7/0.4
$\Delta\eta$ window size	1.4	$3 <  \eta  < 5$
$\Delta\phi$ window size	1.4	1.4

using the MINUIT2 package [5]. It yields the values of the two parameters of Equation (8) for each  $\eta$ -bin and for the electromagnetic and hadronic calorimeter sampling. The computed weights are then stored in a configuration file, which serves as input to the L2 jet algorithm that applies the weights to each identified jet.

#### 5.4 L2 jet parameters

In the configuration of the L2 jet trigger algorithm, the values of the following parameters need to be set:

- the data unpacking method: cell-based or FEB-based,
- the calorimeter window size  $\Delta\eta$  and  $\Delta\phi$ , where data need to be unpacked,
- the radius of the cone  $\Delta R$  used in the jet finding algorithm,
- the number of iterations used in the jet finding algorithm,
- the calibration constants used.

A set of parameter values which yields the optimal balance between short execution times and adequate physics performance must be chosen.

## 6 L2 performance

The performance of the L2 jet algorithm was studied using the simulated dijet event samples described in Table 1.

The parameters used in the reconstruction of the L2 jets are summarised in Table 2. These parameters were found to be a good compromise between the physics performance (e.g., energy resolution and scale) and the algorithm execution time.

The first parameter studied was the number of iterations of the jet finding algorithm. The variation in the jet  $(\eta, \phi)$  coordinate and transverse energy after each iteration of the jet reconstruction algorithm is shown in Fig. 7. The largest variation in  $E_T$ ,  $\eta$  and  $\phi$  happens after the first iteration and thus it has the largest impact on the measurement precision. This suggests that the number of iterations could possibly even be reduced to 2 without losing too much precision on this measurement.

In order to study the effect of the window size used to unpack calorimeter data, the total time spent by the jet algorithm running with different sizes was studied. Windows with dimensions of  $1.0 \times 1.0$  (in  $\eta \times \phi$ ) and  $1.4 \times 1.4$  were studied. A window size of  $1.0 \times 1.0$  is only slightly larger than the diameter of a jet with  $\Delta R = 0.4$ . The maximum initial displacement of a jet with respect to a truth jet is approximately 0.2 in  $\Delta\eta$  or  $\Delta\phi$ , as can be seen in Fig. 7. Therefore, a window size of  $1.0 \times 1.0$  should be adequate for

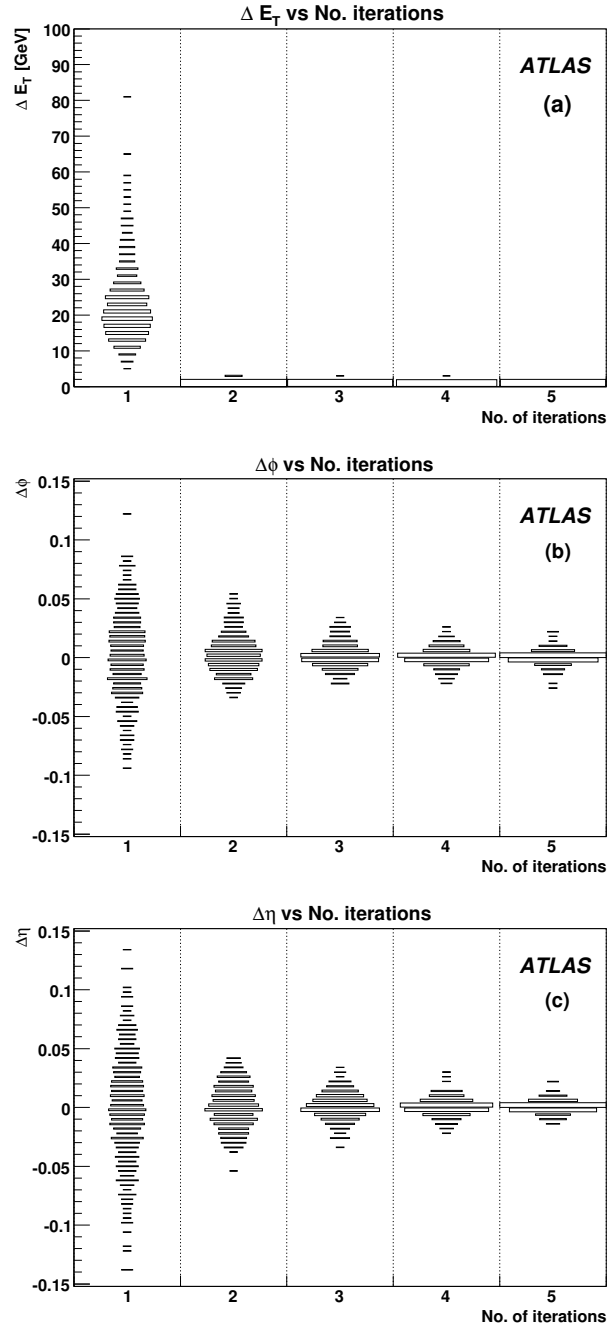

Figure 7: Variation in the (a) transverse energy, (b)  $\phi$  position and (c)  $\eta$  position of jets as function of number of iterations performed by the L2 jet reconstruction algorithm. The area of the boxes is proportional to the number of entries in each bin.

Figure 8: Time spent by the L2 jet reconstruction algorithm for two different window sizes:  $1.4 \times 1.4$  (dashed line) and  $1.0 \times 1.0$  (solid line).

the jet reconstruction. The total time spent by the L2 jet algorithm for two different window size and using three iterations is shown in Fig. 8. A reduction of the window size from  $1.4 \times 1.4$  to  $1.0 \times 1.0$  results in a considerable reduction (of order 30%) in the processing time. As shown in the next section, the energy scale and resolution is not significantly affected by this reduction of the size of the window.

### 6.1 Performance for cell-based reconstruction

The calibration constants used to reconstruct cell-based jets in L2 were extracted using dijet events simulated with PYTHIA [6] and following the approach described in Section 5.3. The L2 jet transverse energy scale and resolution for cell-based jets after calibration are presented in Fig. 9. The transverse energy scale is defined as the L2 jet transverse energy divided by the truth jet  $E_T$ . Truth jets are identified by applying the cone algorithm with  $R_{\text{cone}} = 0.4$  on the collection of truth final state particles. The transverse energy scale is close to unity for all the  $\eta$  coverage of the L2 jet trigger and all the transverse energies studied, demonstrating that the transverse energy is correctly measured within 2%. The jet transverse energy resolution decreases from 12% for the lowest transverse energies to 4% for transverse energies above 1000 GeV. The resolution curves were fitted with the following expression that includes a stochastic term convoluted with a constant term:

$$\frac{\sigma(E)}{E} = \frac{A}{\sqrt{E}} \oplus B \quad (9)$$

Table 3 shows the result of the fits for all the  $\eta$  bins, before and after calibration. A few percent improvement in the resolution is obtained with the current calibration method. A further improvement can be achieved in the future by exploiting the correlation between the fraction of electromagnetic energy and the calibration weights [7].

In another study, two different window sizes were used in order to study the effect on the jet energy scale and resolution. L2 jets were reconstructed using a window size of  $0.7 \times 0.7$  (in  $\eta \times \phi$ ) which was chosen to be slightly smaller than the jet cone diameter ( $2 \times \Delta R = 2 \times 0.4 = 0.8$ ) such that some of the energy of the jet may lie outside the window considered. Results were compared with the performance obtained using the window size dimension of  $1.4 \times 1.4$ . The jet energy calibration constants were calculated independently in both cases and the resulting jet energy scale and resolutions were compared. In both cases, the jet energy scale was found to be within 2% of unity. The resolution of the jets was also found to be similar for both window sizes. This means that the calibration algorithm can adequately correct for a small fraction of the jet energy lost outside the window considered. Therefore, using a window

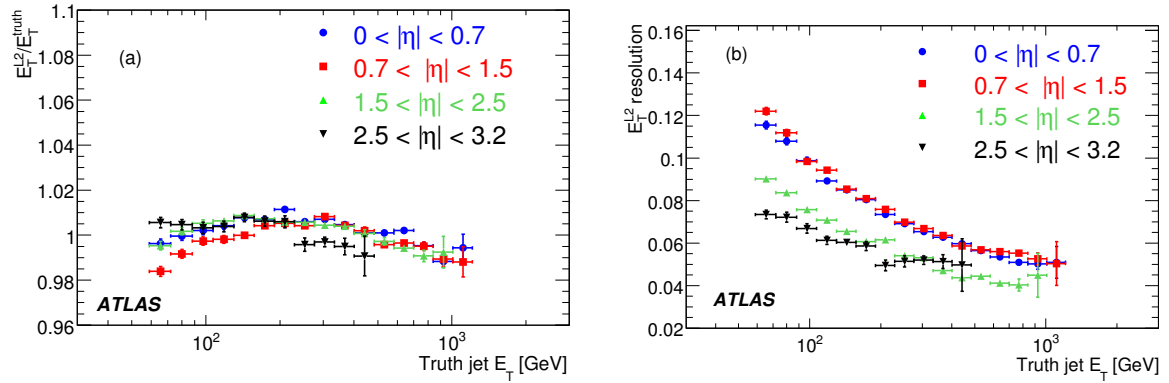

Figure 9: Jet energy scale for the L2 jets as a function of the truth jet  $E_T$  (a), for four different bins in  $\eta$ . Jet energy resolution as a function of the truth energy of the jet (b), for four different bins in  $\eta$ . These results are obtained after calibration.

Table 3: Results of the jet energy resolution fit as a function of the truth jet energy, before and after applying the calibration. The fit was done using Equation (9).

$\eta$ region	Before calibration		After calibration	
	A	B	A	B
(0.0,0.7)	$1.03 \pm 0.03$	$0.059 \pm 0.001$	$0.96 \pm 0.02$	$0.039 \pm 0.001$
(0.7,1.5)	$1.28 \pm 0.03$	$0.064 \pm 0.001$	$1.18 \pm 0.03$	$0.041 \pm 0.001$
(1.5,2.5)	$1.53 \pm 0.04$	$0.046 \pm 0.001$	$1.37 \pm 0.03$	$0.025 \pm 0.002$
(2.5,3.2)	$1.86 \pm 0.13$	$0.063 \pm 0.003$	$1.46 \pm 0.08$	$0.040 \pm 0.003$

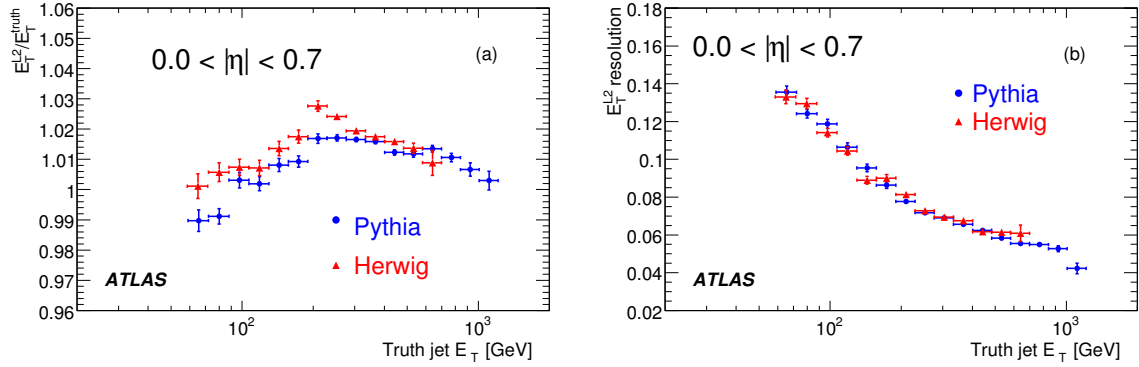

Figure 10: Comparison of the L2 jet energy scale and resolution obtained for two different MC generators, PYTHIA ( blue circles) and HERWIG (red triangles), for jets in the region  $0 < \eta < 0.7$ .

size of  $1.0 \times 1.0$  will reduce processing time while keeping essentially the same physics performance as the larger window ( $1.4 \times 1.4$ ).

The jet energy measured in the calorimeter may be sensitive to the shower development and the hadronisation mechanism that was introduced in the MC simulation. In order to test the sensitivity of the calibration procedure to the simulation, a set of dijet event samples generated with HERWIG [8] was used. Calibration constants were extracted with the PYTHIA dijet samples and used in the reconstruction of the HERWIG dijet events. The jet energy scale and resolution obtained in this way with the HERWIG data sample was compared, in different  $\eta$  regions and  $E_T$  values, with the one obtained for PYTHIA. Figure 10 shows, as an example, such a comparison in one particular  $\eta$  region. Differences between the two generators were found to be smaller than 2%, for all regions of  $\eta$  and jet  $E_T$ , suggesting that the L2 jet energy scale is relatively insensitive to the hadronisation model used in MC generators.

Figure 11 shows the L2 trigger efficiency as function of offline jet  $E_T$  after calibration has been applied for four different L2 thresholds. The L1 threshold of 15 GeV was chosen to be significantly smaller than that for L2 in order to avoid a mixture of resolution and jet energy scale effects from the two different trigger levels. The limited sharpness of the curves shown on Figure 11 is, therefore, dominated by the resolution of the L2 jet energy.

Initially, the detector simulation is not expected to provide an exact model of the real detector. The energy measurement will be mainly affected by an incomplete knowledge of the dead material distribution in front of the calorimeters. To study the effect that the limited knowledge of the detector geometry may have on the performance of the trigger and reconstruction algorithms, dedicated MC dijet event samples were produced. They were reconstructed with a geometry where detectors were slightly displaced from their nominal positions and extra dead material was added. This accounted for 7-10% of a radiation length in the inner detector and a few percent of one radiation length in front of the calorimeter. The knowledge of the dead material distribution is assumed to be worst at the interface between different calorimeter subsystems.

The calibration constants obtained assuming a perfect geometry were used to identify L2 jets in the misaligned samples. Hence, the resulting jet transverse energy scale and resolution can serve as an estimation of how much the performance of the L2 jet reconstruction may be degraded due to the limited knowledge of the detector geometry and dead material distribution at the beginning of the data taking period. Figure 12 shows the jet transverse energy scale and resolution obtained for dijet events reconstructed with this mismatch of calibration constants. For most of the pseudo-rapidity region, the linearity with energy is within 3-4%, slightly worse than before. In the region ( $1.5 < |\eta| < 2.5$ ) the jet

Figure 11: Trigger efficiency as function of offline jet transverse energy for L2 jets after calibration, for four different thresholds (35 GeV, 42 GeV, 70 GeV and 100 GeV). The statistical uncertainty on each point is smaller than the symbols.

Figure 12: Jet transverse energy scale for L2 jets as a function of the truth jet transverse energy (a), for four different  $\eta$  regions. Jet transverse energy resolution as a function of the truth jet transverse energy (b), for four different  $\eta$  regions. Both plots were obtained using dijet event samples reconstructed assuming a limited knowledge of the detector's dead material distribution.

energy scale drops to about 94% due to the extra dead material. The transverse energy resolution is also degraded, as shown in Table 4. The performance of the calibration at the beginning of data taking can be improved using in-situ calibration procedures used to extract the calibration constants directly from the data or to correct the detector response in the MC. Several different procedures are currently under study.

The reconstructed jet position is another parameter used to measure the algorithm performance. Currently no selection on jet position is made at the trigger level, but this may prove useful in the future for some physics channels. The position resolution is shown in Fig. 13. This figure is also included for completeness to compare with the FEB unpacking approach that uses a coarser granularity of data.

## 6.2 Performance for FEB-based reconstruction

Studies were done to evaluate the performance of the L2 jet reconstruction using the FEB-based method of data unpacking. For comparison with results presented in Fig. 12, dijet event samples that assume

Table 4: Results of the jet energy resolution fit as a function of the truth jet energy for the event samples where a limited knowledge of the detector’s dead material is assumed. The fit was done assuming Equation (9).

$\eta$ region	After calibration	
	A	B
(0.0,0.7)	$1.04 \pm 0.02$	$0.038 \pm 0.002$
(0.7,1.5)	$1.24 \pm 0.03$	$0.055 \pm 0.001$
(1.5,2.5)	$1.95 \pm 0.04$	$0.018 \pm 0.004$
(2.5,3.2)	$1.66 \pm 0.09$	$0.039 \pm 0.002$

Figure 13: The  $\eta$ -resolution (a) and  $\phi$ -resolution (b) of L2 cell-based jets with respect to the truth jet energy. The mean and standard deviation of a Gaussian fit of (a) is 0.0006 and 0.03, while the mean and standard deviation of a Gaussian fit of (b) is 0.00005 and 0.01.

Figure 14: (a) Jet energy scale for the L2 FEB-based jets as a function of the truth jet  $E_T$  for four different bins in  $\eta$ . (b) Jet energy resolution as a function of the truth energy of the jet for four different bins in  $\eta$ . Both plots were obtained using dijet event samples reconstructed assuming a limited knowledge of the detector’s dead material distribution.

a limited knowledge of the detector dead material were used to study the transverse energy scale and resolution of FEB-based jets. The transverse energy of jets reconstructed using the FEB-based data unpacking approach was weighted using the default L2 calibration constants obtained using the cell-based method.

Figure 14 shows the jet transverse energy scale and resolution. The energy scale stays within 5% of unity for most of the pseudorapidity range. The transverse energy resolution distribution was fitted using Equation (9) and the results are presented in Table 5. The transverse energy resolution of FEB-based jets is comparable to that of cell-based jets presented in Table 3. The transverse energy scale and resolution of the FEB-based jets depend strongly on the energy cut-off introduced in Equation (3). It was found that using a cut-off at  $2 \cdot \sigma_{\text{noise}}$  gave the best result in terms of transverse energy scale and resolution.

Figure 15 shows the  $\eta$  and  $\phi$  resolution. These distributions were obtained from the difference between a L2 FEB-based jet and its nearest MC truth jet. These results are comparable with those obtained using the cell-based method as shown in Fig. 13.

The L2 trigger efficiency for different thresholds as function of reconstructed jet transverse energy for FEB-based jets is presented in Fig. 16. The initial slope of these efficiency curves is similar to the results obtained with the cell-based method shown in Fig. 11. This indicates that FEB-based jets have a selection efficiency that is comparable to the cell-based one. The FEB-based jet reconstruction significantly reduces the amount of data to be unpacked at L2 compared to the cell-based approach. The impact of the unpacking choice on the processing time of the jet reconstruction algorithm is presented in Section 6.4.

### 6.3 Forward jets

The implementation of L2 forward jet reconstruction must consider constraints on the precision of the L1 forward jet RoI position. Since each L1 FCAL trigger tower spans the entire  $\eta$  range of the FCAL detector, a dedicated optimisation of the jet reconstruction algorithm is required. In order to properly account for the overlap region between the FCAL and endcap calorimeters, a window size of  $3.0 < |\eta| < 5$  was chosen. The cone size ( $\Delta R$ ) must also be modified in order to remove any bias from the initial L1 RoI seed position. Similar to the standard jet reconstruction, three iterations of the jet finding algorithm are performed. An initial cone size of  $\Delta R = 1$  is used to collect sufficient data to remove the L1 bias. In the second and third iteration of the jet finding algorithm, the cone size is reduced to 0.7

Figure 15: The  $\eta$ -resolution (a) and  $\phi$ -resolution (b) of L2 FEB-based jets with respect to the truth jet energy. The mean and standard deviation of a Gaussian fit of (a) is 0.002 and 0.03, while the mean and standard deviation of a Gaussian fit of (b) is -0.00007 and 0.009.

Table 5: Results of the jet energy resolution fit as a function of the truth jet energy for FEB-based jets after applying the default calibration constants obtained using the cell-based data unpacking method. The fit was performed assuming Equation (9).

$\eta$ region	After calibration	
	A	B
(0.0,0.7)	$0.93 \pm 0.05$	$0.02 \pm 0.01$
(0.7,1.5)	$1.18 \pm 0.05$	$0.03 \pm 0.01$
(1.5,2.5)	$1.56 \pm 0.04$	$0.05 \pm 0.01$
(2.5,3.2)	$1.93 \pm 0.01$	$0.01 \pm 0.01$

Figure 16: L2 trigger efficiency as function of reconstructed jet transverse energy for FEB-based jets after calibration, for four different thresholds (35 GeV, 42 GeV, 70 GeV and 100 GeV).

Table 6: L2 trigger efficiency for L2 forward jets with respect to truth jets with  $E_T > 25$  GeV.

Tagged Objects	Data unpacking method	
	cell-based jets (%)	FEB-based jets (%)
Highest $p_T^{\text{truth}}$ forward jets	$98 \pm 1$	$98 \pm 1$
All forward jets	$97 \pm 1$	$91 \pm 1$

and subsequently to 0.4. Calibration constants for forward jets are derived using the method described in Section 5.3.

The L2 forward jet trigger efficiency was determined with respect to truth jet. Reconstructed jets were matched to truth particle jets using the requirement that  $\Delta R = \sqrt{\Delta\eta^2 + \Delta\phi^2} < 0.2$ . In addition, truth jets were required to satisfy  $p_T > 25$  GeV. Results from this study are presented in Table 6.

## 6.4 L2 jet timing

The time budget of approximately 40 ms per event and the strong rejection power needed at the L2 trigger impose strong constraints on the L2 algorithms speed and physics performance.

During the commissioning of the ATLAS Trigger/DAQ system, dedicated Technical Runs are performed in order to test HLT algorithm performance. In these runs all the detector Read Out Systems (ROS) and the full Trigger/DAQ infrastructure are dedicated to exercising the data acquisition system and the trigger. Bytestream files<sup>1</sup> containing a mixture of events close to that expected in LHC collisions (mainly QCD jets, mixed with a few  $Z$  and  $W$  decays to leptons,  $t\bar{t}$  events, etc.) are preloaded into the ROS. These events, which contain the RoIs obtained from the L1 simulation, are then processed by the HLT system. The measurements presented here were made during the Technical Run that took place in November 2007.

In order to compare the difference between the cell-based method and the FEB-based method, two data-collection runs were recorded, one with L2 jets reconstructed using the cell-based approach, and one with L2 jets reconstructed using the FEB-based method. The timing distributions obtained from the cell and the FEB-based methods are shown in Fig. 17(a). Both distributions have a similar shape with peaks corresponding to the number of RoIs per event. The FEB-based approach is however almost 50% faster than the cell-based method.

The distribution of the total processing time shown in Fig. 17(a) includes the data unpacking, jet finding algorithm and calibration, as well as the data collection time from the detector Read Out System (ROS) to the L2 processors, which is shown in Fig. 17(b). The data collection time contributes significantly to the total L2 processing time, about 30% for the cell-based method and about 50% for the FEB-based approach. A detailed description of the data preparation methods and performance can be found in [9].

The processing time distribution per RoI for the different steps involved in the L2 jet reconstruction are shown in Fig. 18(a) and (b) for the cell-based and FEB-based method, respectively. These measurements show that the algorithm execution time is dominated by the data unpacking step. The small features observed in the unpacking time distributions outside the main peak come from RoIs that point in regions where less data needs to be unpacked.

Timing measurements of the L2 forward jet algorithm were also performed. A comparison of the reconstruction time between cell-based and FEB-based jets is presented in Table 7. Due to the limited time available during dedicated Technical Runs, these measurements were obtained by running the L2 jet

<sup>1</sup>Files with the same format as the raw data that will come out of the ATLAS detector.

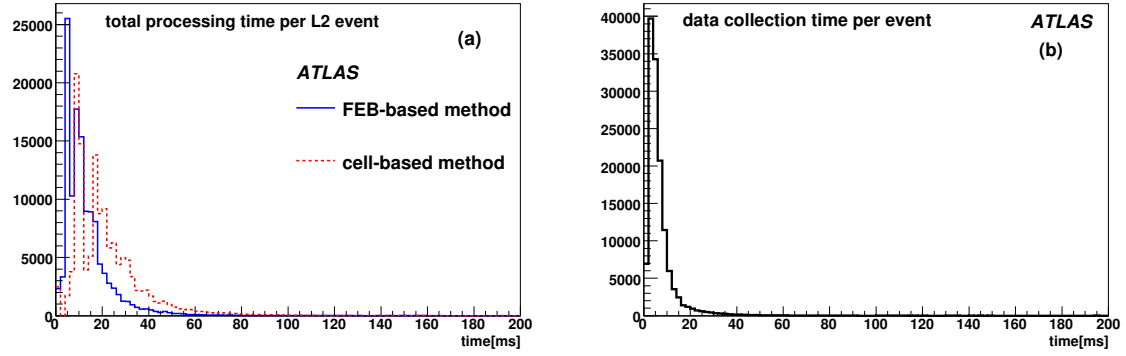

Figure 17: The total processing time per event (a) for the L2 jet algorithm. The solid line is the processing time measured using the FEB-based method (mean 13 ms). The dashed line is the processing time measured using the cell-based method (mean 22 ms). The total data collection time per RoI (b) for both the cell-based and FEB-based data unpacking methods.

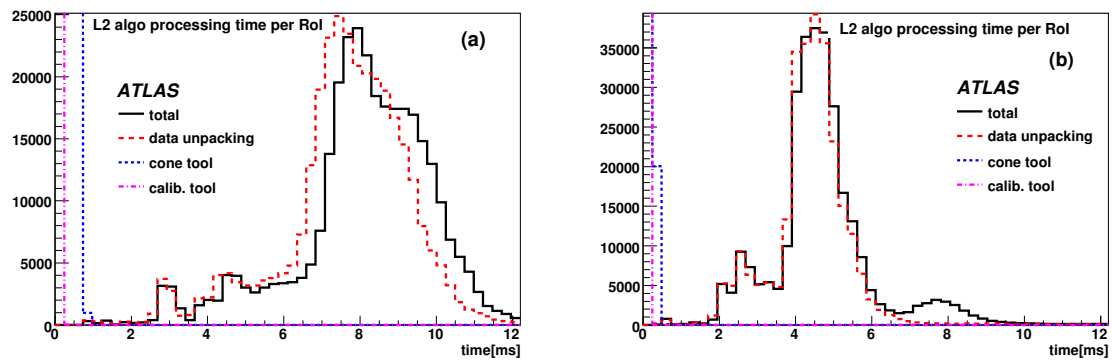

Figure 18: L2 jet algorithm processing time per jet RoI for the cell-based method (a) and FEB-based method (b). The total processing time is shown together with the execution time of the individual steps involved in the L2 jet reconstruction.

Table 7: Comparison of the average L2 jet reconstruction time between the standard and forward jet algorithms in units of ms. Different data unpacking methods are also compared.

Tagged Objects	Data unpacking method	
	cell-based jets	FEB-based jets
Forward Jets	0.9	0.5
Standard Jets	6.1	2.1

algorithms on offline computing resources rather than making use of the full Trigger/DAQ infrastructure. Although the absolute values of reconstruction time should only be taken as an approximate indication of the performance to be expected on the online trigger system, the relative comparison of each measurement is nevertheless informative. For example, although the L2 forward jet algorithm uses a larger  $\eta \times \phi$  window than the standard L2 jet algorithm, it requires less than 25% of the total time used to reconstruct standard L2 jets. This is due to the larger granularity of the forward calorimeter, as compared to the liquid Argon barrel and endcap calorimeters, which results in a smaller amount of data being unpacked on average.

## 7 The event filter jet algorithms

The jet reconstruction in the Event Filter (EF) can be divided into two tasks: the input data preparation and the jet finding. These two tasks are carried out by algorithms used in the offline reconstruction but adapted to run in the online trigger environment. Once an EF jet has been identified, it is passed on to a Hypothesis algorithm which validates whether or not the reconstructed jet satisfies a predefined transverse energy threshold.

### 7.1 Input data preparation

There are three calorimeter data preparation algorithms which, respectively, unpack the calorimeter cell information, build trigger towers and construct calorimeter clusters. The implementation of these data preparation algorithms in the EF has been adapted to allow the running of a subset of the algorithms thereby reducing computing time.

The first data preparation algorithm unpacks calorimeter cell information in a predefined window around the position of the jet found at L2. The size of the window where data needs to be unpacked is a parameter that can be adjusted and is configured at trigger initialisation. The energy of each calorimeter cell, at this point, is set at the EM scale [2, 3]. Although not currently used, this unpacking algorithm provides the ability to apply calibration weights to the energy of individual calorimeter cells.

The second data preparation algorithm performs the calorimeter tower reconstruction. A calorimeter tower is an array of calorimeter cells within an  $(\Delta\eta, \Delta\phi) = (0.1, 0.1)$  region. The EF calorimeter trigger towers granularity is four times finer than that of the L1. Calorimeter trigger towers are the inputs to the jet finding algorithm described in the next Section.

A third data preparation algorithm, currently being studied, is also available in the EF. This algorithm constructs three-dimensional calorimeter clusters instead of towers. These clusters can alternatively be used as input to the jet finding algorithm instead of calorimeter towers.

Parameter	Value
Window size ( $\eta \times \phi$ )	$1.6 \times 1.6$
Input objects	towers
Proto-jet $E_T$ cut	$E_T > 2 \text{ GeV}$
Jet finding algorithm	cone
Jet finding parameter	$R_{\text{cone}} = 0.7$
Calibration scheme	“Energy density”-based cell calibration
Final jet $E_T$ cut	$E_T > 10 \text{ GeV}$

Table 8: Parameter values for the EF jet reconstruction.

## 7.2 Jet finding algorithm

The EF jet reconstruction uses the offline reconstruction algorithms [10] adapted for the EF. It takes as input any  $E_T$  ordered list of calorimeter objects (cells, towers or clusters). The jet reconstruction consists of the following steps:

- Removal of negative energy towers (or clusters) by combining them with adjacent ones. A list of proto-jets is also constructed using a simple pre-clustering algorithm.
- Removal of proto-jets with transverse energy smaller than a given threshold.
- Running of a jet finding algorithm (cone or fast  $K_T$  algorithm [11]).
- Jet calibration
- Removal of reconstructed jets below a given transverse energy

Many different parameters can be modified as part of the jet reconstruction. The parameters used for the configuration of the EF jet reconstruction are summarized in Table 8. Unless specified explicitly, performance studies described subsequently use this configuration.

All calibration methods available for the offline jet reconstruction can be used by the EF jet algorithm. The default method used in the EF is an “energy density”-based cell calibration described in details in [12].

## 8 Event filter performance

The performance and parameter optimisation of the EF jet reconstruction algorithms were made using the simulated dijet event samples summarised in Table 1.

The window size defining how much data is unpacked was chosen by studying the position difference between offline reconstructed jets and jets found by the L2 system. A distribution of the distance  $\Delta R = \sqrt{(\eta_{L2} - \eta_{\text{offline}})^2 + (\phi_{L2} - \phi_{\text{offline}})^2}$  is shown in Fig. 19. Most L2 jet RoI are well within  $\Delta R < 0.2$  of offline reconstructed jets using a cone algorithm with  $\Delta R = 0.7$ . A window size of  $1.6 \times 1.6$  in  $\eta \times \phi$  was therefore chosen to ensure that data is unpacked at the EF in a calorimeter region of sufficient size to reconstruct correctly a jet similar to an offline jet while ensuring complete overlap with the L1 RoI. Additional studies could include the optimization of a variable window size as function of the jet transverse energy as measured by L2.

The EF jet energy scale and resolution were assessed using the same technique as described in Section 6.1. The results are shown in Fig. 20 as a function of the truth jet  $E_T$ . In general, the energy scale

Figure 19: Distance  $\Delta R = \sqrt{(\eta_{L2} - \eta_{\text{offline}})^2 + (\phi_{L2} - \phi_{\text{offline}})^2}$  between L2 and offline reconstructed jets using a cone algorithm of  $R_{\text{cone}} = 0.7$ .

improves with increasing truth jet  $E_T$ . For truth jet energies larger than 200 GeV, the EF jet energy scale is within 2% of unity. The limited window size within which the jet reconstruction takes place in the EF results in some energy leakage that is not corrected for by the offline calibration used in the EF. These results nevertheless suggest that offline calibration are adequate for use in the EF jet reconstruction.

Figure 20: The EF jet transverse energy scale (a) and resolution (b) as function of truth jet  $E_T$ .

The effect of pile-up corresponding to a luminosity of  $10^{33}\text{s}^{-1}\text{cm}^{-2}$  on the jet energy scale and resolution was also studied. Figure 21 shows a comparison of (a) the EF jet transverse energy scale and (b) the EF resolution for simulated dijet event samples with and without pile-up. The effect of pile-up on the overall energy scale is observed to be insignificant, however, a noticeably worse resolution is observed for events with pile-up. The effect is clearly more important for low jet energies where the contribution of pile-up energy can be comparable to the total jet energy.

The EF jet trigger efficiency as function of offline jet energy is shown in Fig. 22 for two different signatures. For an EF trigger threshold close to the L1 threshold, the trigger selection performance is limited by the L1 energy resolution. For EF trigger thresholds significantly higher than the L1 threshold, the excellent EF energy scale improves slightly the performance of the trigger selection as compared to the current L2 capability. These plots emphasize the importance of correctly optimizing the jet trigger thresholds used for each jet signature.

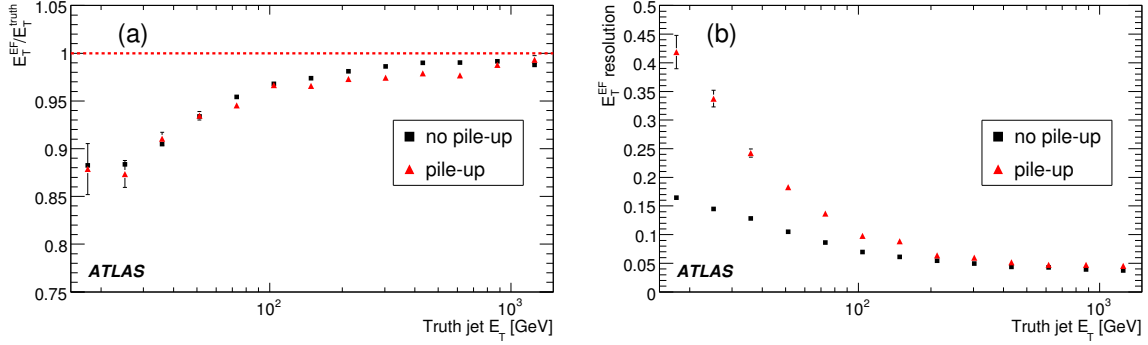

Figure 21: The EF jet transverse (a) energy scale (b) and resolution as a function of truth jet  $E_T$  for simulated dijet event samples with and without pile-up.

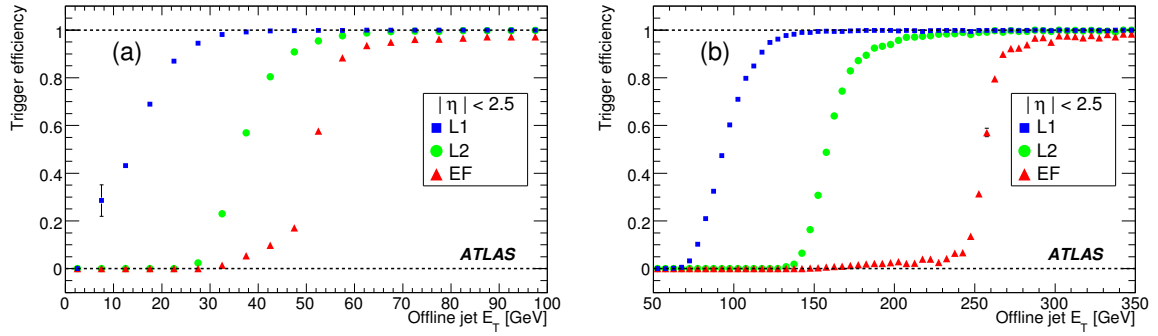

Figure 22: EF trigger efficiency as function of offline jet transverse energy for two different signatures consisting of a set of L1, L2 and EF trigger thresholds: (a)  $E_T^{L1} > 10$  GeV,  $E_T^{L2} > 30$  GeV,  $E_T^{EF} > 50$  GeV; and (b)  $E_T^{L1} > 70$  GeV,  $E_T^{L2} > 150$  GeV,  $E_T^{EF} > 255$  GeV.

### 8.1 Event filter jet algorithm timing

The timing performance of the EF jet reconstruction algorithm has been measured in the November 2007 Technical run described in Section 6.4. Figure 23(a) shows the execution time per RoI for the two EF data preparation steps: the unpacking of calorimeter cell data and the construction of calorimeter towers used by the jet algorithm. Figure 23(b) shows the execution time of the different steps involved in the jet reconstruction described in Section 7.2. The EF jet reconstruction total time per RoI is of order 100 ms. Assuming approximately 4 to 5 jet RoI per event implies a total processing time of order half a second per event which falls within the design budget of approximately one second per event.

## 9 Jet trigger menu

Jet triggers will be used to record many different types of events. Single and multi-jet signatures will identify useful events for various Standard Model QCD measurements. This event sample will also be valuable to study the properties of background events for other analyses and to measure the misidentification efficiency of different offline reconstruction algorithms. Jet trigger requirements are also important when combined with other trigger criteria to identify rare signal events with well-defined topologies.

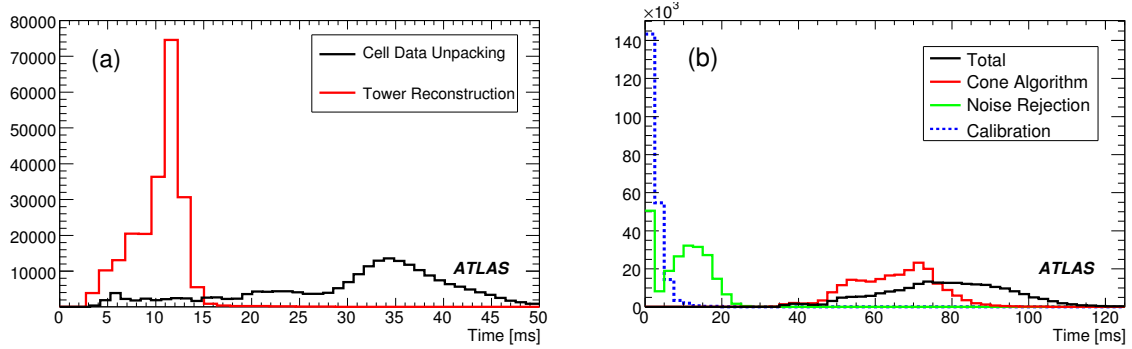

Figure 23: Execution time per RoI for different steps in the EF data preparation (a) and the jet reconstruction (b).

Trigger threshold	J5	J10	J18	J23	J35	J42	J70	J120	3J10	3J18	4J10	4J18	4J23
Prescale factor	300000	42000	6000	2000	500	100	15	1	150	1	30	1	1
Level 1 rate (Hz)	1	4	1	1	1	4	4	8	40	140	40	20	8

Table 9: Summary of the L1 single-jet and multi-jet triggers optimised for the initial data taking period. The L1 prescale factors and expected rate at a luminosity of  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  for each threshold are also presented.

The trigger strategy adopted is to define a set of single and multi-jet signatures that, together, will select events with approximately uniform rates over the entire jet energy spectrum. Table 9 shows the set of L1 single and multi-jet signatures and associated L1 prescale factors optimised for this purpose, assuming an initial luminosity of  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ . The trigger rates were calculated using close to 7 million simulated non-diffractive inelastic events, with an estimated cross-section of 70 mb. These large simulated event samples result in a statistical uncertainty of approximately 0.1 Hz for the rates of un-prescaled triggers. Note that a maximum of 8 different jet thresholds can be defined in the L1 system. The L1 thresholds and prescale factors for the single-jet signatures were chosen to significantly limit the L1 output event rate thereby initially avoiding the need to use the HLT at the beginning of data-taking. The L1 jet trigger menu was also designed to be compatible with a luminosity of up to  $10^{32} \text{ cm}^{-2} \text{ s}^{-1}$  without any changes. Figure 24 shows the differential distribution for the number of events selected by the L1 trigger menu as function of offline reconstructed jet transverse energy for  $1 \text{ fb}^{-1}$  of recorded data.

For commissioning purposes, it is foreseen that the L2 and EF jet algorithms will be initially run for the single-jet signatures in so-called pass-through mode where the result of the HLT selection is recorded with the event data but no events are rejected based on the result of the algorithm selection. The rate of the multi-jet signatures listed in Table 9 will be reduced by using L2 and EF jet requirements. Table 10 summaries the expected rate out of the HLT for all jet signatures foreseen to be run at the beginning of data-taking. In addition to the single and multi-jet signatures discussed above, forward jets signatures are also foreseen. These are also shown in Table 10.

It should be noted that, due to the very large prescales used for the lower threshold jet triggers, the overlap between individual triggers is greatly reduced. This implies that the cumulative rates will rapidly grow, as can be observed in Table 10. The total rate of the entire jet menu has been approximated to be 37 Hz, which represents a little over 18% of the overall trigger output rate budget of 200 Hz.

Figure 24: Differential number of events selected as function of the offline reconstructed transverse energy of the leading jet in the event for  $1 \text{ fb}^{-1}$  of data. The dashed and solid lines show the expected distributions before and after applying the L1 jet trigger menu criteria described in Table 9.

Trigger	Overall Prescale	Rate (Hz)	Cumulative Rate (Hz)
4j23	1	6.9 ( $\pm 0.8$ )	6.9 ( $\pm 0.8$ )
4j18	100	0.14 ( $\pm 0.01$ )	7.0 ( $\pm 0.6$ )

## 10 Summary

A detailed description of the algorithms used to reconstruct jets in the L1, L2 and Event Filter was presented. The performance of each of these algorithms was shown. The physics performance and algorithm timing has been shown to be within the design targets. Nevertheless, optimisation studies to further improve the performance of these algorithms are ongoing. An example trigger menu for jet signatures proposed for the beginning of data-taking was presented. The overall trigger strategy for selecting events based on jet signatures was also described.

# A Study of Minimum Bias Events

## Abstract

This note describes the methods developed for the measurement of the properties of minimum bias events during low luminosity running using the ATLAS detector. These methods aim to reconstruct the inclusive pseudorapidity and transverse momentum distributions of charged particles with  $p_T > 150$  MeV produced from 14 TeV pp collisions. The triggers used to record minimum bias events are described and their acceptances evaluated. An analysis to measure the inclusive distributions is presented and the systematic uncertainties discussed. Finally, there is an overview of future physics studies with minimum bias samples.

## 1 Introduction

This note focuses on how the ATLAS detector [1] can be used to measure the central pseudorapidity and transverse momentum distributions of charged particles produced in inelastic proton-proton (pp) collisions during early running at the LHC. Measuring the characteristics of these collisions allows an understanding of the physics behind these processes to be developed, particularly their energy dependence. The minimum bias events allow the soft-part of the underlying event in high- $p_T$  collisions to be characterised. Studies of inclusive particle distributions in minimum bias events in pp collisions are important to provide the baseline for measurements in heavy-ion collisions, such as allowing differences in the number of particles to be attributed to QCD effects rather than the simple scaling of the number of nucleons. Finally these interactions will be a major background during low luminosity running ( $10^{33} \text{ cm}^{-2}\text{s}^{-1}$ ) and high luminosity running ( $10^{34} \text{ cm}^{-2}\text{s}^{-1}$ ), where the average number of such interactions per beam crossing is  $\sim 2$  and  $\sim 18$ , respectively.

The total proton-proton cross-section can be divided into elastic and inelastic components, and the inelastic component can be further divided into: non-diffractive, single diffractive and double diffractive components [2]. The total cross-section ( $\sigma_{tot}$ ) can then be written as:

$$\sigma_{tot} = \sigma_{elas} + \sigma_{sd} + \sigma_{dd} + \sigma_{nd}$$

where these cross-sections are elastic ( $\sigma_{elas}$ ), single diffractive ( $\sigma_{sd}$ ), double diffractive ( $\sigma_{dd}$ ) and non-diffractive ( $\sigma_{nd}$ ), respectively. The cross-sections for the inelastic subprocesses determined using PYTHIA [3], which was used to generate the event samples for this study, are given in Table 1. For comparison, the cross-sections predicted by PHOJET [4] are also shown in Table 1. The PHOJET predictions include central diffraction, however this hard proton-pomeron interaction only contributes to the cross-section at the few per cent level. As this is not simulated in PYTHIA, it was not considered further in this note.

The acceptance of inelastic events is defined by the trigger, which is usually known as a minimum bias trigger. It is designed to avoid bias in the sample, such as selecting high- $p_T$  events by triggering on high- $p_T$  objects. However, some bias is usually introduced due to effects such as the geometrical acceptance of or minimum energy thresholds in the trigger detector. It is therefore not unusual to find different definitions for minimum bias events in the literature. Historically, the minimum bias triggering used in hadron collider experiments [5–11] often used triggers based on forward-backward coincidences that favoured the detection of non-single diffractive inelastic events (NSD), i.e.  $\sigma_{nsd} = \sigma_{tot} - \sigma_{elas} - \sigma_{sd}$ . Thus, NSD events have often been classified as ‘minimum bias events’. In this

note, results from simulated events selected using the minimum bias triggers are presented. These results have been corrected for detector reconstruction and acceptance effects. The results for the non-single diffractive sample are also presented to allow comparison with previous results from hadron-collider experiments. However, this requires correcting for the trigger acceptance for each of inelastic processes, which depends on the physics model used to generate the different processes.

Minimum bias interactions have previously been studied at a range of different energies at the CERN ISR [5], CERN SppS [6–8] and Fermilab’s Tevatron [9–11] and RHIC colliders. Based on these results, Monte Carlo models have been tuned to generate predictions for LHC multiplicities [12]. Figure 1 shows a comparison of model predictions for the central charged particle density in NSD  $p\bar{p}$  events for a wide range of centre-of-mass energies ( $\sqrt{s}$ ). The data points shown are corrected for detector and trigger effects and efficiencies back to the particle level. Figure 1 compares predictions generated with two different tunings of PYTHIA [3] (ATLAS and CDF tune-A [12]) with the central charged particle density generated with PHOJET [4, 13]. It is clear from this figure that there is a large uncertainty in the predicted central particle density of non-single diffractive interactions at the LHC energy even though the models have been tuned to agree with data at lower energies. This uncertainty arises because the energy dependence in a variety of different models for low- $p_T$  hadronic processes is not well understood. Measuring the central particle density at the LHC will thus be crucial to determining the energy dependence of the central particle density and constraining models of inelastic events.

Figure 1: Central charged particle density for non-single diffractive inelastic events as a function of energy. The lines show predictions from PYTHIA using the ATLAS tune and CDF tune-A, and from PHOJET. The data points are from UA5 and CDF  $p\bar{p}$  data.

This paper is organized as follows: In section 2 we briefly describe the experimental setup and the trigger strategies that have been developed to accept inelastic collisions with minimum bias. The

analysis procedure, corrections, as well as the systematic effects involved in this study are discussed in section 3. Section 4 presents an overview of future work planned to be done with ATLAS minimum bias measurements. Finally, in section 5 we present our conclusions.

Process	Cross-section (mb)	
	PHOJET	PYTHIA
non-diff.	69	55
single diff.	11	14
double diff.	4	10
central diff.	1	-
total inelastic	85	79
elastic	35	23
total	120	102

Table 1: Cross-section predictions for pp interactions at  $\sqrt{s} = 14$  TeV from PYTHIA and PHOJET.

### 1.1 Characteristics of inelastic events

The pseudorapidity ( $\eta$ ) and transverse momentum ( $p_T$ ) distributions of charged particles generated using PYTHIA [3], with the parameter set defined in Ref. [14] and PHOJET [4, 13] with default parameters are shown in Figs. 2(a) and 2(b). These distributions correspond to non-diffractive, single- and double-diffractive inelastic pp interactions at  $\sqrt{s} = 14$  TeV, respectively. They clearly show large uncertainties in model predictions for the LHC and that the events are dominated by low- $p_T$  particles with the highest densities found in the central region  $|\eta| < 3.0$ . Much of this central region is covered by the ATLAS inner detector. The charged particle distributions will be reconstructed from tracks which are measured by the inner detector for  $|\eta| < 2.5$ , with  $p_T$  greater than 150 MeV.

### 1.2 Backgrounds

The main backgrounds in minimum bias events, particularly during early running, will be beam-gas collisions within the beampipe over the length of ATLAS, and beam-halo from interactions in the tertiary collimators in the accelerator. These backgrounds can provide spurious triggers that must be removed from the inelastic event sample to prevent distortion of its characteristics. During early low luminosity running a large fraction of bunch crossings will have no pp interaction. Using a trigger based only on bunch-crossings would result in a large number of empty events, which only contain detector noise, being recorded. Therefore, the trigger must be able to reject such events in order to optimise the use of the trigger bandwidth. In this paper we will present results which include discussions on beam-gas events and empty events but not on beam-halo.

## 2 Simulation and experimental setup

The samples of single-, double-, and non-diffractive inelastic events used in this study were generated with PYTHIA version 6.403 [3]. The PYTHIA event generator was configured according to an underlying event tuning fit [14] from previous experiments and is expected to provide a reasonable description of the non-diffractive part of minimum bias events.

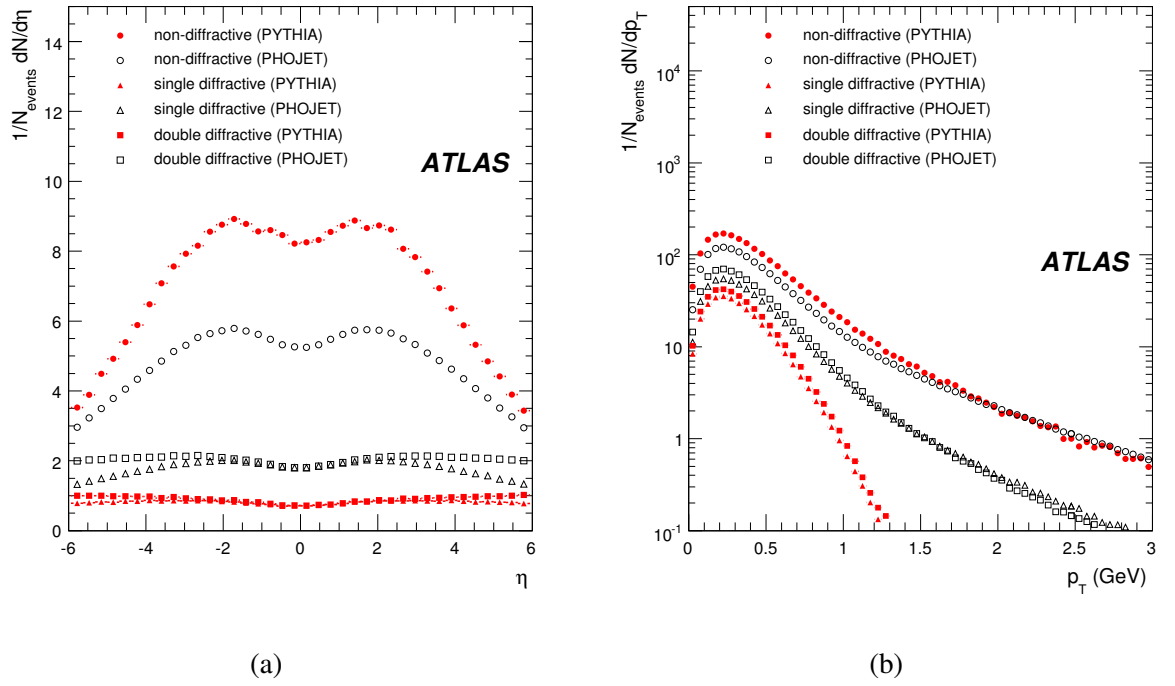

Figure 2: Pseudorapidity (a) and transverse momentum distribution (b) of stable charged particles from simulated 14 TeV pp inelastic collisions generated using PYTHIA and PHOJET event generators.

## 2.1 The ATLAS inner detector

The pseudorapidity and transverse momentum distributions of charged particles are measured using the ATLAS inner detector. The inner detector is described in detail elsewhere [1]. It consists of, in order of increasing radius, a silicon pixel system, a silicon microstrip system (SCT) and a gas-based transition radiation detector (TRT). The inner detector is mounted inside a solenoid magnet which provides a 2 T magnetic field.

The inner detector sub-detectors are designed as independent but also complementary systems. The pixels cover radii of 50.5 mm-149.6 mm, the SCT covers 299 mm-560 mm and the TRT covers 563 mm-1066 mm. The precision tracking detectors (pixel and microstrip) cover  $|\eta| < 2.5$  and are divided into barrel ( $|\eta| < 1.4$ ) and endcaps ( $1.4 < |\eta| < 2.5$ ).

The ATLAS inner detector will provide hermetic and robust pattern recognition, excellent momentum resolution and both primary and secondary vertex measurements for charged tracks above a  $p_T$  threshold, which is nominally 500 MeV but can be as low as 100 MeV within  $|\eta| < 2.5$ . The nominal  $p_T$ -cut of 500 MeV corresponds to tracks traversing the full inner detector, however as discussed in section 1.1 a measurement of the properties of minimum bias events requires a  $p_T$ -cut of  $\leq 200$  MeV. A  $p_T$ -cut of 150 MeV, used in this paper, corresponds to tracks that traverse the precision Si tracker (pixels and SCT) allowing low- $p_T$  tracks to be well reconstructed.

## 2.2 The minimum bias trigger scintillators

The Minimum Bias Trigger Scintillators (MBTS) [15] are mounted on the inner surface of the liquid argon endcap cryostats and cover a pseudorapidity range of  $2.12 < |\eta| < 3.85$ . The MBTS is constructed from 2 cm polystyrene-based scintillator counters. Each side of the MBTS is made up of 16 counters each of which is split into two regions of equal pseudorapidity ( $2.12 < |\eta| < 2.83$ ,  $2.83 < |\eta| < 3.85$ ) and covering  $\frac{\pi}{4}$  in azimuth. The MBTS is read out through the tile calorimeter electronics providing a fast L1 signal, which is discriminated above a voltage threshold, relative to the bunch-crossing signal.

## 3 Minimum bias trigger scenarios

A minimum bias trigger should select inelastic collisions with as little bias as possible, precluding the use of the standard high- $p_T$  triggers. Ideally, the L1 random trigger [16] with beam pickup would be used to accept events with zero bias, and inelastic collisions would be selected offline. However, during early running when the luminosity is expected to be  $< 10^{30} \text{ cm}^{-2}\text{s}^{-1}$ , the random trigger will be very inefficient since the probability of an interaction during a bunch crossing is  $< 1\%$ . Therefore, validation of the L1 random trigger is required in the high-level-trigger (HLT). The use of tracking in the HLT to validate the random trigger and a dedicated L1 trigger based on the minimum bias trigger scintillators (MBTS) has been studied. A minimum bias trigger stream consisting of the random trigger, track trigger and the MBTS is shown in Figure. 3. The random-based track trigger and the MBTS triggers are discussed in sections 3.1 and 3.2, respectively. In addition, the L1 MBTS could be used in conjunction with the pixel and SCT spacepoints reconstructed at L2 and the Event Filter (EF) track trigger. However, this was not studied in this note.

As the luminosity increases from  $\sim 10^{31} \text{ cm}^{-2}\text{s}^{-1}$  to  $10^{32} \text{ cm}^{-2}\text{s}^{-1}$  and higher values, the mean number of interactions per bunch crossing will be around 1. The random trigger will then record interactions for each crossing without requiring further triggers at L2 or EF to reject empty bunch

events. This will allow a zero bias sample to be efficiently accepted by ATLAS using the random trigger.

For the purposes of this note, a luminosity of  $10^{31} \text{ cm}^{-2}\text{s}^{-1}$  with a bunch spacing of 75 ns has been assumed. The rate of inelastic events under those conditions is 792 kHz, and the mean number of events per bunch crossing is 0.06. Trigger efficiencies were calculated using around  $10^5$  events of

Figure 3: Minimum bias trigger slice.

simulated hydrogen beam-gas, single diffractive, double diffractive, non-diffractive and empty events. Each of these simulated samples were reconstructed and passed through the trigger logic and the trigger efficiency was then calculated from the number of events satisfying the trigger logic.

### 3.1 Random-based track trigger

The selection of minimum bias events by a track trigger is performed by the high-level trigger. The aim is to reject empty bunch and beam-gas events. After the random event selection at L1, the L2 trigger rejects empty events by requiring a minimum number of spacepoints in the pixel and SCT detector. The trigger efficiency curves for different types of events (ddiff: double diffractive, ndiff: non-diffractive and sdiff: single diffractive) are shown in Figure 4. The efficiency of empty bunch events as a function of spacepoints clearly shows that a modest constraint on either the number of pixel or SCT spacepoints rejects events containing only random noise. The thresholds for the number of pixel and SCT spacepoints were determined from the requirement to have a signal to background for non-diffractive to empty bunch events of 100:1. Given that the beam conditions assumed in this paper correspond to a probability of a pp non-diffractive inelastic interaction of 0.05, this corresponds to constraining the efficiency of empty bunch events to be less than  $5 \times 10^{-4}$ . This requires setting the threshold on the number of spacepoints to be 12 and 3 in the pixel and SCT respectively.

While the spacepoint (SP) trigger reduces the number of beam-gas events accepted, the rate can be further reduced by requiring the presence of reconstructed tracks within a small  $z$ -region around the nominal interaction point. A full track reconstruction scan with a minimum  $p_T$  of 200 MeV is carried out in the EF on the events that pass the SP trigger. These tracks are then used to select events using the cuts defined in Table 2. The trigger efficiency is plotted with respect to the number of reconstructed tracks in Figure. 5. The empty events are rejected by the cut on the number of pixel and SCT spacepoints resulting in an efficiency of zero.

Figure 4: Trigger efficiency as a function of the number of pixel spacepoints (a) and the number of SCT spacepoints (b).

Track parameter	2 Trigger cut
Number of tracks	$\geq 2$
Track z0	$< 200$ mm

Table 2: Track cuts for EF track trigger.

Figure 5: Trigger efficiency as a function of the number of reconstructed tracks for events satisfying the L2 spacepoint requirement.

### 3.2 Minimum bias triggers using the MBTS

Two simple MBTS L1 trigger strategies were considered for minimum bias event selection: MBTS\_1\_1 and MBTS\_2. MBTS\_1\_1 is defined as at least one MBTS counter above threshold on each side, where the threshold of 40 mV was chosen from measurements of cosmic commissioning data. MBTS\_2 is defined as two or more MBTS counters above threshold anywhere in the MBTS system. The trigger efficiencies as a function of MBTS counter threshold for inelastic non-diffractive, double-diffractive, single-diffractive, beam-gas and empty bunch events are given in Fig. 6.

Figure 6: MBTS L1 trigger threshold scans for the two trigger configurations: (a) MBTS\_1\_1 (b) and MBTS\_2.

### 3.3 Trigger efficiency

A summary of the trigger efficiencies for the track-based and MBTS triggers are given in Table 3. The efficiency of diffractive events is around half of that of non-diffractive events. This is primarily due to the low particle multiplicity in diffractive events and because the triggers cover the central region and are therefore only sensitive to a fraction of the diffractive cross-section corresponding to high mass diffractive states.

The acceptances for the different processes i.e. the efficiencies weighted by the fraction of the inelastic cross-section are given in table 4. This shows that due to lower efficiencies and smaller cross-sections the acceptance of diffractive events is significantly suppressed. The acceptance of the proposed minimum bias triggers is around 85-92% and this will consist of around 80% of non-diffractive events and roughly equal numbers of single and double diffractive events.

## 4 Analysis

The goal of the analysis is to reconstruct the number of primary charged particles per unit of pseudorapidity and per unit of transverse momentum for inelastic pp interactions taken with the minimum bias trigger. Primary particles are defined as particles produced in the pp collision, but excluding secondary

	MBTS_1_1	MBTS_2	SP	SP & EF Tracks
Non-diffractive	99%	100%	100%	100%
Double-diffractive	54%	83%	66%	65%
Single-diffractive	45%	69%	57%	57%
Beam-gas	40%	54%	47%	40%

Table 3: MBTS and random-track trigger efficiencies.

	MBTS_1_1	MBTS_2	SP	SP & EF Tracks
Non-diffractive	69%	70%	70%	70%
Double-diffractive	7%	10%	8%	8%
Single-diffractive	8%	12%	10%	10%

Table 4: MBTS and random-track trigger acceptances.

particles from weak decays of strange hadrons or from electromagnetic or hadronic interactions in the detector material.

A sample of  $\sim 150,000$  inelastic events, with ND, SD and DD events mixed in the proportion given by the PYTHIA cross-sections, was reconstructed and used in this study (MB sample). A typical non-diffractive event contains around 45 reconstructed tracks of which 37 are from primary particles and 8 are from secondary particles. The efficiencies and corrections were derived from half the sample and used in the analysis of the other half of the sample.

#### 4.1 Event selection

Two selection criteria are applied to the set of reconstructed events: the event must be triggered by the minimum bias trigger and it must contain at least one reconstructed vertex. The sample of inelastic events selected by the MBTS\_2 trigger, described in Section 3.2, was used for this analysis. No beam-gas or pileup events were included in the sample studied here. An additional criterion should be added to exclude events with multiple pp interactions in a bunch-crossing but this was not included in this analysis as the samples of simulated data used for this study contained events with a single pp interaction in a bunch-crossing.

#### 4.2 Track selection

Tracks were reconstructed using tracking with the minimum  $p_T$  set to 100 MeV rather than the default 500 MeV. To avoid threshold effects, tracks with  $p_T > 150$  MeV were used in the analysis. The relative  $p_T$ -resolution,  $\sigma(\frac{1}{p_T})p_T$ , was found to be around 1.5% for  $|\eta| < 0.8$  and 4.3% for  $|\eta| > 1.6$ .

Cuts on the measured track parameters were used to select a set of well reconstructed tracks for the analysis. These cuts are listed in Table 5. The requirement of a hit in the inner pixel layer, the b-layer, removes a sizable portion of fake tracks and tracks associated to secondary particles since they frequently do not leave a hit in the first layer of the pixel detector. The cut on the number of pixel and SCT hits is a standard track scoring cut applied during reconstruction and is listed here only for completeness. The values of the cuts were chosen by fitting each of the distributions with a gaussian and cutting at  $\sim 3\sigma$ .

Quality cuts	No. of b-layer hits $\geq 1$ No. of Silicon hits $\geq 5$
Resolution cuts	$ \sigma_{d_0}  < 1.6 \text{ mm}$ $ \sigma_{z_0}  < 6.0 \text{ mm}$ $ \sigma_\phi  < 0.03$ $ \sigma_\theta  < 0.015$ $ \sigma_{q/p_T}  < 0.0003 \text{ (GeV)}^{-1}$
Track-to-vertex cut	$N_\sigma < 3$

Table 5: Track selection cuts used in this analysis. The resolutions  $\sigma_{d_0}^2$ ,  $\sigma_{z_0}^2$ ,  $\sigma_\phi^2$ ,  $\sigma_\theta^2$  and  $\sigma_{q/p_T}^2$  are the five diagonal elements in the track parameter covariance matrix. For more information on the tracking Event Data Model (EDM) see [17].

The track-to-vertex cut is the selection that most effectively cuts away tracks from secondary particles while accepting tracks from primaries. It is made by cutting on the distance of closest approach to the nearest reconstructed vertex, normalized by the error. The normalized distance to the vertex is defined as

$$\Delta R \equiv \sqrt{\left(\frac{\Delta d_0}{\sigma_{d_0}}\right)^2 + \left(\frac{\Delta z_0}{\sigma_{z_0}}\right)^2}, \quad (1)$$

where  $\Delta d_0/\sigma_{d_0}$  and  $\Delta z_0/\sigma_{z_0}$  are the normalized distances in the transverse and longitudinal directions, respectively. The number of  $\sigma$  to the vertex as a function of  $\Delta R$  (for a two-dimensional gaussian) is given by

$$N_\sigma = \sqrt{2} \text{erf}^{-1}(1 - e^{-\Delta R^2/2}). \quad (2)$$

Note that the above formula assumes no correlations between the resolutions in the transverse and longitudinal direction.

To determine the effects of the cuts and evaluate efficiencies and acceptances, the reconstructed tracks are matched to the generated primary and secondary particles. The track that has the highest percentage of hits that overlap with the trajectory of a generated particle is matched to that generated particle. A track is well matched to a particle if greater than 50% of its hits overlap with the generated particle's trajectory. A primary track is one matched to a primary particle and similarly a secondary track is one matched to a secondary particle. If a track is not matched to any generated particle, it is classified as a fake.

Table 6 shows the influence of the track cuts on the reconstructed sample. Each row shows the percentage of tracks that did not pass each of the specified cuts. Note that a single track can fail several cuts and therefore give counts in several rows. Three of the rows show the percentage of tracks that fail any of the quality cuts ('Quality'), any of the resolution cuts ('Resolution') and any of the quality or resolution cuts ('Q || R'). The strongest and most effective cut is the track-to-vertex cut, which rejects about 88% of the secondaries. The second last row shows the percentage of reconstructed tracks that are outside the pseudorapidity and  $p_T$  range used in the analysis ( $|\eta| > 2.5$ ,  $p_T < 150 \text{ MeV}$ ).

Cut	% Cut All	% Cut Primary tracks	% Cut Secondary tracks
b-layer hit	15.9	8.5	46.8
$\text{cov}_{d0}$	11.5	6.0	34.2
$\text{cov}_{z0}$	9.4	5.0	27.4
$\text{cov}_{\phi}$	8.9	5.1	24.3
$\text{cov}_{\theta}$	4.9	4.2	8.2
$\text{cov}_{q/p_T}$	6.4	4.3	14.9
Quality	15.9	8.5	46.8
Resolution	16.7	10.9	40.4
Q    R	24.6	15.6	62.1
Track-to-Vtx	30.7	16.9	87.8
$\eta$    $p_T$	1.2	1.3	0.9
Total	38.6	24.6	96.5

Table 6: Fraction of tracks cut away by the selection cuts.

### 4.3 Procedure & corrections

The  $dN_{ch}/d\eta$  and  $dN_{ch}/dp_T$  distributions are obtained by starting with the measured number of selected tracks in selected events and applying the following three corrections:

- Track-to-particle correction
- Vertex reconstruction correction
- Trigger bias correction

The first correction accounts for the difference between the number of measured tracks and the number of primary charged particles. This is essentially a correction for the inner detector acceptance and efficiency of the tracking software [18]. The second correction takes into account the vertex reconstruction efficiency and corrects for events that have no reconstructed vertex. These two corrections account for detector dependent effects and produce the minimum bias sample, in which the data have been corrected for detector reconstruction and acceptance but have not been corrected for the trigger acceptance.

The trigger bias correction depends both on the detector simulation and on the physics model used in the event generator to simulate inelastic pp interactions. Different corrections for the trigger can be applied to correct the measured distributions back to different physics processes, i.e. inelastic, non-single-diffractive or non-diffractive interactions.

The track-to-particle correction is applied only at the track level. The vertex correction and the trigger bias correction are applied at the track and event level. The track-level vertex and trigger bias corrections are needed to compensate for any bias on the measured track distribution due to vertex and trigger requirements. All track-level corrections are determined as a function of pseudorapidity ( $\eta$ ),  $p_T$  and the  $z$ -position of the collision vertex,  $v_z$ . The event level corrections are determined as a function of  $v_z$  and the number of reconstructed tracks in the event.

The corrections are 3-D and 2-D histograms but the principal corrections shown in the figures below are plotted as projections of  $p_T$   $\eta$   $z$ -position or the number of reconstructed tracks as appropriate for clarity.

#### 4.3.1 Track-to-particle correction

The number of selected reconstructed tracks differs slightly from the number of primary charged particles due to a number of different effects: the acceptance of the detector, the detector and track reconstruction efficiency, the contribution from secondaries and fakes, and the acceptance of the track selection cuts. The track-to-particle correction takes all these effects into account and is calculated as

$$C_{trk}(\eta, v_z, p_T) \equiv \frac{\text{No. of primary charged particles}}{\text{No. of selected reconstructed tracks}}. \quad (3)$$

The numerator and denominator are calculated for the same events taken through the full detector simulation and reconstruction.

Figure 7 shows the projection of the 3-dimensional track-to-particle correction onto the  $\eta$  and  $p_T$  axes. The correction is significant and changes rapidly with  $p_T$  below 200 MeV where the reconstruction efficiency is lower due to a lower number of hits on a track and the effects of material and multiple scattering. Above 200 MeV the correction is small and has a small dependence on  $p_T$ .

Figure 7: The track-to-particle correction  $C_{trk}$  as a function of (a)  $\eta$  and (b)  $p_T$ .

#### 4.3.2 Vertex reconstruction correction

The vertex correction takes into account the bias introduced by events that are not counted because their vertex was not found by the vertex reconstruction algorithm. The event-level correction is calculated as a function of  $v_z$  and number of reconstructed tracks in the event:

$$\tilde{C}_{vtx}(v_z, N) \equiv \frac{\text{No. of triggered events}}{\text{No. of triggered events with } \geq 1 \text{ reconstructed vertex}}. \quad (4)$$

The track-level vertex correction is calculated as a function of  $\eta$ ,  $v_z$  and  $p_T$ :

$$C_{vtx}(\eta, v_z, p_T) \equiv \frac{\text{No. of tracks in all triggered events}}{\text{No. of tracks in triggered events with } \geq 1 \text{ reconstructed vertex}}. \quad (5)$$

Although the vertex correction is essentially a detector correction, some model dependence is present since only triggered collisions are taken into account to compute the correction factors. However, the use of only triggered events has the advantage that the correction can be computed directly from the data, without relying on any simulation. Once data are available it will also be possible to compare the properties of the triggered events with no reconstructed vertex to the corresponding events in the simulation. This may help minimize and better estimate any systematic uncertainties.

Figure 8 shows the event-level vertex reconstruction correction as a function of the number of reconstructed tracks,  $N$ , and vertex  $z$ -position. A vertex can be defined using a single well reconstructed track. As the number of tracks increases, the correction approaches unity. For events with  $N > 10$ , a vertex is always found and the correction is no longer required.

Figure 9 shows projections of the 3-dimensional track-level vertex correction onto the  $v_z$  and  $p_T$  axes. These corrections are found to be at the level of a few percent.

Figure 8: The event-level vertex correction as a function of (a)  $v_z$  and (b) the number of reconstructed tracks ( $N$ ).

### 4.3.3 Trigger bias correction

The trigger bias correction accounts for the difference between the MB sample selected by the minimum bias trigger and the physics process of interest. This correction depends on the trigger detector simulation and on the models of the pp interactions used in the event generator. Therefore, this correction is dependent on the relative cross-sections of the inelastic processes used and on the modelling of particle production for the different inelastic processes.

After an initial model-independent measurement is made, the MB sample, the trigger bias correction can be used to obtain distributions for other samples of interest: non-diffractive (ND), non-single diffractive (NSD) or inelastic (INEL) collisions. Each of these samples corresponds to a different trigger correction and each correction can be applied to yield the final distributions for the different collision samples. In general the correction from MB to NSD collisions is the smallest since these

Figure 9: The track-level vertex correction as a function of (a)  $v_z$  and (b)  $p_T$ .

two event samples are almost identical, while the correction from MB to INEL is on the order of 1.2 (integrated over  $N$  and  $v_z$ ).

The trigger bias correction is determined on event level as a function of  $v_z$  and multiplicity, defined as in the vertex correction:

$$\tilde{C}_{trig}(v_z, N) \equiv \frac{\text{No. of interactions in sample of interest}}{\text{No. of triggered events}}, \quad (6)$$

and on track-level as a function of  $\eta$ ,  $v_z$  and  $p_T$ :

$$C_{trig}(\eta, v_z, p_T) \equiv \frac{\text{No. of tracks in sample of interest}}{\text{No. of tracks in triggered events}}. \quad (7)$$

In this analysis it is assumed that there is only one interaction per event since the events have been simulated in this way. This will need to be verified in the real data for any events with more than one reconstructed vertex by looking at the multiplicity of each of the vertices and the distance between the vertices. As in the vertex correction, all tracks are counted since the track-to-vertex distance is undefined for events with no reconstructed vertex.

Figure 10 shows the event-level trigger bias correction for the NSD sample as a function of multiplicity and vertex  $z$ -position. Using the MBTS.2 trigger, the correction is only important for  $N < 25$ ; for higher multiplicities the correction factor is not needed. It is largest for  $N < 5$  which are principally diffractive events that have a lower trigger efficiency relative to the non-diffractive events as discussed in section 3.

Figure 11 shows projections of the 3-dimensional track-level trigger bias correction for the NSD sample to two of the three 2-dimensional planes and to the  $v_z$  and  $p_T$  axes.

#### 4.4 Corrected distributions

An  $\eta$ - $v_z$ - $p_T$  (3-D) histogram is filled for each track in each event and weighted with the values of the track-level corrections described above. A  $v_z$ - $N$  (2-D) histogram is also filled for each event and

Figure 10: The event-level trigger bias correction for the NSD sample as a function of (a)  $v_z$  and (b) number of reconstructed tracks ( $N$ ).

Figure 11: The track-level trigger bias correction for the NSD sample as a function of (a)  $v_z$  and (b)  $p_T$ .

weighted with the values of the event-level corrections. This histogram is needed to provide the proper normalization factor for the analysis.

After filling the histograms, a vertex range is chosen and the  $v_z$  variable is integrated out. In the case of  $dN_{ch}/d\eta$ , the  $p_T$  variable is integrated for  $p_T > 150$  MeV; in the case of  $dN_{ch}/dp_T$ , the  $\eta$  variable is integrated over  $-2.5 < \eta < 2.5$ . Each  $\eta$ -bin or  $p_T$ -bin is then divided by the total number of events, calculated by integrating the weighted event distribution histogram over  $N$  and  $v_z$ . Finally, the distribution is normalized by the inverse width of the bins. No correction was made for the effect of the  $p_T$  cutoff in the reconstruction. However, the stability of the results will be tested by varying the  $p_T$  cutoff in data.

The distributions are presented for the sample events accepted by the minimum bias trigger. For this analysis MBTS.2 is used, and are labelled as MB. The MB distributions have only been corrected for the acceptance and efficiencies associated with reconstructing tracks and vertices. To obtain the NSD distributions to allow comparisons with other results, the MB distributions are corrected for the trigger bias.

The correction procedure can be expressed mathematically for one bin, corresponding to a certain region of phase space, in the following way. The number of particles  $P$  and number of interactions  $I$  are calculated as:

$$P(\eta, v_z, p_T) = \sum_{events} \sum_{tracks} (C_{trk}(\eta, v_z, p_T) \cdot C_{vtx}(\eta, v_z, p_T) \cdot C_{trig}(\eta, v_z, p_T)), \quad (8)$$

$$I(v_z, N) = \sum_{events} (\tilde{C}_{vtx}(v_z, N) \cdot \tilde{C}_{trig}(v_z, N)). \quad (9)$$

Tracks are weighted by the track-to-particle correction  $C_{trk}(\eta, v_z, p_T)$ , by the track-level vertex correction  $C_{vtx}(\eta, v_z, p_T)$  and the track-level trigger bias correction  $C_{trig}(\eta, v_z, p_T)$ . Events are weighted by the event-level vertex correction  $\tilde{C}_{vtx}(v_z, N)$  and the event-level trigger bias correction  $\tilde{C}_{trig}(v_z, N)$ .

For a given vertex range  $[V_1, V_2]$  the  $dN_{ch}/d\eta$  and  $dN_{ch}/dp_T$  are then calculated as:

$$\left. \frac{dN_{ch}}{d\eta} \right|_{\eta=\eta'} = \frac{\int_{V_1}^{V_2} \int P(\eta', v_z, p_T) dp_T dv_z}{\int_{V_1}^{V_2} \int I(v_z, N) dN dv_z}, \quad (10)$$

$$\left. \frac{dN_{ch}}{dp_T} \right|_{p_T=p'_T} = \frac{\int_{V_1}^{V_2} \int P(\eta, v_z, p'_T) d\eta dv_z}{\int_{V_1}^{V_2} \int I(v_z, N) dN dv_z}. \quad (11)$$

To exercise the analysis chain, the complete reconstructed sample was divided in half: one part was used to calculate the corrections and the other used as ‘data’ input to the analysis.

Figures 12 and 13 show the corrected pseudorapidity distribution ( $p_T > 150$  MeV) and the corrected transverse momentum spectrum ( $|\eta| < 2.5$ ) for the MB and NSD event samples. Statistical errors on the corrected distributions are shown. The aim was to achieve statistical errors on the corrections of less than 2% per bin. The errors are mostly negligible since sufficient statistics were used to determine the correction factor. Data in regions where small statistical errors could not be achieved (i.e. near the edges of the acceptance) are not included in the analysis.

#### 4.5 Systematic uncertainties

The systematic uncertainties have been estimated by changing the parameters in the generation, reconstruction or analysis and then re-evaluating the corrections and applying them to the analysis input sample. Although many of the systematic uncertainties are correlated, the different effects are studied here independently. The systematic uncertainties investigated include:

(a)

(b)

Figure 12: Corrected normalised pseudorapidity and  $p_T$  distributions, together with the input Monte Carlo truth (full line) for the MB sample (blue triangles). (a)  $\eta$  distributions for  $p_T > 150$  MeV, where the lower part, the ratio of the analysis result over the Monte Carlo prediction is shown. The corresponding scale is drawn on the right axis. (b)  $p_T$  spectra for  $|\eta| < 2.5$ .

(a)

(b)

Figure 13: Corrected normalised pseudorapidity and  $p_T$  distributions, together with the input Monte Carlo Truth (full line) for the NSD sample (blue triangles). (a)  $\eta$  distributions for  $p_T > 150$  MeV, where the lower part, the ratio of the analysis result over the Monte Carlo prediction is shown. The corresponding scale is drawn on the right axis. (b)  $p_T$  spectra for  $|\eta| < 2.5$ .

- **Track selection:** Based on the estimated track resolutions ( $\sigma$ ) for their distance from the vertex of the interaction,  $d_0$ , tracks with  $d_0 > 3\sigma$  are removed from the track sample. The error associated with this cut was estimated by varying the cut value by  $\pm 0.5\sigma$  and observing the change in the number of accepted tracks. A mis-estimate of  $\pm 0.5\sigma$  leads to a change in the number of accepted tracks of less than 2%.
- **Secondaries:** Before track selection cuts are applied, the number of tracks originating from secondaries is about 25% of the number of tracks originating from primaries. After the track selection the total number of accepted secondary tracks is about 2.2% of the number of the accepted tracks. The error on the number of secondaries was estimated by changing the number of secondaries in the reconstructed sample by  $\pm 50\%$ . The total number of accepted secondary tracks was found to change by 1.1%. The effect is strongest in the low- $p_T$  region and vanishes only for  $p_T > 5$  GeV. The systematic uncertainty was therefore estimated to be 1.5%.
- **Vertex reconstruction bias:** Since the  $z$ -position of the reconstructed vertex is integrated out, it is possible that a bias from the reconstruction of the vertex could introduce a systematic effect on the measurement. Bias due to the vertex reconstructed was evaluated by repeating the  $dN_{ch}/d\eta$  analysis using the generated  $v_z$  instead of the reconstructed  $v_z$ . The observed difference was found to be 0.1%.
- **Misalignment:** The systematic effect from misalignment was estimated by re-running the reconstruction with a different geometry that corresponded to a misaligned and distorted detector, and comparing the  $dN_{ch}/d\eta$  produced with that produced for a detector that is ideally aligned. The misaligned geometry was misaligned both globally and locally. However, the local misalignments had been corrected for using the alignment procedure. The two distributions agreed at the level of 5-6% across the barrel and forward regions. This is the expected level that can be achieved with cosmics and early data. A systematic uncertainty of 6% was attributed to misalignment.
- **Beam-gas interactions:** The presence of background events coming from beam-gas would result in additional systematics on the measurement.

The rate of beam-gas interactions is highly dependent on the particular beam conditions during startup such as the number of protons per bunch and the beam current. Studies by the LHC group have estimated the rate of beam-gas collisions within ATLAS to be 100 Hz [19]. Assuming a pp collision rate during early running of  $8 \times 10^5$  Hz this corresponds to approximately 1 beam-gas event per 8000 pp events. Preliminary studies with simulated beam-gas events have also shown that only a very small fraction ( $< 1\%$ ) of beam-gas events passed the vertex reconstruction requirement. Therefore the effect of beam-gas events is expected to be small.

The systematic uncertainty due to beam-gas events was estimated to be  $\sim 1\%$ .

- **Particle composition:** The track-to-particle correction is calculated from events generated with PYTHIA [14]. Although  $\pi^\pm$ ,  $K^\pm$ , and  $p^\pm$  compose over 98% of the charged particle multiplicity in these events, the efficiency for detecting each of these is considerably different for  $p_T < 500$  MeV. This model dependent effect introduces an additional systematic error on the measurement since relative abundances in PYTHIA could differ from reality.

Relative abundances of charged pions, kaons and protons and anti-protons were enhanced and reduced by  $\pm 50\%$  to estimate the systematic uncertainty due to variations in the particle com-

position. The systematic uncertainty obtained by this method is estimated to be around 2%. This is highly dependent on the low- $p_T$  cut used in track reconstruction.

- **Relative process frequency:** The trigger bias and vertex reconstruction corrections are calculated from a sample of inelastic events where the relative cross-sections are as predicted by PYTHIA [3]. Since the trigger and vertex reconstruction efficiencies are different for each of the inelastic components (non-diffractive, single diffractive, and double-diffractive), these corrections are dependent on the relative cross sections of the different components.

The relative cross sections between non-diffractive, single-diffractive and double-diffractive components were enhanced and reduced to estimate the systematic due to the uncertainty from the PYTHIA event generator. The corrections have been calculated by changing the diffractive cross sections by  $\pm 50\%$  of the PYTHIA prediction, i.e.  $7.1 \text{ mb} < \sigma_{SD} < 21.4 \text{ mb}$  and  $5.1 \text{ mb} < \sigma_{DD} < 15.3 \text{ mb}$ , which, as can be seen in Table 1, covers the difference in the predicted relative cross sections between PYTHIA and PHOJET.

Changing the diffractive cross sections by  $\pm 50\%$  changes the result of the analysis by about 4% on the final NSD sample. For the minimum bias sample in which no trigger bias correction is applied, this systematic error is approximately zero.

Name	Level	Estimated Uncertainty
Track selection cuts	Analysis	2%
Mis-estimate of secondaries	Analysis	1.5%
Vertex reconstruction bias	Reconstruction	0.1%
Misalignment	Reconstruction	6%
Beam-gas and pileup	Offline Trigger	1%
Particle composition	Generation/Simulation	2%
Diffractive cross sections (NSD sample)	Generation	4%
Total		8%

Table 7: Summary of the various systematic uncertainties and the level at which they are introduced. The total systematic uncertainty assumes each of the individual uncertainties are independent.

A summary of the systematic uncertainties is given in Table 7 along with the step in the full chain at which they are introduced. The uncertainties in the track selection, vertex reconstruction bias and mis-estimate of secondaries are dominated by the low- $p_T$  tracks ( $< 500 \text{ MeV}$ ). Any uncertainties at the generator level are due to uncertainties in predictions of physics models at LHC-energy and are unavoidable in the final analysis. However, the principal error in the reconstruction arises from alignment of the inner detector. The estimate of 6% is for initial running and is likely to improve.

## 5 Future work

### 5.1 Work required for first data

A number of issues have arisen during the work for this note that need to be studied further. Many of these studies are already in progress and should be completed before the first pp collisions from the LHC are recorded. The main topics currently under investigation are:

- *Studies with other Monte Carlo generators:* The studies of pp interactions in this note have been carried out using PYTHIA [3]. The biases introduced by the trigger will certainly depend on the particular physics models employed by PYTHIA.

The generator PHOJET [4, 13] is being used to simulate samples of LHC inelastic pp collisions (non-diffractive, single- and double-diffractive). The physics studies discussed previously in the analysis section are going to be repeated with PHOJET samples and the results compared with those shown in this note. Comparing the results from analyses in different samples will provide us indications on the systematic uncertainties due to different physics models.

- *Vertexing:* During initial running at low luminosities, there will still be periods where there will be more than one event per bunch crossing. It is therefore important to be confident that an event contains only one interaction by identifying events with a single vertex. Further work is required to look at vertex reconstruction with low levels of additional events to evaluate how well events with several vertices can be reconstructed.
- *MBTS readout:* The MBTS L1 trigger readout is currently being upgraded as part of the tile calorimeter refurbishment. As a part of this refurbishment the 3-in-1 cards connected to the MBTS readout are being switched from low gain to high gain. This modification means that the signal to noise should be 5-6 times better than the values used in Section 3.2. In addition to the L1 improvements, the MBTS will be readout at L2 to allow verification of the L1 trigger decision using the precision readout of the Tile Calorimeter electronics. Work is ongoing to implement software to match these requirements. Once the software has been validated, the MBTS L1 and L2 trigger performance will be reevaluated.
- *Beam-gas and beam halo estimate from commissioning runs:* Recent efforts to produce more accurate predictions for beam gas rates will allow a re-run of studies on how best to optimize the MBTS and the track-trigger to reduce this background in the measured minimum bias sample. For both cases, strategies on how to estimate the rates of beam-gas and halo events from data during commissioning runs with a single proton beam are beginning to be discussed.
- *ATLAS Beam Conditions Monitor* The Beam Conditions Monitor [20] is designed to distinguish collisions from background through time-of-flight measurement and can improve our understanding of beam-gas and halo rates.

## 5.2 Physics studies beyond first data

Following the first physics studies with minimum bias data a series of applications can be foreseen. Among them we would highlight:

- *Retuning Monte Carlo generators:* LHC predictions for minimum bias events generated with tuned MC generators PYTHIA and PHOJET indicate that although these tuned models give comparable descriptions of lower energy data, they disagree typically by  $\sim 30\%$  for minimum bias multiplicity distributions [12].

Measuring the global properties of minimum bias interactions as presented in this paper will provide enough information to revisit the generator predictions and retune event generators to describe interactions at the LHC energy. This will not only allow us to distinguish which physics model and assumptions better agree with the data, but will also allow the reassessment of systematic uncertainties in various channels.

- *Multiparton interactions:* Charged particle multiplicity distributions [21] have been widely used as important tools for studying multiple particle production in inelastic hadronic events [5, 6, 10, 11]. They are particularly useful when displayed in terms of multiplicity scaled variables known as KNO variables [21]. Plotted as a function of KNO variables, the charged multiplicity distributions provide a clearer display of fluctuations seen for both very low (less than half of the average multiplicity) or very high multiplicity (more than the double the average) events. The rise of the high multiplicity tail in these distributions has been interpreted as an effect caused by multiparton interactions [10, 11] and the LHC measurement of this effect will contribute greatly to a better understanding of the underlying physics in inelastic collisions.
- *Contribution to the measurement of the total cross section:* A measurement of the total inelastic rate by combining the NSD analysis with a measurement of single diffractive cross section by the ALFA detector should be possible. Simultaneously measuring the elastic t-spectrum, which can then be extrapolated to  $t \rightarrow 0$ , will enable us to determine the total cross section ( $\sigma_{tot}$ ) in a luminosity-independent way or to calibrate the absolute luminosity in  $\sigma_{tot}$ -independent way, using the optical theorem.
- *Baseline for heavy-ion studies:* A measurement of the particle yield from a single minimum bias event can and will be used to cross-check components and assumptions made by models for heavy-ion collisions which will then be tuned according to the LHC data. This procedure is expected to help in generating more reliable predictions for the heavy-ion runs.

## 6 Conclusions

We have investigated methods for measuring the characteristics of inelastic collisions with the ATLAS detector during early LHC running. The main goal of our study was to reconstruct the normalised central pseudorapidity ( $\frac{1}{N_{ev}} \frac{dN}{d\eta}$ ) and transverse momentum ( $\frac{1}{N_{ev}} \frac{dN}{dp_T}$ ) distributions of charged primaries in pp interactions selected by a minimum bias trigger. Triggering strategies for minimum bias event selection have been developed and an analysis to determine the charged particle distributions were presented.

Aiming at selecting inelastic collisions with as little bias as possible, two scenarios were proposed for triggering: a random-based track trigger and using the minimum bias trigger scintillators. The random-based track trigger combines random event selection at L1 with the use of information from the ID in the HLT; spacepoints from the pixel detector and the SCT at L2 and tracks reconstructed in the EF. Minimum bias selection with the MBTS is performed by recording events that pass L1 MBTS hit requirements. It has been shown that both triggers are highly efficient at selecting non-diffractive inelastic samples. However, the acceptance of the diffractive component is highly suppressed relative to the non-diffractive component, and the acceptance of the single-diffractive sample is similar to that of the double-diffractive sample. This means that the ATLAS minimum bias triggers do not select a NSD sample as previous experiments have and therefore model dependent corrections will be required to compare ATLAS measurements to results from previous experiments.

Results were presented for two samples: the MB sample, which has only been corrected for detector effects, and the NSD sample where the MB sample has been further corrected for the trigger acceptance, which is model dependent. The analysis was performed on a sample of  $\sim 75,000$  events, corresponding to a luminosity of  $10^{-6} \text{ pb}^{-1}$ . The uncertainty on  $\frac{1}{N_{ev}} \frac{dN}{d\eta}$  for both samples is dominated by the systematic uncertainty from alignment and there is an additional uncertainty on the NSD sample due to the model dependence of the relative cross-sections. The systematic uncertainty on  $\frac{1}{N_{ev}} \frac{dN}{d\eta}$  for

the MB sample was estimated to be 6% and 8% for the NSD sample. This will be sufficient to distinguish between different models of minimum bias events.

# Electroweak Boson Cross-Section Measurements

## Abstract

This report summarises the ATLAS prospects for the measurement of  $W$  and  $Z$  production cross-section at the LHC. The electron and muon decay channels are considered. Focusing on the early data taking phase, strategies are presented that allow a fast and robust extraction of the signals. An overall uncertainty of about 5% can be achieved with  $50 \text{ pb}^{-1}$  in the  $W$  channels, where the background uncertainty dominates (the luminosity measurement uncertainty is not discussed here). In the  $Z$  channels, the expected precision is 3%, the main contribution coming from the lepton selection efficiency uncertainty. Extrapolating to  $1 \text{ fb}^{-1}$ , the uncertainties shrink to incompressible values of 1-2%, depending on the final state. This irreducible uncertainty is essentially driven by strong interaction effects, notably parton distribution uncertainties and non-perturbative effects, affecting the  $W$  and  $Z$  rapidity and transverse momentum distributions. These effects can be constrained by measuring these distributions. Algorithms allowing the extraction of the  $Z$  differential cross-section are presented accordingly.

## 1 $W$ and $Z$ cross-section measurements at the LHC

The study of the production of  $W$  and  $Z$  events at the LHC is fundamental in several respects. First, the calculation of higher order corrections to these simple, colour singlet final states is very advanced, with a residual theoretical uncertainty smaller than 1% [1]. Such precision makes  $W$  and  $Z$  production a stringent test of QCD.

Secondly, more specifically for  $Z$  production, the clean and fully reconstructed leptonic final states will allow a precise measurement of the transverse momentum and rapidity distributions, respectively  $d\sigma/dp_T$  and  $d\sigma/dy$ . The transverse momentum distribution will provide more constraints on QCD, most significantly on non-perturbative aspects related to the resummation of initial parton emissions, while the rapidity distribution is a direct probe of the parton density functions (PDFs) of the proton. The high expected counting rates will bring significant improvement on these aspects, and this improvement translates to virtually all physics at the LHC, where strong interaction and PDF uncertainties are a common factor.

From the experimental point of view, the precisely measured properties of the  $Z$  boson provide strong constraints on the detector performance. Its mass, width and leptonic decays can be exploited to measure the detector energy and momentum scale, its resolution, and lepton identification efficiency very precisely.

Finally, a number of fundamental electroweak parameters can be accessed through  $W$  and  $Z$  final states ( $M_W$ , through the  $W$  boson decay distributions;  $\sin^2\theta_W$ , via the  $Z$  forward-backward asymmetry; lepton universality, by comparing electron and muon cross-sections). These measurements are long term applications where the understanding of the hadronic environment at the LHC is crucial, and to which the above-mentioned measurements are necessary inputs.

The present note summarises the ATLAS preparations for  $W$  and  $Z$  cross-section measurements, in the context of the early running of ATLAS and the LHC. The electron and muon decay channels are considered. A baseline integrated luminosity of  $\mathcal{L} = 50 \text{ pb}^{-1}$  is assumed for the total cross-section analyses; based on these results, we estimate our prospects for  $\mathcal{L} = 1 \text{ fb}^{-1}$ . Anticipating that the measurement precision will soon be limited by the above-mentioned theoretical uncertainties, differential cross-section analyses are presented in the second part of this work. We consider the Drell-Yan mass spectrum below the  $Z$  peak, and the  $y$  and  $p_T$  distributions on the  $Z$  resonance.

The note is organised as follows. Section 2 gives technical details about cross-section measurements, lists the simulation samples used in the analyses, and reviews the main reconstruction aspects. Sections 3 and 4 describe the selections that allow extraction of the  $W$  and  $Z$  signals, give the expected statistics, and discuss the uncertainties on the background rates, as these are specific to each channel. Common systematic uncertainties affecting the cross-section determination are discussed in Section 5. Section 6 then presents the expected performance for total cross-section measurement. Differential cross-sections are discussed in Section 7, and Section 8 summarizes our results.

## 2 General discussion

This section describes the general procedure used to extract physical cross-sections, and the simulation samples used to evaluate the expected performance.

### 2.1 Total cross-section measurements

The number of events  $N$  passing a given set of selections is expressed as follows:

$$N = \mathcal{L} \sigma A \varepsilon + B \quad (1)$$

where  $\mathcal{L}$  is the integrated luminosity;  $\sigma$  the signal cross-section;  $A$  the acceptance of the signal, defined as the fraction of the signal that passes the kinematic and angular cuts;  $\varepsilon$  is the reconstruction efficiency of the signal within the fiducial acceptance;  $B$  is the number of background events. In the above,  $\varepsilon$  is to be understood as averaged over the phase space accepted by the selections. Conversely, the measured total cross-section is expressed as:

$$\sigma = \frac{N - B}{\mathcal{L} A \varepsilon} \quad (2)$$

and the overall measurement uncertainty gets contributions from the different terms as below:

$$\frac{\delta\sigma}{\sigma} = \frac{\delta N \oplus \delta B}{N - B} \oplus \frac{\delta\mathcal{L}}{\mathcal{L}} \oplus \frac{\delta A}{A} \oplus \frac{\delta\varepsilon}{\varepsilon} \quad (3)$$

Above,  $\delta N \sim \sqrt{N}$  is of purely statistical origin, and the relative uncertainty decreases with increasing luminosity following  $\delta N/N \sim 1/\sqrt{\mathcal{L}}$ . The terms  $\delta B$ ,  $\delta A$  and  $\delta\varepsilon$  are of both theoretical and experimental origin. They are considered as systematic uncertainties in the cross-section measurements, but can be constrained *via* auxiliary measurements. We thus expect these terms to improve over time, provided the auxiliary measurements have statistically dominated uncertainties. The machine luminosity  $\mathcal{L}$  will be measured with different methods. The uncertainty on this parameter,  $\delta\mathcal{L}$ , is expected to decrease through improved understanding of the LHC beam parameters and of the ATLAS luminosity detector response [2].

## 2.2 Signal and background samples. Benchmark cross-sections

Our main signals,  $W$  and  $Z$  events decaying into electrons and muons, are generated using PYTHIA [3]. The analysis described in Section 7, a measurement of the low-mass Drell-Yan cross-section, exploits samples produced using HERWIG [4].

The  $W$  and  $Z$  samples are filtered at generation-level, requiring at least one lepton within the fiducial acceptance. The electron channels require  $|\eta_e| < 2.7$  and  $p_T^e > 10$  GeV; the muon channels require  $|\eta_\mu| < 2.8$  and  $p_T^\mu > 5$  GeV. These filters have an efficiency of about 85% for  $Z$  events, and about 65% for  $W$  events. In the case of the  $Z$  sample, the available energy for the hard process is limited by  $\sqrt{\hat{s}} > 60$  GeV. The low-mass Drell-Yan samples have the same fiducial cuts on both leptons, but require  $8 < \sqrt{\hat{s}} < 60$  GeV. The  $W$  and  $Z$  cross-sections are normalised to the NNLO cross-sections as provided by the FEWZ program [1].

The backgrounds considered in the analyses originate from  $W$  and  $Z$  events decaying to  $\tau$ -leptons, with subsequent leptonic  $\tau$  decays;  $t\bar{t}$  events involving at least one semileptonic decay, and from inclusive jet events filtered to favour the presence of real leptons or hadrons misidentified as leptons. Low-mass Drell-Yan events, analysed only in the electron channel ( $\gamma^* \rightarrow ee$ ), also account for backgrounds from boson pair production.

The  $W \rightarrow \tau\nu_\tau$  and  $Z \rightarrow \tau\tau$  events are produced as the signal samples (generators and filters). The  $t\bar{t}$  samples are generated inclusively, using MC@NLO [5] to provide both the final states and the cross-section. They are filtered for the presence of at least one electron or muon, without kinematic constraints. Diboson events, one of the main background in the low-mass Drell-Yan analysis, are generated using MC@NLO. For the  $WW$  process only  $W \rightarrow e\nu$  decays are considered, while the  $ZZ$  and the  $WZ$  are generated inclusively. No filters are applied.

The jet events are produced using PYTHIA. The transverse momentum defined in the rest frame of the hard interaction is required to be above 15 GeV for jet samples used in  $W$  and  $Z$  analyses, whilst no such  $p_T$  cut is required for the sample used in low-mass Drell-Yan analysis. Jet backgrounds for the muon channels are generated as inclusive jets, then requiring a final state with one ( $W$  analysis;  $p_T(\mu) > 15$  GeV) or two ( $Z$  analysis;  $p_T(\mu) > 5$  and 15 GeV) muons from  $b$ -hadron decays with  $|\eta_\mu| < 2.5$ . Background events from hadron punch-through and from decays in flight of long lived particle are found negligible. Background events from cosmic muons can be eliminated in a very efficient way with timing cuts. Relying on the Tevatron results [6], this background is neglected. This appears as a safe approximation for the ATLAS experiment, since the Tevatron experiments are built close to the surface, while the ATLAS detector is  $\sim 100$  m underground. In the electron channels, fake electrons are an important issue. Therefore, rather than requiring a true electron in the final state, the events are required to contain at least one narrow cluster of energetic final state particles. In practice, there should exist a tower of size  $\Delta\eta \times \Delta\phi = 0.12 \times 0.12$  containing a total transverse energy greater than 17 GeV for use in  $W$  and  $Z$  analyses and 6 GeV for low-mass Drell-Yan analysis. Events passing this filter are considered likely to produce fake electrons and passed through the simulation step.

All samples are interfaced to the CTEQ6L1 or CTEQ6M parton density sets [7] depending if the generator uses a leading or next to leading order calculation, respectively. The events are processed through full simulation using Geant 6.4 and a special misaligned geometry, as described in Ref. [8]. While summarised here, the cross-sections used are described and justified, together with their uncer-

tainties, in Ref. [9]. Tables 1 and 2 summarise the signal and background samples and their properties. The first column in these Tables indicates explicitly the cases in which a specific leptonic decay have been required at the generation level. For this reason, the second column represents in some case (like for the  $t\bar{t}$  dataset) the total production cross section and in other cases the total cross-section multiplied by the leptonic branching ratio(s). The third column indicates the efficiency of the filter which is applied on the generated final states described in the first column.

Channel	$\sigma(\times B_r)$	$\epsilon_{filter}$	$N_{evt} (\times 10^3)$	$\mathcal{L} (\text{pb}^{-1})$
$W \rightarrow e\nu$	20510 pb	0.63	140	11
$\gamma/Z \rightarrow ee, \sqrt{\hat{s}} > 60 \text{ GeV}$	2015 pb	0.86	399	230
$\gamma/Z \rightarrow ee, \sqrt{\hat{s}} < 60 \text{ GeV}$	9220 pb	0.022	197	969
$W \rightarrow \tau\nu_\tau$	20510 pb	0.20	32	8
$Z \rightarrow \tau\tau$	2015 pb	0.05	13	129
$t\bar{t}$	833 pb	0.54	382	850
Inclusive jets ( $p_T > 6 \text{ GeV}$ )	70 mb	0.058	2480	0.0006
Inclusive jets ( $p_T > 17 \text{ GeV}$ )	2333 $\mu\text{b}$	0.09	3725	0.02
$WW \rightarrow (e\nu)(e\nu)$	1.275 pb	1.	20	15608
$ZZ$	14.8 pb	1.	43	2922
$WZ$	29.4 pb	1.	50	1699

Table 1: Signals and background samples in the electron channels.  $W$  and  $Z$  cross-sections are normalised to the NNLO prediction; the  $t\bar{t}$  cross-section is computed at NLO; the jet cross-section is the LO result. The filters are described in the text. The number of simulated events and the corresponding integrated luminosity are also indicated.

Channel	$\sigma(\times B_r)$	$\epsilon_{filter}$	$N_{evt} (\times 10^3)$	$\mathcal{L} (\text{pb}^{-1})$
$W \rightarrow \mu\nu$	20510 pb	0.69	190	13
$\gamma/Z \rightarrow \mu\mu, \sqrt{\hat{s}} > 60 \text{ GeV}$	2015 pb	0.89	446	249
$W \rightarrow \tau\nu_\tau$	20510 pb	0.20	32	8
$Z \rightarrow \tau\tau$	2015 pb	0.05	13	129
$t\bar{t}$	833 pb	0.54	382	850
$b\bar{b} \rightarrow \mu + X$	766 $\mu\text{b}$	$2.1 \times 10^{-4}$	110	0.67
$b\bar{b} \rightarrow \mu\mu + X$	25 $\mu\text{b}$	$1.6 \times 10^{-4}$	140	35

Table 2: Signals and background samples in the muon channels.  $W$  and  $Z$  cross-sections are normalised to the NNLO prediction; the  $t\bar{t}$  cross-section is computed at NLO; the  $b\bar{b}$  cross-section is the LO result. The filters are described in the text. The number of simulated events and the corresponding integrated luminosity are also indicated.

### 2.3 Common selection aspects

As already mentioned,  $W$  and  $Z$  boson final states are selected through their decays into electrons and muons. The reconstruction of electrons is based on a cluster measured in the electromagnetic

calorimeter, geometrically matching a track reconstructed in the Inner Detector. The identification of isolated high- $p_T$  electrons is then based on the shapes of the electromagnetic showers, and on track reconstruction information. Three sets of identification criteria have been defined. The Loose criterion consists of simple shower-shape cuts; the Medium criterion adds further cuts on shower-shape and on track quality; the Tight criterion tightens the track-matching requirement, adds a cut on the energy-momentum ratio and further selections based on the vertexing-layer hits and on the Transition Radiation Tracker. Electron reconstruction and its performance are described in Ref. [10].

The muon reconstruction is done with the Muon Spectrometer, possibly completed by the Inner Detector. Stand-alone muons are defined as consisting of a reconstructed track in the spectrometer only, and combined muons are the subset of the above that include a matching track in the Inner Detector. Muon reconstruction is documented in Ref. [11].

The measurement of missing energy in the transverse plane ( $\cancel{E}_T$ ) is an important requirement for  $W$  boson cross-section measurements, as significant  $\cancel{E}_T$  reflects the presence of at least one neutrino in the final state. The algorithm exploits the energy deposits in the calorimeter cells, the reconstructed muon tracks, and an estimate of the energy lost in the cryostat. The calorimeter cells are calibrated according to the physical object they represent (electrons or photons, taus, jets and muons). Cells corresponding to electrons, photons and muons are calibrated at the electromagnetic scale, whereas all other cells are calibrated at the hadronic scale. The  $\cancel{E}_T$  value is then computed as the vector sum of the cell transverse energies. If muons are reconstructed in the event, their transverse momentum is added to the calorimetric sum. A complete description of the  $\cancel{E}_T$  reconstruction can be found in Ref. [12].

Jets are reconstructed from calorimeter cells. The Cone algorithm is used, where the jet size parameter,  $\Delta R = \sqrt{(\Delta\eta)^2 + (\Delta\phi)^2}$ , is set to  $\Delta R = 0.7$ .

At low luminosity,  $\mathcal{L} = 10^{31} \text{ cm}^{-2}\text{s}^{-1}$ , the relevant trigger items require at least one electron or muon with  $p_T > 10 \text{ GeV}$ , at least two electrons with  $p_T > 5 \text{ GeV}$ , or two muons with  $p_T > 4 \text{ GeV}$ . No isolation criteria are imposed on the leptons. As the LHC luminosity ramps up towards its design value, tighter selections will be needed to control the rates. The thresholds are raised, and isolation criteria are imposed on the electrons. The trigger items relevant for  $W$  boson selection require at least one isolated electron with  $p_T > 22 \text{ GeV}$ , or one muon with  $p_T > 20 \text{ GeV}$ . For  $Z$  production, two isolated electrons with  $p_T > 12 \text{ GeV}$  or two muons with  $p_T > 10 \text{ GeV}$  can be required in addition to the above. The trigger items described above are summarised in Table 3. Many more trigger items exist; a complete description can be found in Ref. [13, 14].

The reconstruction efficiency for electrons and muons, and the resolution of the  $\cancel{E}_T$  reconstruction algorithm are illustrated in Fig. 1. For electrons the Medium identification efficiency is illustrated, and for muons the combined reconstruction efficiency is shown. With looser criteria, higher efficiency and weaker  $\eta$  dependence are obtained, at the cost of larger backgrounds. A complete description of the ATLAS detector and its performance can be found in Ref. [15].

Trigger item	Description
e10, e20	One electron, $p_T > 10, 20$ GeV
mu10, mu20	One muon, $p_T > 10, 20$ GeV
2e5	Two electrons, $p_T > 5$ GeV
2mu4	Two muons, $p_T > 4$ GeV
e22i	One isolated electron, $p_T > 22$ GeV
mu20	One isolated muon, $p_T > 20$ GeV
2e12i	Two isolated electrons, $p_T > 12$ GeV
2mu10	Two isolated muons, $p_T > 10$ GeV

Table 3: Main trigger items relevant for the selection of  $W$  and  $Z$  boson final states. The first group of trigger items is relevant to the  $\mathcal{L} = 10^{31} \text{ cm}^{-2}\text{s}^{-1}$  trigger menu; the second group is relevant for the  $\mathcal{L} = 10^{33} \text{ cm}^{-2}\text{s}^{-1}$  trigger menu.

Figure 1: From left to right : Medium identification efficiency for electrons vs.  $\eta$ ; muon combined reconstruction efficiency vs.  $\eta$ ;  $E_T$  resolution. The efficiencies are obtained from  $Z$  boson events, and integrated over  $p_T > 20$  GeV. The  $E_T$  resolution is obtained from  $W \rightarrow e\nu$  events.

Selection	$W \rightarrow e\nu$	jets	$W \rightarrow \tau\nu$	$Z \rightarrow ee$
Trigger	$37.01 \pm 0.09$	$835 \pm 18$	$1.73 \pm 0.02$	$6.07 \pm 0.01$

Table 4: Number of expected signal and background events ( $\times 10^4$ ) in the  $W \rightarrow e\nu$  channel after all selections, for an integrated luminosity of  $50 \text{ pb}^{-1}$ . The quoted uncertainties refer to the finite Monte-Carlo statistics only; systematic uncertainties are discussed in the text.

### 3 Electron final states

This section describes the event selections in the electron final states, the expected event rates, and estimations of the uncertainties on the remaining backgrounds.

#### 3.1 $W \rightarrow e\nu$

**Event selection.** The selection of  $W \rightarrow e\nu$  events proceeds as follows. First, the e20 trigger item of the  $10^{31}$  trigger menu should be passed. Then, exactly one electromagnetic (EM) cluster, matched with a track and such that  $E_T > 25 \text{ GeV}$ ,  $|\eta| < 1.37$  or  $1.52 < |\eta| < 2.4$ , should be present in the event. This object should satisfy the Medium electron identification criterion. Finally, the reconstructed missing transverse energy, reflecting the missing final state neutrino, should satisfy  $\cancel{E}_T > 25 \text{ GeV}$ , and the transverse mass of the  $(l, \nu)$  system should satisfy  $M_T > 40 \text{ GeV}$ .

Due to the high di-jet cross-section and the high rejection power of the selections, the available Monte Carlo statistics is not sufficient to evaluate this background directly. To overcome this difficulty, the jet background has been estimated by applying the trigger and electron identification selections only, and correcting the result with a factor obtained by computing the rejection power due to the  $\cancel{E}_T$  and  $M_T$  cuts only.

The number of signal and background events after the successive cuts are given in Table 4 for an integrated luminosity of  $50 \text{ pb}^{-1}$ . The statistical uncertainty on the expected number of events corresponding to  $50 \text{ pb}^{-1}$  is  $\Delta_{N_S} = 0.04 \cdot 10^4$ . The resulting transverse mass distribution is shown in Fig. 2.

**Background estimation.** As can be seen from Table 4, jet events constitute the largest background component. In addition, the jet production cross-section and fragmentation properties at the LHC are largely unknown and induce a significant uncertainty on the magnitude of this background; an uncertainty of about a factor 3 is estimated. It is therefore important to develop methods allowing to monitor the jet background using the data. An attempt is presented below.

The principle of the method is to measure the normalisation and shape of the jet background ahead of the  $\cancel{E}_T$  cut, in a sufficiently pure jet sample. It is thus needed to find a jet sub-sample that is free of signal events, but exhibits a transverse mass distribution and jet multiplicity close to that of the jet background to  $W \rightarrow e\nu$  at this level of the selection. This sub-sample is then used to evaluate the

Figure 2: Transverse mass distribution in the  $W \rightarrow e\nu$  channel, for signal and background after all selections, for  $\mathcal{L} = 50 \text{ pb}^{-1}$  after all selections except  $M_T$  cut.

rejection of  $\cancel{E}_T$  cut, allowing a realistic estimation of the jet background in the  $W \rightarrow e\nu$  selection.

In this approach, the signal sample is obtained by applying the same trigger, kinematics and electron identification selection as described before and removing in addition events with a second high- $p_T$  electromagnetic cluster giving an invariant mass, together with first selected electron, close to the  $Z$  boson mass ( $65 < M_{ll} < 130 \text{ GeV}$ ).

The jet background control sample is selected using a single photon trigger with  $E_T > 20 \text{ GeV}$ , and subsequent photon identification using the same calorimetric variables as the electron identification. The photon cluster should also satisfy the same kinematics cuts of the electron candidate in the signal sample. There should be no Inner Detector track matching the photon cluster, to reject events with true electrons (e.g.  $W$  events) contaminating this photon sample. Simulation studies show that these selections provide a sample essentially composed of jet events, even at high values of  $\cancel{E}_T$ , and that the shape of the  $\cancel{E}_T$  distribution is identical, within the statistical precision, to that of the jet background in the  $W \rightarrow e\nu$  sample (see Fig. 3). Above  $\cancel{E}_T > 10 \text{ GeV}$ , the slope can be described with the convolution of an exponential and a second degree polynomial function.

After the subtraction of the estimated background to the signal sample, the analysis then proceeds applying the  $\cancel{E}_T$  selection mentioned above. This data-driven estimation yields a jet background fraction of  $(0 + 4 - 0)\%$ . The uncertainty corresponds to a number of events,  $\delta B = 0.92 \times 10^4$  events. Besides, a relative uncertainty of 3% is assumed on the  $W \rightarrow \tau\nu$  background, as estimated from the experimental uncertainties on the  $W$  and  $\tau$  branching fractions. This process thus contributes  $\delta B = 0.01 \times 10^4$  events.

### 3.2 $Z \rightarrow ee$

**Event selection.** This analysis relies on the e10 trigger. Events are further preselected by requiring two EM clusters with  $E_T > 15 \text{ GeV}$  and  $|\eta| < 2.4$ . The presence of two electrons in the final state allows application of the Loose electron identification criteria, which we briefly describe below. Three

Figure 3: Left: ratio of the  $E_T$  distributions in jet background events and in the control sample. Right: comparison of the jet background (points with error bars) and the fitted background (rectangles), for an integrated luminosity of  $50 \text{ pb}^{-1}$ .

Figure 4: The electron identification criteria described in the text: the cluster hadronic to EM energy ratio (left); the cluster width in the first calorimeter sampling (right). The distributions are normalised to the number of background entries.

discriminant variables are used to separate EM clusters, deposited by electrons, from the hadronic background.

The first one is based on the longitudinal shower shape, and represents the ratio of the transverse energy deposited in the first compartment of the hadronic calorimeter divided by the transverse energy of the EM cluster. This ratio is expected to be small for EM objects, and large for hadronic clusters.

The second and third one are based on the shower width measured in the EM calorimeter. In the second compartment of the EM calorimeter, the width is computed from the ratio of the shower energy deposited in a region of size  $\Delta\eta \times \Delta\phi = 0.075 \times 0.175$ , divided by the energy deposited within  $\Delta\eta \times \Delta\phi = 0.175 \times 0.175$  around the cluster barycenter. In the first compartment, the cluster spread is used, computed as the root-mean-square (RMS) of the cluster energy distribution. These two variables discriminate the narrow EM clusters from the wider hadronic clusters. Distributions of the three discriminators for electrons and hadrons are shown in Fig. 4 and in Fig. 5.

Figure 5: The electron identification criteria described in the text: cluster width in the second calorimeter sampling (left) and electron isolation variable (right). The distributions are normalised to the number of background entries.

Selection	$Z \rightarrow ee$	jets
Trigger	$6.70 \pm 0.01$	$3110 \pm 40$
$E_T > 15 \text{ GeV}$ , $ \eta  < 2.4$ , $80 \text{ GeV} < M_{ee} < 100 \text{ GeV}$	$2.76 \pm 0.01$	$11.1 \pm 0.8$
Electron ID	$2.64 \pm 0.01$	$0.8 \pm 0.2$
Isolation	$2.48 \pm 0.01$	$0.2 \pm 0.1$

Table 5: Number of expected signal and background events ( $\times 10^4$ ) in the  $Z \rightarrow ee$  channel after all selections, for an integrated luminosity of  $50 \text{ pb}^{-1}$ . The quoted uncertainties refer to the finite Monte-Carlo statistics only; systematic uncertainties are discussed in the text.

Electrons identified as above are then required to be isolated. The isolation variable is computed from the total measured energy in a cone of size  $\Delta R = 0.45$  around and excluding the electron, divided by the electron energy. Electrons are isolated if this ratio is smaller than 0.2. Distributions of this variable for the signal and the background are shown in Fig. 5.

The number of signal and background events after the successive cuts are given in Table 5 for an integrated luminosity of  $50 \text{ pb}^{-1}$ . The expected signal counting rate is  $N = (2.48 \pm 0.02) \times 10^4$  events. The uncertainty quoted here is obtained by scaling the statistics of the Monte-Carlo sample to  $50 \text{ pb}^{-1}$ . The resulting di-electron invariant mass distribution is shown in Fig. 6.

**Background estimation.** As in the  $W \rightarrow e\nu$  analysis, the simulation-based jet background estimate of Table 5 is replaced by a data-driven estimate. In this analysis, the signal and background fractions are estimated simultaneously, *via* a fit to both contributions. The signal is described by the convolution of a Breit-Wigner and a Gaussian resolution function, and the background, completely dominated by jet events, by an exponential function.

At the preselection level (just ahead of the electron identification and without the  $M_{ee}$  cut), the background largely dominates the signal and allows to determine the exponential slope. After the identification and isolation cuts, the fit yields a background fraction of  $(8.5 \pm 1.5)\%$ , or  $B = (0.23 \pm 0.04) \times$

Figure 6: Di-electron invariant mass distribution in the  $Z \rightarrow ee$  channel, for signal and background, for  $50 \text{ pb}^{-1}$ , after all selection cuts, except  $M_{ee}$  cut.

$10^4$  events. The uncertainty on the background fraction derives from the modelling of the signal and background shapes.

The relatively important background rate is explained by the rather loose identification cuts. The present selections are chosen to illustrate the robustness of the signal extraction, and to exemplify the background extraction method.

## 4 Muon final states

### 4.1 $W \rightarrow \mu \nu$

**Event selection.** The  $W \rightarrow \mu \nu$  signal is selected as follows. The events should contain exactly one muon track candidate, passing the mu20 trigger item and satisfying  $|\eta| < 2.5$  and  $p_T > 25 \text{ GeV}$ . The energy deposited in the calorimeter around the muon track, within a cone of radius  $\Delta R = 0.4$ , is required to be lower than  $5 \text{ GeV}$ . The event missing transverse energy should satisfy  $\cancel{E}_T > 25 \text{ GeV}$ , and  $M_T > 40 \text{ GeV}$  is required.

For the initial luminosity the  $p_T$  cut of the trigger on the muon track is expected to be  $20 \text{ GeV}$ . Having a higher  $p_T$  threshold, however, can further reduce the backgrounds in particular from heavy flavour hadron decays and from decays in flight of long lived particles. The isolation,  $\cancel{E}_T$  and  $M_T$  cuts are also effective to reduce those backgrounds.

After all selections, the overall efficiency for the signal is expected to be close to 80%, with very large rejection factors for  $b\bar{b}$  and  $t\bar{t}$  events. The number of events that are expected to pass the selection criteria for an initial integrated luminosity of  $50 \text{ pb}^{-1}$  are shown in table 6. The expected background level corresponds to a fraction of  $\sim 7\%$ . Figure 7 shows the corresponding W transverse mass distribution before the transverse mass cut (last cut of table 6).

**Background estimation.** In contrast to the electron channels, the jet background is less important here and does not dominate the overall background. Muons from heavy flavour decays are rejected

Selection	$W \rightarrow \mu\nu$	$W \rightarrow \tau\nu$	$Z \rightarrow \mu\mu$	$b\bar{b} \rightarrow \mu X$	$t\bar{t}$
Trigger	$44.44 \pm 0.07$	$1.53 \pm 0.01$	$2.03 \pm 0.01$	$83.34 \pm 0.09$	$0.53 \pm 0.07$
$p_T > 25 \text{ GeV},  \eta  < 2.5$	$35.55 \pm 0.06$	$1.22 \pm 0.01$	$1.62 \pm 0.01$	$68.27 \pm 0.08$	$0.42 \pm 0.06$
Isolation	$34.80 \pm 0.06$	$1.20 \pm 0.01$	$1.59 \pm 0.01$	$9.67 \pm 0.03$	$0.35 \pm 0.06$
$\cancel{E}_T > 25 \text{ GeV}$	$28.59 \pm 0.05$	$0.72 \pm 0.01$	$1.10 \pm 0.01$	$1.00 \pm 0.01$	$0.30 \pm 0.05$
$M_T > 40 \text{ GeV}$	$28.03 \pm 0.05$	$0.57 \pm 0.01$	$1.10 \pm 0.01$	$0.10 \pm 0.01$	$0.24 \pm 0.05$

Table 6: Number of expected signal and background events ( $\times 10^4$ ) in the  $W \rightarrow \mu\nu$  channel, for an integrated luminosity of  $50 \text{ pb}^{-1}$ . The quoted uncertainties refer to the finite Monte-Carlo statistics.

Figure 7: Transverse mass distribution in the  $W \rightarrow \mu\nu$  channel, for signal and background, for  $50 \text{ pb}^{-1}$  after all selections except  $M_T$  cut.

using the  $p_T$  and the isolation cuts, and muons from decays in flight of long lived particles could be further rejected using loose impact parameter cuts. The  $t\bar{t}$  background and its uncertainty are small.

As can be seen in Table 6, the dominant backgrounds are expected from  $W \rightarrow \tau\nu$  and  $Z \rightarrow \mu\mu$  events. These processes are well understood theoretically, in particular with respect to the  $W \rightarrow \mu\nu$  signal, and can be safely estimated based on simulation. A relative uncertainty of 3% is assumed on the  $W \rightarrow \tau\nu$  background, as estimated from the experimental uncertainties on the  $W$  and  $\tau$  branching fractions. Exploiting the CTEQ6.5 eigenvector sets (cf. Section 5), an uncertainty of 2% is assumed on the  $Z$  event rate passing the selections.

The jet background (mostly muons from  $b$ -hadron decays) is theoretically not well known. An uncertainty of 100% is assumed on this background component.

A theoretical uncertainty of about 15% on the  $t\bar{t}$  cross-section is assumed. In addition, an uncertainty of 10% is considered on the rejection obtained from the isolation cut. This leads to a total uncertainty of about 20% on the  $t\bar{t}$  background rate.

## 4.2 $Z \rightarrow \mu\mu$

**Event selection.** The  $Z \rightarrow \mu\mu$  analysis uses the 10 GeV single muon trigger. The triggered data sample is further reduced by requiring at least two reconstructed muon tracks. The present analysis

Figure 8: Distributions of the muon isolation variables for signal and backgrounds after all selection cuts. Left : track multiplicity within  $\Delta R = 0.5$  around the muon. Right : total transverse momentum of these tracks.

relies on the muon spectrometer only. The reconstructed muon tracks should satisfy  $|\eta| < 2.5$  and  $p_T > 20$  GeV. The reconstructed charges must be opposite, and the invariant mass of the muon pair is required to fulfil  $|91.2 \text{ GeV} - M_{\mu\mu}| < 20 \text{ GeV}$ .

Muons in jet events tend to be produced within a decay cascade of further particles, and should therefore not appear isolated in the detector, in contrast to the leptonic decays of  $Z$  and  $W$  bosons. To quantify the isolation of the muons, the number of Inner Detector tracks within a cone around the candidate muon, as well as the total transverse momentum of these tracks are used. The cone size is  $\Delta R = 0.5$ , and the muon track itself is excluded from the calculation.

The distributions of the isolation variables for signal and background processes normalised to their cross sections is shown in Fig. 8, after the above-mentioned cuts.

The isolation and  $p_T$  cuts are chosen to minimise the statistical uncertainty on the cross-section measurement. The expected number of events after each cut are shown in Table 7. The chosen cuts select about 70% of the  $Z \rightarrow \mu\mu$  events with muons in the detector acceptance. The residual background fraction of this selection is  $0.004 \pm 0.001(\text{stat})$ . The corresponding invariant mass distribution is shown in Fig. 9.

**Background uncertainty.** In this channel, the dominant background originates from  $t\bar{t}$  events. Besides a theoretical uncertainty of about 15% on the cross-section, an uncertainty of 10% is assumed on the rejection obtained from the isolation cuts. This leads to a total uncertainty of about 20% on the  $t\bar{t}$  background rate.

The jet background (mostly muons from b-hadron decays) is expected to be smaller, but is theoretic-

Selection	$Z \rightarrow \mu\mu$	$b\bar{b} \rightarrow \mu\mu X$	$W \rightarrow \mu\nu$	$Z \rightarrow \tau\tau$	$t\bar{t}$
Trigger	$3.76 \pm 0.01$	$10.08 \pm 0.04$	$36.7 \pm 0.1$	$0.09 \pm 0.01$	$0.69 \pm 0.01$
2 muons + opp. charge	$3.33 \pm 0.01$	$3.00 \pm 0.04$	$1.14 \pm 0.02$	$0.04 \pm 0.01$	$0.35 \pm 0.01$
$M_{\mu\mu}$ cut	$3.04 \pm 0.01$	$0.26 \pm 0.01$	$0.04 \pm 0.01$	$(14 \pm 4) \times 10^{-4}$	$0.02 \pm 0.01$

Table 7: Number of expected signal and background events ( $\times 10^4$ ) in the  $Z \rightarrow \mu\mu$  channel, for an integrated luminosity of  $50 \text{ pb}^{-1}$ . The quoted uncertainties refer to the finite Monte-Carlo statistics.

Figure 9: Di-muon invariant mass distribution in the  $Z \rightarrow \mu\mu$  channel, for signal and background, for  $50 \text{ pb}^{-1}$ , after all cuts, except the isolation and  $M_{\mu\mu}$  cuts.

cally not well known. An uncertainty of 100% is assumed on this background component. The other backgrounds are smaller, theoretically well known in comparison to the above, and contribute negligibly to the overall background uncertainty.

## 5 Common systematic uncertainties

### 5.1 Trigger and reconstruction efficiency

As has been seen in Sections 3 and 4, the selection of leptonic  $Z$  boson decays provides clean signals with low backgrounds. This allows determination of the lepton trigger [13, 14] and reconstruction efficiencies [10, 11] using the well-known tag-and-probe method, which is briefly outlined below.

Selecting  $Z \rightarrow ee$  and  $Z \rightarrow \mu\mu$  events as in Sections 3 and 4, *i.e.* requiring a single lepton trigger and two reconstructed leptons, the efficiency of a given trigger item is defined as the fraction of the selected events where the second reconstructed lepton passes this trigger item.

The off-line reconstruction efficiency can be determined in a similar way. Requiring one reconstructed lepton satisfying tight identification criteria, and requiring a second isolated, high- $p_T$  object such that the invariant mass of the pair is close to the  $Z$  boson mass, provides a sufficiently pure  $Z \rightarrow ll$  sample; the efficiency of a given identification criterion is then defined as the fraction of events where the second object is indeed identified. Conversely, the efficiency of the isolation cuts can be determined by requiring the second object to be identified, and counting the fraction of events where the isolation cut is passed.

The above methods are exact in the limit where backgrounds vanish. For tight trigger and off-line cuts, this is the case in practice : the background magnitude and uncertainty have a negligible impact on the efficiency determination. Backgrounds are larger when assessing looser identification and isolation cuts, and lower trigger thresholds. In this case, interpreting the observed dilepton mass spectrum as a sum of signal and background contributions (described by the convolution of a Breit-Wigner resonance and a Gaussian resolution function, and by an exponential or polynomial function, respectively) allows to extract the background fraction and correct the computation accordingly. This procedure was performed and shown to provide efficiency estimates that are unbiased within the statistical precision expected for  $\mathcal{L} = 50 \text{ pb}^{-1}$ .

Figures 10 and 11 illustrate this discussion, on the examples of the e20 trigger item and Medium electron identification cut, and of the mu20 trigger item and combined muon reconstruction. For the selections used in the analyses of Section 3 and 4, the overall efficiency can be reconstructed with a precision of  $\delta\epsilon/\epsilon = 0.02$  for electrons and muons.

The overall reconstruction efficiencies in Fig. 10, 11 reflect the performance of the reconstruction software at the time of writing this note. Improved performance and results are presented in [10, 11, 13, 14].

### 5.2 Theoretical systematic uncertainties

This section presents comparisons on the acceptance for  $W \rightarrow l\nu$  and  $Z \rightarrow ll$  events, as obtained from the Pythia, Herwig and MC@NLO. The purpose of this study is to determine the contribution of the

Figure 10: Electron detection efficiency vs.  $\eta$ , as measured from the tag-and-probe method and compared to the truth, for  $50 \text{ pb}^{-1}$ . The product of the  $e_{20}$  trigger efficiency, and Medium electron identification efficiency is represented.

Figure 11: Muon detection efficiency vs.  $\eta$ , as measured from the tag-and-probe method and compared to the truth, for  $50 \text{ pb}^{-1}$ . The  $\mu_{20}$  trigger efficiency, and the combined muon reconstruction efficiency are represented.

uncertainties on the acceptance to the overall systematic uncertainty on the cross-section.

The kinematic cuts described in Sections 3 and 4 are applied to the generator-level particles for each of the above generators. For  $W$  events, the acceptance varies by 2.5% from one program to the other. For  $Z$  events the observed variation is of order 3.2%. The sources which could explain the observed differences are the Initial State Radiation (ISR), the intrinsic  $k_T$  for the incoming partons, the Underlying Event (UE), final state photon radiation, Parton Density Functions (PDFs) and matrix element corrections applied to the parton shower (ME).

To quantify the impact of the individual sources, samples are generated with ISR,  $k_T$ , UE and ME all switched off. The impact of each effect is then studied by switching on this effect individually. For the sake of clarity, the discussion is given explicitly for  $W \rightarrow e\nu$  production only; at the end of the section results are given for both  $W$  and  $Z$  production.

The effects of electroweak corrections on the acceptance have been studied using PHOTOS. By running alternatively with and without PHOTOS, one obtains an effect of 1.8% for  $W$  events.

Switching on ISR, or changing the intrinsic  $k_T$  of the incoming partons has an important impact on the lepton  $\eta$  and  $p_T$  distributions. Specifically, ISR introduces a difference of 10.2% on the acceptance for  $W$  events. Similarly, turning on and off the  $k_T$ , ME and UE, the following differences on the  $W$  acceptance are obtained: 1.9% for the intrinsic  $k_T$ , 1.0% for the UE and no effect for the ME.

For these sources, the systematic uncertainty is estimated as 20% of the above numbers, which amounts to assuming that the models describing the above are correct within 20%. One thus obtains the following uncertainties for  $W \rightarrow e\nu$ : 2.0% (ISR), 0.4% ( $k_T$ ) and 0.2% (UE). In the case of PHOTOS, one has an uncertainty of 0.3%.

The PDFs are an important source of differences in the acceptances. The uncertainty is determined using the CTEQ6.5 PDF uncertainty sets. An uncertainty of 0.9% is found.

To simplify the procedure, we assume no correlations between the different sources and calculate the total uncertainty from the quadratic sum of all numbers, finding  $\delta A/A = 2.3\%$  for  $W$  events. Repeating the same exercise with  $Z$  events gives a very comparable systematic uncertainty. While these uncertainties will be significantly reduced with the analysis of the LHC data, we assume these figures hold for our initial cross-section measurements.

## 6 Total cross-section results

Cross-section results for  $\mathcal{L} = 50 \text{ pb}^{-1}$  are presented first. At the end of the section, the performance is extrapolated to higher luminosity.

### 6.1 Results for $\mathcal{L} = 50 \text{ pb}^{-1}$

We gather below the results of the analyses performed in Sections 3 and 4, and of the discussion of systematic uncertainties of Section 5. Table 8 contains our estimations of statistical and systematic uncertainties, the cross-section values and their uncertainties computed according to Equations 2 and 3.

Process	$N(\times 10^4)$	$B(\times 10^4)$	$A \times \varepsilon$	$\delta A/A$	$\delta \varepsilon/\varepsilon$	$\sigma$ (pb)
$W \rightarrow e\nu$	$22.67 \pm 0.04$	$0.61 \pm 0.92$	0.215	0.023	0.02	$20520 \pm 40 \pm 1060$
$W \rightarrow \mu\nu$	$30.04 \pm 0.05$	$2.01 \pm 0.12$	0.273	0.023	0.02	$20530 \pm 40 \pm 630$
$Z \rightarrow ee$	$2.71 \pm 0.02$	$0.23 \pm 0.04$	0.246	0.023	0.03	$2016 \pm 16 \pm 83$
$Z \rightarrow \mu\mu$	$2.57 \pm 0.02$	$0.010 \pm 0.002$	0.254	0.023	0.03	$2016 \pm 16 \pm 76$

Table 8: Measured cross-sections, their uncertainties and overall selection efficiency  $A \times \varepsilon$ , for an integrated luminosity of  $50 \text{ pb}^{-1}$ . The uncertainty on  $N$  is statistical, the other sources are systematic. The quoted cross-section uncertainties include the mentioned statistical and systematic contributions but not an overall luminosity uncertainty.

As can be seen from Table 8, the results are dominated by the systematic error, even for  $\mathcal{L} = 50 \text{ pb}^{-1}$ . The luminosity uncertainty is common to all cross-sections, and vanishes in cross-section ratios, e.g.  $\sigma_W/\sigma_Z$ . In the  $W$  channels, the systematic uncertainty is dominated by the background uncertainty. This can be expected given the important fraction of jet events. This background could be further reduced, notably by requiring the absence of jets, but this would jeopardize the inclusive nature of the cross-section measurement. The efficiency and acceptance uncertainties give a slightly smaller contribution.

The  $Z$  channels benefit from smaller backgrounds, due to the presence of two decay leptons. For the same reason, the efficiency uncertainty is also larger than in the  $W$  channels. Given the smaller acceptance uncertainty, the efficiency uncertainty is the largest source of uncertainty.

## 6.2 Prospects for $\mathcal{L} = 1 \text{ fb}^{-1}$

For higher integrated luminosity, the statistical uncertainty on the counting ( $N$ ) becomes negligible, and the efficiency uncertainty, which is determined from measurement and also of statistical nature, strongly decreases.

With increased luminosity, a number of modifications will have to be applied to the analyses. Most prominently, in the electron channels, the single electron trigger threshold will be increased to 22 GeV, and the Tight electron identification is expected to be used. In  $Z \rightarrow \mu\mu$  channel, spectrometer muons are replaced by combined muons, and the muon isolation cuts are refined by exploiting calorimetric information in addition to the track-based isolation used in the low-luminosity analysis. The  $W \rightarrow \mu\nu$  analysis is unchanged.

Table 9 summarizes the expected signal yields and the cross-section determination in this case. On this timescale,  $\mathcal{L}$  might be measured with improved precision, exploiting elastic proton scattering at very small angles [2]. Compared to the low-luminosity analysis, the systematic uncertainties from backgrounds and efficiency are expected to scale with statistics. Without further input, the acceptance uncertainty does not decrease and dominates the result.

Process	$N(\times 10^5)$	$B(\times 10^5)$	$A \times \varepsilon$	$\delta A/A$	$\delta \varepsilon/\varepsilon$	$\sigma$ (pb)
$W \rightarrow e\nu$	$45.34 \pm 0.02$	$1.22 \pm 0.41$	0.215	0.023	0.004	$20520 \pm 9 \pm 516$
$W \rightarrow \mu\nu$	$60.08 \pm 0.02$	$4.02 \pm 0.05$	0.273	0.023	0.004	$20535 \pm 7 \pm 480$
$Z \rightarrow ee$	$5.42 \pm 0.01$	$0.46 \pm 0.02$	0.246	0.023	0.007	$2016 \pm 4 \pm 49$
$Z \rightarrow \mu\mu$	$5.14 \pm 0.01$	$0.02 \pm 0.001$	0.254	0.023	0.007	$2016 \pm 4 \pm 49$

Table 9: Measured cross-sections, their uncertainties and overall selection efficiency  $A \times \varepsilon$ , for an integrated luminosity of  $1 \text{ fb}^{-1}$ . The uncertainty on  $N$  is statistical, the other sources are systematic. The quoted cross-section uncertainties include the mentioned statistical and systematic contributions but not an overall luminosity uncertainty.

## 7 Differential cross-sections

As it is clear from the previous sections, total cross-section measurements are dominated by the systematic uncertainty even for modest integrated luminosity. The main cross-section uncertainty is related to the acceptance uncertainty, which in turn comes from our limited knowledge of the underlying physics (notably non-perturbative mechanisms and PDFs). It is therefore important to measure the distributions, which will help to constrain these uncertainties. Three examples are given below, namely the measurement of the Drell-Yan invariant mass spectrum at low mass, and the rapidity and transverse momentum distributions for  $Z$  events.

Compared to the inclusive analyses, the differential measurements require larger statistics. For this reason the differential distributions shown in this section refer to an integrated luminosity of  $200 \text{ pb}^{-1}$ , which corresponds to the available statistics of the Monte Carlo signal samples.

### 7.1 Low-mass Drell-Yan production

**Event selection.** This study relies on a low threshold single electron trigger,  $e10$ , possible at low luminosity. At the reconstruction level, exactly two oppositely charged electrons are required, each satisfying the tight identification criteria, and with  $p_T > 10 \text{ GeV}$ . Offline electron reconstruction is limited to  $|\eta| < 2.5$ . After these preselections, the reconstructed missing transverse energy in the event,  $E_T^{\text{miss}}$ , should be smaller than  $30 \text{ GeV}$ . Finally, the di-electron invariant mass,  $m_{ee}$ , is required to be in the range  $20 < m_{ee} < 60 \text{ GeV}$ . Table 10 shows the impact of these cuts on signal and background. Only the main backgrounds except the one arising from QCD dijets are considered at this level; the dijet background is discussed separately.

The kinematical acceptance, given by the final state requirement of two electrons satisfying  $p_T > 10 \text{ GeV}$  and  $|\eta| < 2.5$ , is 17% in the range  $20 < m_{ee} < 60 \text{ GeV}$ . For  $40 < m_{ee} < 60 \text{ GeV}$ , the acceptance reaches 34%. The  $e10$  trigger channel provides an efficiency of about 89% for signal events within the kinematical acceptance. The trigger efficiency is about 74% for di-electron pair masses of  $m_{ee} = 20 \text{ GeV}$ , and reaches 97% at  $m_{ee} = 60 \text{ GeV}$ . The offline electron selection efficiency is 36% [10], and the further kinematic selections have an efficiency of 83%.

**Dijet background estimation.** The background contributions listed in Table 10 are estimated from simulation, by counting the events that pass the selection criteria described above. This method can not be applied to the dijet background which, due to very high rejection factors, can not be simulated

cut	$\gamma^* \rightarrow ee$	$\tau\tau$	$t\bar{t}$	di-boson
Preselections	$2632 \pm 12$	$48 \pm 3$	$218 \pm 3$	$342 \pm 3$
$E_T^{miss} < 30 \text{ GeV}$	$2604 \pm 12$	$38 \pm 3$	$28 \pm 1$	$164 \pm 2$
$20 < m_{ee} < 60 \text{ GeV}$	$2189 \pm 11$	$30 \pm 3$	$7 \pm 1$	$7 \pm 1$

Table 10: Signal and background event rates, following the selections described in the text. For all samples, the normalization corresponds to  $50 \text{ pb}^{-1}$ . The  $\gamma^*/Z \rightarrow ee$  signal with  $m_{ee} > 60 \text{ GeV}$  is excluded from these numbers, at all levels of the selection. The dominant dijet background is not displayed here, and discussed separately below.

in sufficient amounts.

An alternative estimation, based on single electron rejection factors, is used. This method relies on the probability for an event to display a single fake electron. On the inclusive jet sample, this probability is found to be  $(1.5 \pm 0.1) \times 10^{-4}$ . Assuming no correlations, the probability to find a fake di-electron pair with opposite charge is then estimated as one-half of the square of the single fake probability. The invariant mass distribution of fake electron pairs is estimated using Monte Carlo information.

The invariant mass distribution of the signal and backgrounds are displayed in Figure 12 (left). The estimated background represents about one third of the selected sample. It is dominantly composed of inclusive jets (96%), the other backgrounds being negligible.

Two thirds of the dijet events that contain one tight electron candidate are true electrons from heavy quark decays, while the remainder are due to light hadrons mis-identified as electrons and to photon conversions. It may be possible to reduce the jet background further by optimizing the selection criteria for these low  $E_T$  electrons. Additional event variables, like hadronic activity estimators, could also be used to reduce or constrain the size of the dijet background. However, the large fraction of electrons from heavy quark decays indicates that the uncertainty on the background composition related to different rejection factors for heavy flavour and light jets under the the Drell-Yan signal is large and requires further study.

**Measurement of the cross-section.** The raw measured differential cross-section may be corrected bin by bin in di-electron mass, as follows:

$$\left( \frac{d\sigma}{dM} \right)_i = \frac{N_i - B_i}{\varepsilon_i A_i \Delta m_i \mathcal{L}} \quad (4)$$

where  $N_i$  is the number of signal events in mass bin  $i$ ,  $B_i$  is the expected number of background events,  $A_i$  is the kinematical and angular acceptance efficiency,  $\varepsilon_i$  is the overall efficiency accounting for trigger, identification and further selections.  $\Delta m_i$  is the width of bin  $i$  and  $\mathcal{L}$  represents the integrated luminosity.

In practice, the corrections can be considered to be of two types: those correcting for experimental effects (backgrounds and efficiencies), and those correcting for the kinematic acceptance of the electron  $p_T$  and  $\eta$  requirements. Figure 12, right, illustrates the two corrections. The agreement between the corrected distribution and the expected distribution from theory provides a technical consistency

Figure 12: Left: Mass distributions of the measured raw events (solid line), Drell-Yan signal events (dashed line) and background contributions arising from inclusive jets,  $\tau\tau$ ,  $t\bar{t}$ , di-boson in decreasing numerical importance. Right: invariant mass distributions of the selected sample before any corrections (rectangles with error bars), the theoretical signal within the fiducial acceptance (dashed line), the corrected Drell-Yan signal sample (unshaded rectangles with error bars) and the complete theoretical distribution (solid line).

check of the method.

The integrated cross-section can be calculated by integrating the corrected histogram; the statistical error on the cross-section is estimated by adding the error from each bin in quadrature. The total Drell-Yan cross section in the electron channel, for  $20 < m_{ee} < 60$  GeV is  $\sigma_{\text{DY}} = 1.07$  nb. The corresponding statistical uncertainty is 4% for  $\mathcal{L} = 50 \text{ pb}^{-1}$  and 1% for  $\mathcal{L} = 1 \text{ fb}^{-1}$ . This can be compared with the PDF contribution to the cross-section uncertainty, estimated to be 6.9% using CTEQ6.1M [7].

The statistical sensitivity provides a natural target for the different contributions to the systematic uncertainty: the knowledge of the background level, and of the efficiency and acceptance corrections should match the statistical sensitivity. The efficiency can be determined with sufficient precision using the methods discussed in Section 5. The acceptance corrections are mostly affected by the transverse momentum distribution of the Drell-Yan pairs in this mass range; this has large theoretical uncertainties, and will have to be measured from data. The invariant mass resolution, about 1 GeV, is found to have no significant effect on the Drell-Yan spectrum. As discussed above, the most serious challenge is posed by the understanding of the jet background, where the current uncertainties are much larger than the expected statistical precision. Further study is needed to assess the precision of techniques to constrain this background directly from data; this is beyond the scope of the current work.

## 7.2 Z differential cross-section : bin by bin correction method

Category $i$	Definition	$n_i$
1	All events	398 750
2	Fiducial and kinematics (generation)	172 544
3	Trigger and off-line (fiducial, kinematics and ID)	49 754
4	Intersection of categories 2 and 3	48 436

Table 11: Event categories used for the extraction of detector smearing corrections, geometric acceptance and event selection efficiency in the electron channel.

**Electron channel.** In the electron channel, only events that pass the 2e12i trigger condition are considered. Furthermore, it is required that they contain exactly two, oppositely charged electrons, each of them satisfying  $|\eta| < 2.5$  and  $p_T > 20$  GeV. Both electrons are required to pass the Tight electron identification criteria.

The background is dominated by hadrons misidentified as electrons in inclusive jet events. Taking into account that with the Tight identification criteria the expected rate of hadrons misidentified as electrons is very low (see [10]), the background to the di-electron signal is neglected in the following.

After all selections, the following event categories are defined. In the following,  $n_1$  denotes the total sample size;  $n_2$  is the number of events having two generator-level electrons satisfying  $|\eta| < 2.5$ ,  $p_T > 20$  GeV, and  $75 \text{ GeV} < M_{ee} < 105 \text{ GeV}$ . The number of events satisfying these conditions at the reconstruction level is noted  $n_3$ ; finally,  $n_4$  counts the events passing these criteria on both generation and reconstruction levels. Table 11 summarises these definitions and contains values for the  $n_i$ , directly counted from the simulated signal sample.

**Muon channel.** In the muon channel, only events that pass the mu20 trigger condition are considered. The events should further contain exactly two oppositely charged muons, each of them satisfying  $|\eta| < 2.5$ . Both muons should be reconstructed in the Inner Detector and in the Muon Spectrometer. The most energetic muon should satisfy  $p_T > 20$  GeV; the second one should have  $p_T > 15$  GeV. The muon pair invariant mass should lie between 76 and 106 GeV.

Contamination from  $W \rightarrow \mu\nu$  and  $t\bar{t}$  events effectively disappears after the selection process, but  $b\bar{b} \rightarrow \mu\mu$  contamination is still about 3.5% of the signal. To minimise the  $b\bar{b}$  background, two isolation quantities are studied. The first one is the number of tracks in a cone of size  $\Delta R = 0.45$  around the muon track; the second one is the total calorimeter transverse energy in the same cone. The distributions of these two quantities for the four samples, corresponding to  $40 \text{ pb}^{-1}$  of integrated luminosity, are shown in Fig. 13. A muon track is accepted if the first isolation variable is less than six and the second isolation variable is less than 20 GeV. These cuts are applied to both muons in the event.

The isolation cut efficiency for the signal sample is larger than 98%, and the residual contamination is less than 0.5%. The sample is pure enough at this point that we can neglect the background contamination in the differential cross-section plots.

As in the electron channel, four event categories are defined to allow the computation of the differen-

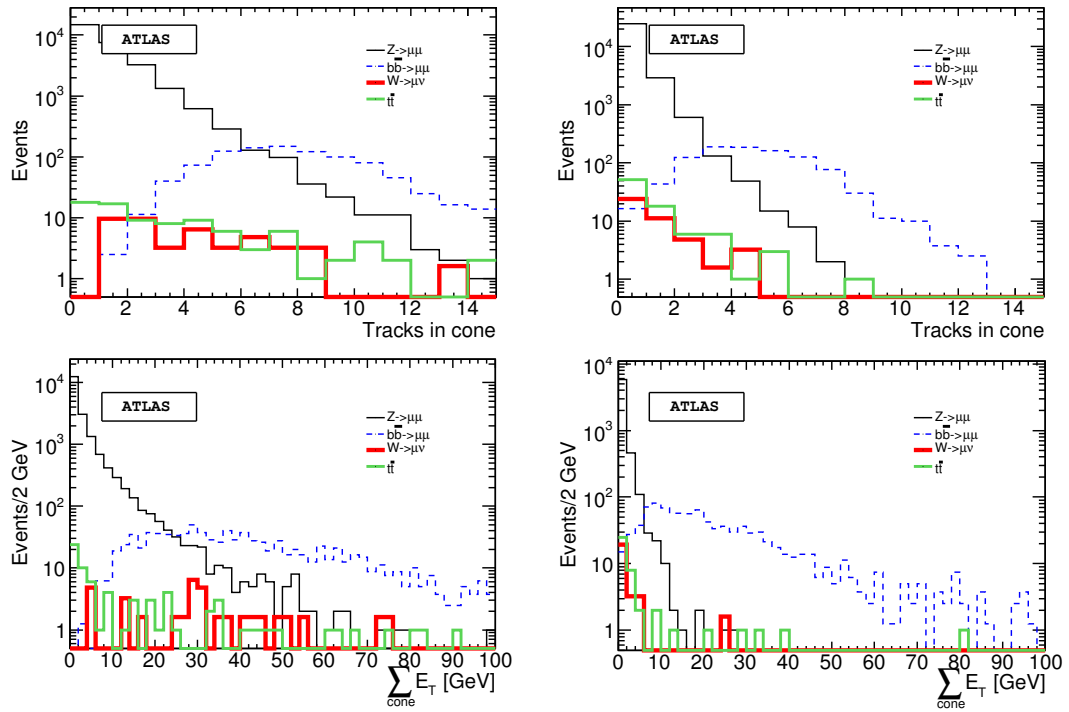

Figure 13: Number of tracks (top) and calorimeter  $E_T$  in a cone  $R = 0.45$  (bottom). Distributions for the muon with the higher value of the quantity is shown on the left, and distributions for the muon with the lower value of the quantity on the right. Black line:  $Z \rightarrow \mu\mu$ , red (or dark grey line):  $W \rightarrow \mu\nu$ , dashed line:  $b\bar{b} \rightarrow \mu\mu$ , green (or light grey line):  $t\bar{t}$ .

Category $i$	Definition	$n_i$
1	All events	445650
2	Fiducial and kinematics (generation)	234610
3	Trigger and off-line (fiducial, kinematics and ID)	181652
4	Intersection of categories 2 and 3	180260

Table 12: Event categories used for the extraction of detector smearing corrections, geometric acceptance and event selection efficiency in the muon channel.

tial cross-section. The categories and their sizes  $n_i$  are given in Table 12.

**Extraction of  $d\sigma_Z/dp_T dy$**  The Z boson phase space is sliced in rapidity and transverse momentum regions, or bins. In each region, labeled  $\alpha$ , the differential cross-section is obtained from the raw event count using the usual expression:

$$\sigma_\alpha = \frac{S_\alpha}{\mathcal{L}} \frac{d_\alpha - b_\alpha}{\epsilon_\alpha A_\alpha}, \quad (5)$$

where  $S_\alpha$ ,  $\epsilon_\alpha$  and  $A_\alpha$  respectively represent the detector smearing correction (correcting for event migration to and from bin  $\alpha$ , due to resolution effects), overall event selection efficiency and geometric acceptance in region  $\alpha$ ;  $d_\alpha$  is the observed event count and  $b_\alpha$  the estimated background in this region, and  $\mathcal{L}$  is the integrated luminosity. In terms of the definitions in Tables 11 and 12, we have:

$$S_\alpha = \frac{n_{3,\alpha}}{n_{4,\alpha}}, \quad \epsilon_\alpha = \frac{n_{3,\alpha}}{n_{2,\alpha}}, \quad A_\alpha = \epsilon_{filter} \frac{n_{2,\alpha}}{n_{1,\alpha}}, \quad d_\alpha = n_{3,\alpha}, \quad (6)$$

where the  $n_{i,\alpha}$  are computed in each bin  $\alpha$  of the Z phase space. The acceptance values account for the generator-level filtering efficiency, as described in Section 2.2.

**Differential cross-section results** In the electron channel, the Z boson phase space was divided in 50  $p_T$  bins and 9 rapidity bins. The  $p_T$  bins have a width of 2 GeV, in the range  $0 < p_T < 100$  GeV. The rapidity bins have a width of 0.3, in the range  $0 < |y| < 2.7$ . A good agreement is found between the reconstructed cross-sections and the true distributions, obtained from a statistically independent sample. Figure 14 shows the Z boson differential cross-section in the electron channel in rapidity and transverse momentum bins.

In the muon channel, the Z boson phase space is divided as in the electron channel. A good agreement is again found between the reconstructed cross-sections and the true distributions. Figure 15 shows the Z boson differential cross-section in the dimuon channel in rapidity and transverse momentum bins.

The plots have been normalised to the total NNLO cross-section of 2015 pb times a global acceptance factor of 0.73. Since the correction factors and measurement were both extracted from the same dataset, the good agreement is a check of consistency of the method.

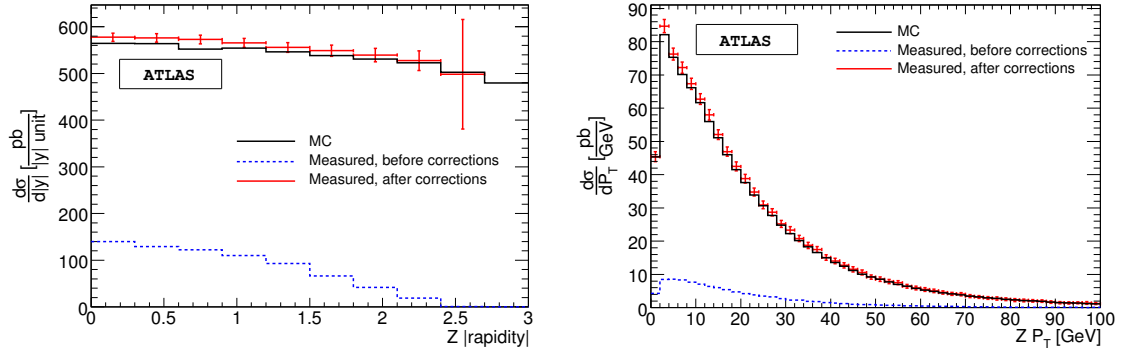

Figure 14: Left:  $d\sigma_Z/dy$ , integrated over  $p_T$ . Right:  $d\sigma_Z/dp_T$ , integrated over  $-2.7 < y < 2.7$ . Distributions obtained in the electron channel, with a precision corresponding to an integrated luminosity of  $200 \text{ pb}^{-1}$ . The black line histograms correspond to the generated cross-section, the dashed histograms to the measured cross-section before corrections are applied, while the crosses show the measured cross-section after all corrections have been applied.

### 7.3 Z differential cross-section : alternative method

The method presented here attempts to fully exploit the phase space of the Z boson and its decay products. Writing the cross-section in terms of the complete phase space allows to extract, in addition to the Z boson distributions, possible  $p_T$ ,  $\eta$  or  $\phi$  dependencies of the lepton selection efficiency.

**Method** The events are classified in bins both for the Z and for the decay leptons. We define  $N_{yZ}$  bins along  $y^Z$ , and  $N_{pTZ}$  bins along  $p_T^Z$ . As before, the Z boson phase space intervals are labelled  $\alpha$ . In addition, we define  $N_{Et}$  intervals in the lepton transverse energy distribution, and  $N_\eta$  intervals for the leptons pseudorapidity. The lepton phase space is labelled  $i, j$  (one index for each lepton).

For each  $\alpha$ , we measure  $N_{ij}^\alpha$ , which is the number of lepton pairs reconstructed with one lepton in bin  $i$  and one lepton in bin  $j$ . The following relation holds, in the practical absence of background, as justified in the previous sections:

$$N_{ij}^\alpha = \varepsilon_i \varepsilon_j P_{ij}^\alpha \mathcal{L} \Delta\sigma^\alpha, \quad (7)$$

where  $P_{ij}^\alpha$  is the probability, computed on Monte Carlo, that a Z boson produced in bin  $\alpha$  decays into two leptons in bins  $i$  and  $j$ ;  $\varepsilon_i$  is the lepton reconstruction efficiency in bin  $i$ ;  $\mathcal{L}$  is the integrated luminosity, and  $\Delta\sigma^\alpha$  is the Z production cross-section in bin  $\alpha$ .

Resolution effects, primarily on the lepton  $E_T$ , are accounted for as follows. When the  $P_{ij}^\alpha$  histograms are filled, the lepton  $E_T$  is first smeared according to its expected,  $E_T$  and  $\eta$  dependent resolution. The smeared quantities are then used to compute the Z variables ( $p_t, y$ ). In this way the above equation is unchanged and all detector effects can be incorporated in the  $P_{ij}^\alpha$  factors. Writing the above for all  $\alpha, i, j$  provides an over-constrained system whose unknowns are the efficiencies and cross-sections. We can then compute the  $\varepsilon_i$  in each bin  $\alpha$ , up to a factor related to  $\mathcal{L} \Delta\sigma^\alpha$ .

The system can be solved analytically, using for example the singular value decomposition method, or SVD. A drawback of this method is that it is based on least squares; it is thus not valid in the case of low statistics. In particular, at low luminosity, the statistics are such that several bins contain only a few events. To avoid bias in the efficiency determination, a likelihood using Poisson probabilities is constructed and used to fit the efficiencies numerically. In order to help the fit to converge, we first solve the system using the SVD method, and we use the results as initial parameters of the fit. Since the  $\varepsilon_i$  are expected not to depend on  $\alpha$ , we can compute their weighted average over the bins  $\alpha$ .

In case of low statistics, the bin sizes should be large enough to integrate a sufficient statistics in each bin. If the lepton reconstruction efficiency is not constant within each bin, the hypothesis that the efficiency does not depend on the Z boson phase space might be violated. To avoid such effects, the lepton binning is chosen such that the efficiency is *a priori* constant within each bin. This results in bins with variable width, which does not affect the method.

In any given Z phase space interval  $\alpha$ , we can write for each lepton bin  $(i, j)$  the following relation:

$$\mathcal{L} \Delta\sigma^\alpha = \frac{N_{ij}^\alpha}{\langle \varepsilon_i \rangle \langle \varepsilon_j \rangle P_{ij}^\alpha}, \quad (8)$$

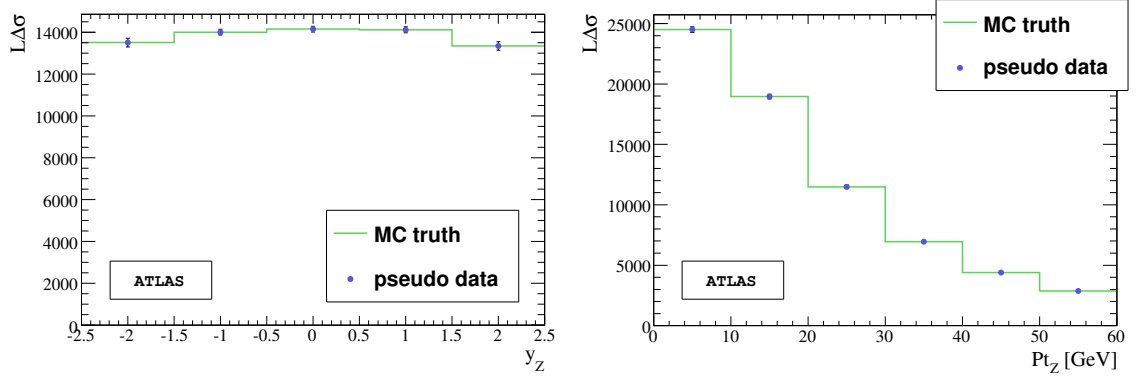

Figure 16: Left:  $\mathcal{L}\Delta\sigma$  versus  $y^Z$ , integrated over  $p_T^Z$ . Right:  $\mathcal{L}\Delta\sigma$  versus  $p_T^Z$ , integrated over  $y^Z$ .

where  $\langle \varepsilon_i \rangle$  and  $\langle \varepsilon_j \rangle$  are the average efficiencies computed at the previous step. Finally,  $\mathcal{L}\Delta\sigma^\alpha$  is computed by averaging over all  $(i, j)$ .

**“Classical limit” of the method.** As discussed above, the method proposed here might need significant integrated luminosity to be applied safely. The classical method is reached by simply setting  $N_{Et} = N_\eta = 1$ , and accordingly computing the acceptance and efficiencies from Monte-Carlo in each  $Z$  boson phase space interval  $\alpha$ .

Resolution effects are taken into account as before, by smearing the Monte Carlo input before determining the acceptance. Once the acceptance and efficiency are determined in each bin  $\alpha$ , just counting the number of events  $N^\alpha$  in the bin and allows to deduce the differential cross-section using the usual cross-section expression in the absence of background:

$$\mathcal{L}\Delta\sigma^\alpha = \frac{N^\alpha}{\varepsilon^\alpha \varepsilon_A^\alpha}. \quad (9)$$

**Results.** The complete method has been tested on the  $Z \rightarrow \mu\mu$  samples described in Section 2.2. Due to the limited statistics, the  $Z$  phase space was mapped using  $N_{pTZ} = 10$  for  $0 < p_T^Z < 60$  GeV,  $N_{yZ} = 5$  for  $-2.5 < y^Z < 2.5$ . The muon reconstruction efficiency has no  $p_T$ -dependence above 10 GeV; this allows to set  $N_{Et} = 1$ . The definition of the muon  $\eta$  intervals is dictated by the detector geometry which affects the efficiency as a function of  $\eta$ ; we set  $N_\eta = 7$ , with the intervals  $[-2.7, -1.6]$ ,  $[-1.6, -1.4]$ ,  $[-1.4, -0.1]$ ,  $[-0.1, 0.1]$ ,  $[0.1, 1.4]$ ,  $[1.4, 1.6]$ ,  $[1.6, 2.7]$ .

The results are illustrated in Fig. 16. The  $Z$  boson rapidity and  $p_T$  distributions are correctly reconstructed. Measured and true distributions agree within the statistical precision, which varies from 3% in regions where the differential cross-section is high, to about 20% in the tails of the  $Z$  boson phase space ( $y^Z > 1.5$ ). In addition, the  $\eta$  dependence of the reconstruction efficiency can be measured accurately. Given the interval definition above and the size of our sample, a precision of about 2% is obtained for each point. This is competitive with the tag-and-probe determination described in Section 5, and illustrated in Fig. 17.

Figure 17: Muon reconstruction efficiency versus  $\eta$ , measured simultaneously with the differential cross-section.

For cross-checks, the classical limit of the method has been tested using the  $Z \rightarrow ee$  samples. The intervals are defined as before, except  $N_{yZ}=10$  and  $N_{pTZ}=20$ . The following selection criteria are applied: two reconstructed electrons of opposite charge are required in the detector acceptance ( $|\eta| \geq 2.5$ ), with  $20 \text{ GeV} \leq p_t \leq 80 \text{ GeV}$ . Both electrons should pass the Tight identification criterion.  $Z$  events are selected around the mass peak ( $87 \text{ GeV} \leq M_Z \leq 95 \text{ GeV}$ ), with  $p_T^Z \leq 60 \text{ GeV}$ . The acceptance cuts on the electrons imply  $y^Z \leq 2.5$ .

The results of the differential cross-section  $d\sigma/dy^Z$ , integrated over  $p_T^Z$ , and  $d\sigma/dp_T^Z$ , integrated over  $y^Z$  are shown in Fig. 18. The squares represent the raw distribution, the dots represent the measurements, corrected by the acceptance and the efficiency factors. The shows the input value. The measurements are consistent with the input, which proves the consistency of the method.

## 8 Summary and perspectives

This work presents the ATLAS prospects for the measurement of  $W$  and  $Z$  boson cross-sections at the LHC. In the four considered channels ( $W \rightarrow e\nu$ ,  $Z \rightarrow ee$ ,  $W \rightarrow \mu\nu$ ,  $Z \rightarrow \mu\mu$ ), the analyses confirm the high purity of the samples after fairly usual selections (high- $p_T$  lepton identification, isolation, and  $\cancel{E}_T$  in the  $W$  final states). The jet background is poorly predicted, and dedicated studies are needed to monitor its magnitude using real data. Data-driven methods are presented that seem to have sufficient sensitivity to keep the jet background at a level where it does not prevent a precise cross-section measurement.

With  $50 \text{ pb}^{-1}$ , the background and signal acceptance uncertainties contribute similarly to the measured cross-section uncertainty, at the level of 2-4% depending on the channel. The uncertainty on the integrated luminosity is not included in the present discussion. Extrapolating to  $1 \text{ fb}^{-1}$ , all uncertainties are expected to scale with statistics, except the acceptance uncertainty. This leads to the conclusion (see also, for example, [16, 17]) that the  $W$  and  $Z$  cross-sections can not be measured to a

Figure 18: Left:  $\mathcal{L}\Delta\sigma$  versus  $y^Z$ , integrated over  $p_T^Z$ . Right:  $\mathcal{L}\Delta\sigma$  versus  $p_T^Z$ , integrated over  $y^Z$ .

precision better than about 2 %.

This argument however ignores the additional input from differential cross-section measurements. In contrast to total cross-sections, the differential ones benefit from small acceptance uncertainties, and have the potential to constrain the uncertainties that affect total cross-sections. The examples of the dilepton mass spectrum below the  $Z$  peak, and of the  $Z$  boson rapidity and  $p_T$  distributions are studied here. The methods presented are shown to provide correct estimations of the differential cross-sections. The natural next step of these analyses, *i.e.* quantify their physical implications, is beyond the scope of this note and reserved for the real data.

# Production of Jets in Association with Z Bosons

## Abstract

We simulate a measurement of the inclusive  $Z(\rightarrow e^+e^-/\mu^+\mu^-) + \text{jets}$  cross-section with the ATLAS experiment in pp collisions at 14 TeV for an integrated luminosity of  $1 \text{ fb}^{-1}$  using fully-simulated signal and background Monte Carlo data sets. The reconstruction of leptons and of missing transverse energy becomes more complex in the presence of a multi-jet final state. We quantify the reconstruction differences with respect to those observed for inclusive Z production. We derive statistical and systematic limitations in terms of probing the perturbative QCD predictions and discriminating between predictions of different event generators.

## 1 Introduction

The production of  $W/Z + \text{jets}$  in pp collisions at 14 TeV is an important part of the physics program at ATLAS. The processes are interesting in their own right as tests of perturbative QCD at the LHC, as well as forming important backgrounds for both Standard Model and Beyond Standard Model physics processes. The results of the measurements can be compared directly with fixed-order predictions at leading order (LO) and next-to-leading order (NLO) in QCD and the gauge boson mass provides a large scale for the perturbative calculations. In addition, the measurements can be used to test the performance of Monte Carlo event generators that will also be used to simulate the backgrounds for other physics processes.

In this analysis we present a feasibility study of the cross-section measurements for data corresponding to an integrated luminosity of  $1 \text{ fb}^{-1}$  performed with fully-simulated signal and background Monte Carlo samples. The goal of the analysis is to test the performance of the lepton and jet triggering and reconstruction algorithms in high jet multiplicity events, to develop the necessary analysis techniques (unfolding, background subtraction) and to evaluate the statistical and systematic limitations of the data, in terms of probing the fixed-order QCD predictions and of discriminating between predictions of different Monte Carlo event generators. The primary end-result of the analysis with real ATLAS data will be hadron-level cross-sections. In this note we will concentrate on  $Z + \text{jets}$  in final states with electrons and muons, but with techniques applicable to the case of  $W + \text{jets}$  as well. Much of the effort on the triggering and reconstruction of leptons is in common with the inclusive  $W/Z$  note [1]; thus, we do not reproduce all of the details from that note, but rather comment on the impact of a multi-jet environment on these issues.

## 2 Reference Cross-Sections and Monte Carlo Datasets

Reference cross-sections are collected in [2], but we briefly discuss here the cross-sections relevant for this note. NLO is the first order at which the  $Z + \text{jets}$  cross-sections have a realistic normalization (and realistic shape for some kinematic distributions) [3]. The current state of the art for NLO calculations is for  $Z + 2 \text{ jets}$ , although there is ongoing work for the calculation of 3 jet final states. Cross-sections for  $Z + 0, 1$  and 2 (3) jet final states can be conveniently calculated at LO and NLO (LO only) using the parton-level MCFM [4] program (version 5.1. interfaced with LHAPDF 5.2.3 [5]), and it is from this program that we determine our reference cross-sections. We use the CTEQ6.1 parton distribution functions (PDFs) [6] and a dynamic renormalization/factorization scale of  $m_Z^2 + p_{T,Z}^2$ . We apply similar

kinematic cuts on the leptons and jets and the same jet algorithm on the partons as will be described in Section 3. The error on the cross-section stemming from the PDF uncertainty is calculated using the complete set of error PDFs in the CTEQ6.1 set.

## 2.1 Monte Carlo Datasets

The most important Monte Carlo data sets for the signal processes ( $Z \rightarrow e^+e^-$  and  $Z \rightarrow \mu^+\mu^-$ ) used in these studies are generated with ALPGEN [7] (v 2.05), interfaced with HERWIG [8] and using the leading order PDF set CTEQ6LL [9]. (Hereafter, when we refer to ALPGEN it is understood that it is interfaced with HERWIG.) The generation is done with a renormalization/factorization scale of  $m_Z^2 + p_{T,Z}^2$  and a MLM [10] matching cut at  $p_T = 20$  GeV (jets below this cut are generated by the parton shower and not by the matrix element) and  $|\eta| < 6$ . A discussion of the uncertainty in predictions for  $Z$  + jets final states using different matrix element + Monte Carlo calculations and different matching cuts is beyond the scope of this study, but is given in Ref. [10].

The final Monte Carlo data sets are obtained following the standard prescription [10], by merging the samples of  $Z$  +  $n$  partons (where  $n=0-5$ ), each sample weighted with the product of the respective sample cross-section, the MLM matching efficiency and the efficiency of the generator-level filter. All but the highest jet multiplicity sample are exclusive, i.e. events are only kept if all jets with  $p_T > 20$  GeV and  $|\eta| < 6$  are matched to a matrix element parton. The highest multiplicity sample,  $Z$  + 5 partons, is inclusive; events with additional jets softer than the partons from the matrix element are not discarded. Thus, there can be more than 5 jets in this sample. The di-lepton mass is required to be larger than 40 GeV and lower than 200 GeV. A generator-level filter requires one seeded-cone jet, with a radius of  $R = \sqrt{\Delta\eta^2 + \Delta\phi^2} = 0.4$ , with  $p_T > 20$  GeV and  $|\eta| < 5.0$ , and two electrons/muons with  $p_T > 10$  GeV and  $|\eta| < 2.7$  in the event.

For the comparison with the fixed-order theoretical predictions, the merged data sets are normalized to the NLO inclusive  $Z \rightarrow e^+e^-$  and  $Z \rightarrow \mu^+\mu^-$  cross-sections. Because of the jet filter used in their generation, the fully-simulated data sets can not be used to derive the global normalization factor. For this purpose, we use additional  $Z \rightarrow e^+e^-$  and  $Z \rightarrow \mu^+\mu^-$  ALPGEN data sets which are produced with the same conditions, but without the generator-level filter applied.

PYTHIA [11] signal and background samples are generated with version 6.323 ( $Z \rightarrow e^+e^-$ ,  $Z \rightarrow \mu^+\mu^-$ ,  $Z \rightarrow \tau\tau$ , and  $W \rightarrow e\nu$ ) or 6.403 ( $t\bar{t}$ , filtered QCD multi-jet) using the corresponding ATLAS underlying-event tune [2]. PYTHIA  $Z \rightarrow e^+e^-$  and  $W \rightarrow e\nu$  events are preselected with a generator-level filter requiring one electron with  $p_T > 10$  GeV and  $|\eta| < 2.7$ . The filter for the corresponding processes with muon final states requires one muon with  $p_T > 5$  GeV and  $|\eta| < 2.8$ . PYTHIA  $Z \rightarrow \tau\tau$  events are generated with a filter requiring two electrons/muons with  $p_T > 5$  GeV and  $|\eta| < 2.8$ . For each of the  $Z \rightarrow \ell\ell$  samples, the di-electron (di-muon, di-tau) mass is required to be larger than 60 GeV. The jet background for the electron channel is simulated with a PYTHIA QCD multi-jet sample with a minimum hard-scattering transverse momentum of 15 GeV. A generator-level filter requires a jet of  $p_T = 17$  GeV clustered in a narrow region of  $\Delta\eta/\Delta\phi = 0.06$ , a size similar to an electron cluster. The QCD multi-jet background for the muon channel is estimated with a PYTHIA  $b\bar{b}$  sample. Two muons with  $p_T > 4$  GeV and 6 GeV, respectively, are required in the final state.

## 2.2 Corrections from Parton to Hadron Level

Comparisons of data cross-section measurements and LO/NLO predictions are to be made at the hadron level (particle level). Hence, the MCFM predictions for the observables have to be corrected with respect to the non-perturbative effects resulting from jet fragmentation and from the underlying

event. The impact of the underlying event correction is to add energy to the MCFM jets, while the jet fragmentation correction subtracts energy. Both corrections are expected to decrease with increasing jet  $p_T$ . The non-perturbative corrections are determined from the current ATLAS PYTHIA tune by comparing the multiplicity and the  $p_T$  distribution of jets with a cone radius of 0.4 clustered on the final-state particles in  $Z \rightarrow \mu^+ \mu^-$  Monte Carlo samples generated with PYTHIA 6.403 (a) using the standard ATLAS PYTHIA tune [2] and (b) with fragmentation and multiple-particle interactions switched off. To the extent to which the two partons that can comprise a jet in MCFM mimic the effects of the parton shower in PYTHIA, the corrections derived from the above procedure can be applied to the MCFM output [3]. For jets with cone radius 0.4 with  $p_T > 40$  GeV, the effects of fragmentation and underlying event cancel up to a residual correction at the percent level, which is then applied to the MCFM predictions. These corrections are expected to be re-done with the underlying event measurements determined from ATLAS data.

### 3 Particle Identification and Trigger

We adopt as much as possible definitions and cuts in common with the other analyses, and in particular with the inclusive  $W/Z$  study [1].

#### 3.1 Particle Identification

The electron candidates are required to have  $p_T > 25$  GeV, and to lie in the range  $|\eta| < 2.4$ , excluding the barrel-to-endcap calorimeter crack region ( $1.37 < |\eta| < 1.52$ ). The electrons are required to fulfill the medium electron-identification signature [12], which consists of requirements on the calorimeter shower-shape and the matched track. The  $Z$  selection requires two electron candidates with an invariant mass of  $81 < m_{ee} < 101$  GeV and  $\Delta R > 0.2$  between the electrons. No calorimeter isolation cuts are applied for this analysis, although they will be applied for actual data analysis. There is an implicit isolation cut, however, present in the trigger [13].

A muon candidate requires the combined reconstruction of an inner detector track and a track in the muon spectrometer [14]. Muons are required to have  $p_T > 15$  GeV and  $|\eta| < 2.4$ , with the range  $1.2 < |\eta| < 1.3$  being excluded. Isolation is applied by requiring the energy deposition in the calorimeter to be less than 15 GeV in a cone of  $\Delta R = 0.2$  around the extrapolation of the muon track. The  $Z$  selection requires that there be two muon candidates with an invariant mass of  $81 < m_{\mu\mu} < 101$  GeV.

For the analyses in this study, we use jets clustered with the standard ATLAS seeded-cone algorithm with a radius of  $R = 0.4$ , built from either calorimeter towers ( $Z \rightarrow e^+ e^-$  analysis) or topological clusters [15] ( $Z \rightarrow \mu^+ \mu^-$  analysis), and calibrated to the hadron level. The lepton and jet candidates must be separated by  $\Delta R_{lj} > 0.4$ . It is required that the jet transverse momentum be larger than 40 GeV and that the jet be in the range  $|\eta| < 3.0$ .

#### 3.2 Trigger Selection

The trigger selection used here is the same as that used in the inclusive analyses [1]. In the electron channel,  $Z \rightarrow e^+ e^- + \text{jets}$  events are required to pass the isolated di-electron trigger or the isolated single-electron trigger. In the muon channel,  $Z \rightarrow \mu^+ \mu^- + \text{jets}$  events are required to pass the isolated di-muon trigger. The trigger efficiencies at the first, second and event filter levels are evaluated as a function of the jet multiplicity. The trigger efficiency is also studied as a function of the overall hadronic activity, the  $p_T$  of the leading jet and the  $Z$  transverse momentum. For this purpose, the

generated Monte Carlo information and the data driven tag-and-probe method are compared. Good agreement between the two methods is found. The efficiency for an electron to pass the isolated single-electron trigger is found to decrease with increasing jet multiplicity,  $p_T$  of the leading jet and with decreasing distance to the closest jet.

## 4 Measurement of $Z + \text{jets}$ Cross-Sections

We study the comparison of theory and measurement for quantities suited to compare with a fixed-order NLO calculation: the inclusive cross-section for  $Z \rightarrow \ell\ell'$  with at least 1 jet, 2 jets and 3 jets and the differential cross-sections with respect to the  $p_T$  of the leading and the next-to-leading jets.

### 4.1 Lepton Reconstruction in a Multi-jet Environment

The presence of additional jets in the event has an impact on the kinematics of both the leptons and jets: the leptons are more boosted (larger  $p_T$  and lower  $\Delta\phi$  between leptons) in events with jets and the distance between leptons and jets becomes smaller in high-multiplicity events. The average jet  $p_T$  increases with the number of jets. Due to the combination of the single electron and di-electron trigger channels used in this analysis and due to the boost of the electrons with large jet activity, the efficiency loss of the isolated electron triggers for large jet multiplicities has only a negligible impact. The total  $Z$  reconstruction efficiency (offline+trigger) is stable with respect to both the jet multiplicity and the transverse momentum of the leading jet.

Muon reconstruction efficiencies and rejections for QCD multi-jet background are investigated for different isolation requirements. The isolation requirement for this analysis (see Section 3.1) is chosen such that it presents no significant bias for events with large jet multiplicities and large jet  $p_T$  while at the same time providing a sufficiently large rejection for the QCD multi-jet background.

### 4.2 Background Estimation

For the evaluation of backgrounds to the  $Z \rightarrow e^+e^- + \text{jets}$  signal we consider processes with real electrons ( $t\bar{t}$ ,  $W \rightarrow e\nu$ ,  $Z \rightarrow \tau^+\tau^-$ ) and QCD multi-jet production. Statistics of the multi-jet background sample are increased by applying a very loose electron selection and then reweighting the events with the rejection from the final electron identification cuts. For the  $Z \rightarrow \mu^+\mu^-$  analysis the background is dominated by processes with real muons ( $t\bar{t}$ ,  $W \rightarrow \mu\nu$ , and QCD multi-jets). QCD multi-jet backgrounds for isolated highly-energetic muons result mainly from decays of  $b\bar{b}$  mesons. We thus use a  $b\bar{b}(\rightarrow \mu^+\mu^-)$  sample to evaluate this background. For both analyses, all backgrounds are estimated from fully-simulated Monte Carlo samples, generated with PYTHIA. They are compared with the signal distributions, derived from the respective ALPGEN  $Z + \text{jets}$  data sets.

Table 1 provides an overview of the accepted cross-section and the corresponding signal and background fractions within the selected event sample, for several jet multiplicities and for the electron and the muon channel respectively. The uncertainties displayed in the table are of statistical nature only. The total background is at the level of 5-15 % depending on the jet multiplicity. With increasing jet multiplicity,  $t\bar{t}$  replaces QCD multi-jet production as the dominant background source in both analysis channels. Due to the larger acceptance and the larger lepton reconstruction efficiency, we obtain more than twice as many signal events in the muon channel. Since the dominant ( $t\bar{t}$ ) background also contains two real leptons, the signal-to-background ratio is comparable in both analyses.

Figures 1(a+b) show the combined distribution of the di-muon mass and the jet multiplicity for events with at least one jet for signal and background events in the  $Z \rightarrow \mu^+\mu^- + \text{jets}$  channel. Fig-

Process	$Z \rightarrow \ell\ell + \geq 1\text{jet}$		$Z \rightarrow \ell\ell + \geq 2\text{jets}$		$Z \rightarrow \ell\ell + \geq 3\text{jets}$

Table 1: The accepted cross-sections ( $\sigma$ , in fb) and the corresponding fraction of the total sample (in %) for signal and for the background channels in the  $Z \rightarrow e^+e^- + \text{jets}$  and the  $Z \rightarrow \mu^+\mu^- + \text{jets}$  analyses, after applying the cuts outlined in Section 3. The numbers in brackets are extrapolated from results obtained for a lower jet multiplicity. Errors shown are statistical only.

ures 1(c+d) show the distribution of signal and backgrounds for the  $p_T$  of the leading and the next-to-leading jet in the  $Z \rightarrow e^+e^- + \text{jets}$  channel. The jets from the QCD multi-jet background have a similar  $p_T$  distribution as the jets from the signal events, while the jets from the  $t\bar{t}$  background tend to be harder.

#### 4.2.1 Background Subtraction

The  $Z \rightarrow \tau^+\tau^-$ ,  $t\bar{t}$  and  $W \rightarrow e\nu$  backgrounds are subtracted using the Monte Carlo estimates. The systematic uncertainty from the limited background statistics is propagated into the systematic uncertainty of the cross-section measurement. Special care will be needed in validating against data the differential cross-section for the  $t\bar{t}$  process, since it is the dominant background for large jet multiplicities. The QCD multi-jet background is expected to be determined with data-driven methods. From the simulations we expect a multi-jet background fraction independent of the jet  $p_T$  such that it can be subtracted by applying a global factor. We assume in the following an uncertainty of 20% on the measurement of the QCD multi-jet fraction. The error is propagated into the systematic error on the measured cross-section.

#### 4.3 Unfolding of Detector Effects

The reconstructed data have to be unfolded from the detector level to the hadron level, correcting for efficiency, resolution and non-linearities in electron and jet reconstruction. In this study, the individual unfolding corrections are assumed to factorize in leading approximation, and the individual contributions are investigated and corrected for separately. The corrections are detailed in the following for the case of the  $Z \rightarrow e^+e^-$  channel. Unfolding of the  $Z \rightarrow \mu^+\mu^-$  final state is done in a similar way. All corrections are derived with fully-simulated ALPGEN Monte Carlo samples.

The dominant correction on the inclusive cross-section for the  $Z \rightarrow e^+e^-$  channel stems from the

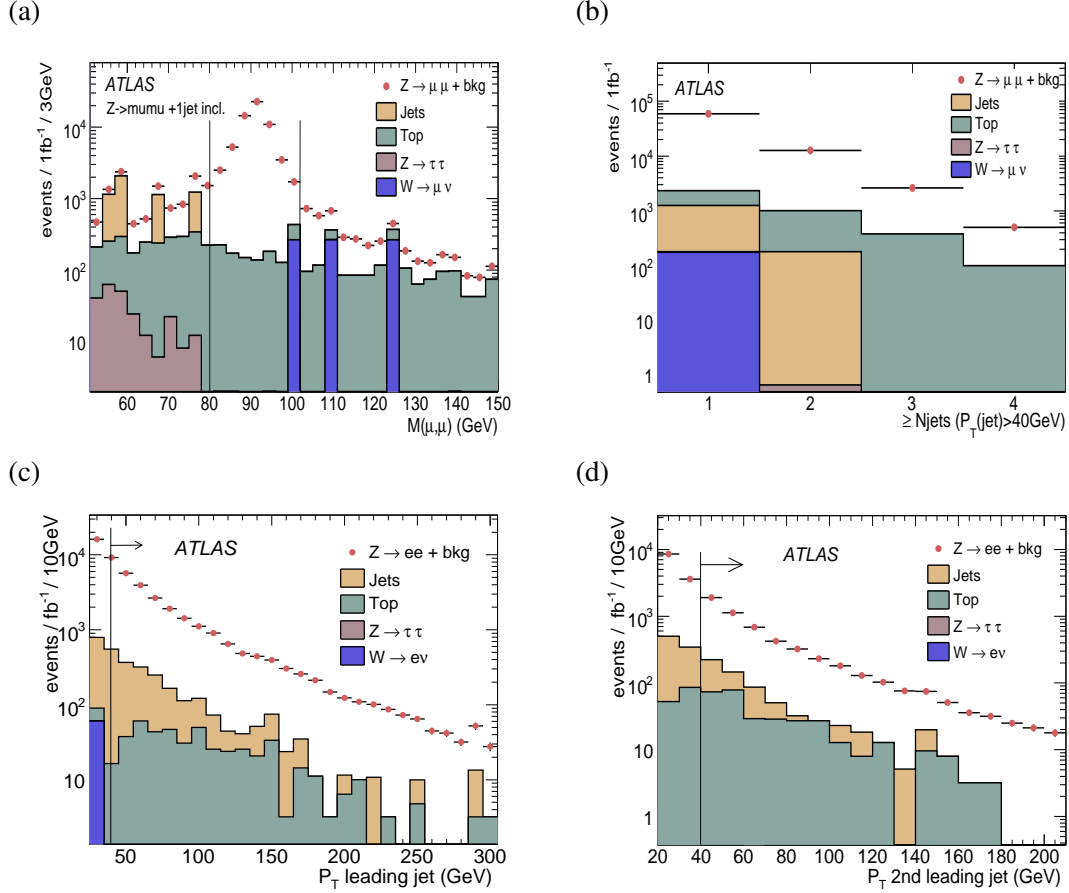

Figure 1: The distribution of the di-muon mass (a) and the inclusive jet multiplicity (b) for signal and backgrounds in the muon channel. In order to provide higher statistics for the background determination, background events in an invariant mass window of 51 – 131 GeV, are scaled down for an invariant mass window of 81 – 101 GeV. Also shown is the distribution of  $p_T$  of the leading (c) and the next-to-leading (d) jet in the electron channel for  $\int L dt = 1 \text{ fb}^{-1}$ . The vertical lines in (a), (c) and (d) indicate the kinematic cuts applied in the analysis.

electron reconstruction. For each of the two electrons, the cross-section is corrected for the electron reconstruction efficiency, given as a function of the electron pseudo-rapidity and transverse momentum. The cross-section is also corrected for the trigger efficiency with respect to the offline selection. Corrections from jet reconstruction have a comparably small impact on the overall cross-section but bias the jet  $p_T$  spectrum since, in general, the detector effects are greater for low  $p_T$  jets. The reconstructed jet  $p_T$  is corrected for the non-linearity of the jet energy scale, and for each jet in the required selection, the cross-section is corrected for the reconstruction efficiency and for the effect of the jet energy resolution. The uncertainties on deriving these corrections, stemming from the limited Monte Carlo statistics, are taken into account as systematic uncertainties on the cross-section measurement.

Figure 2 compares the distributions of the  $p_T$  of the leading jet and the next-to-leading jet, in different unfolding stages, with the  $p_T$  distribution of the original (hadron-level) Monte Carlo jets. Within the statistical and systematic errors, the  $p_T$  distributions of the Monte Carlo jets and the corrected reconstructed jets are in agreement, thus providing a consistency check for the unfolding corrections.

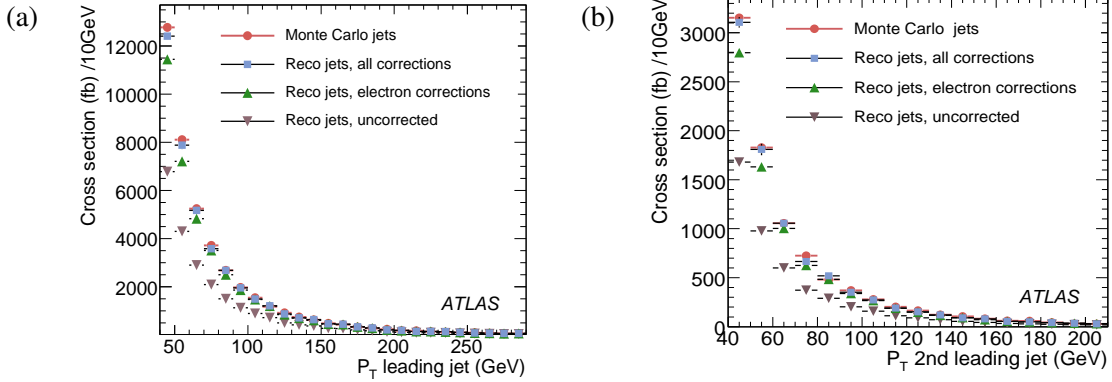

Figure 2: Comparison of the distribution of the  $p_T$  of the leading jet (a) and the next-to-leading jet (b) for the generated (hadron-level) Monte Carlo and for the reconstructed quantities without any correction, after the corrections for electron triggering and reconstruction and after applying in addition the jet-related corrections.

#### 4.4 Comparison of Event Generator and MCFM Predictions at the Hadron Level

One of the goals of our study is to evaluate the statistical and systematic precision of the  $Z + \text{jets}$  cross-section measurement and to compare this precision with the size of the uncertainties that are expected in the first inverse femtobarn of data. Since this study deals with the measurements from the first data, we compare the precision of the measurement with the differences in the predictions of our LO and NLO QCD calculations and with the predictions from matrix element and parton-shower generators.

##### 4.4.1 Generator Comparisons

In this section we compare the prediction for the inclusive jet cross-section from the generators PYTHIA and ALPGEN with those from the MCFM partonic level event generator. In order to separate the reconstruction from the generation effects we use only Monte Carlo hadron-level generator information.

Figures 3(a)-(c) show the comparison of the distribution of the jet multiplicities and the  $p_T$  of the leading and next-to leading jets for ALPGEN and PYTHIA  $Z \rightarrow \mu^+ \mu^- + \text{jets}$  samples with the NLO (LO) calculations from MCFM. The errors on the generator distributions are purely Monte Carlo statistics whereas the errors on the MCFM cross-section correspond to the PDF uncertainties and to the error from the unfolding to the hadron level. MCFM predictions are corrected to the hadron level as specified in section 2.2. The two Monte Carlo samples are normalized to the inclusive NLO  $Z$  cross-section, as determined in MCFM.

The NLO MCFM predictions for the  $Z + 1$  jet and  $Z + 2$  jets cross-sections are, in general, greater than the LO predictions by 20 to 30%. PYTHIA predicts a larger  $Z + 1$  jet cross-section than ALPGEN, but also predicts a lower average jet multiplicity. Both Monte Carlo generators predict a lower cross-section than the NLO MCFM calculation for final states with more than one jet. The difference between the predictions of PYTHIA and ALPGEN, and between both generators and MCFM, amounts to 10-60% depending on the jet multiplicity. A comparison of the differential cross-section as a function of the jet  $p_T$  indicates that the inclusive cross-sections shown in Figure 3(a) depend very much on the minimum jet  $p_T$  required by the selection. PYTHIA predicts larger cross-sections than

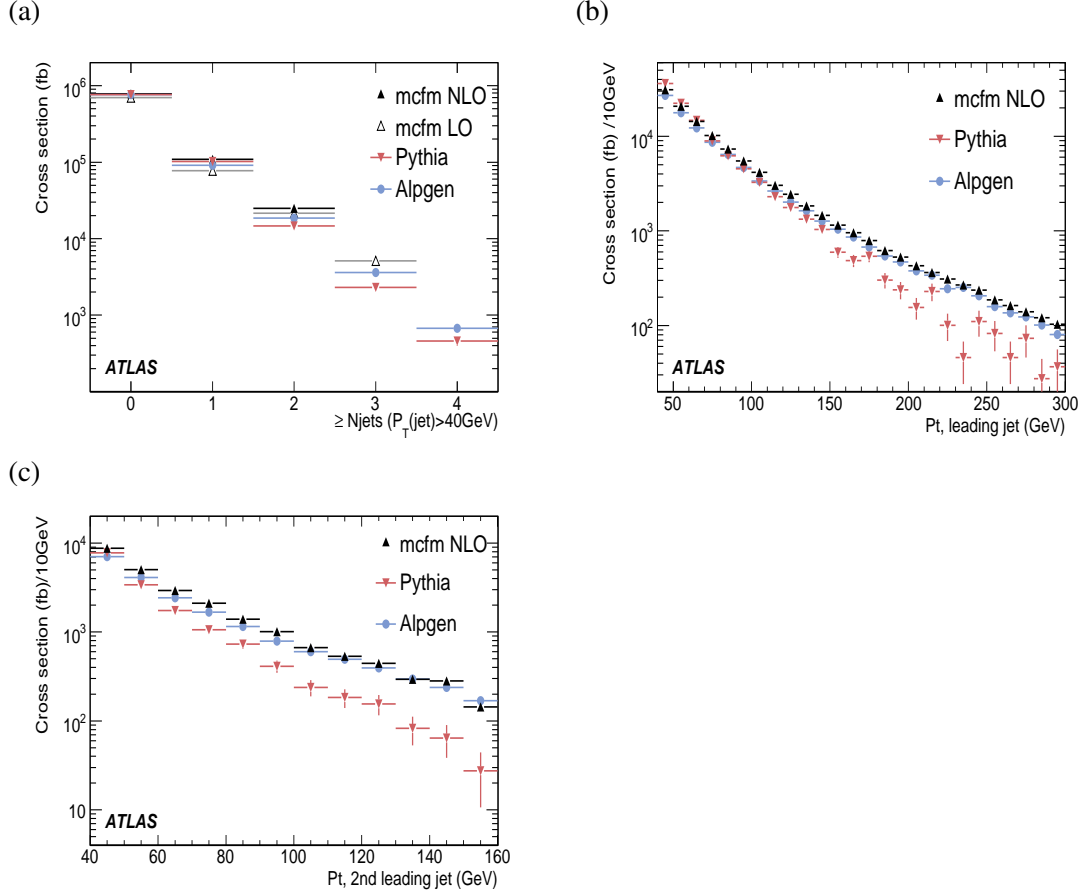

Figure 3: Comparison of the inclusive jet cross-section (a) and the  $p_T$  of the leading jet (b) and of the next-to-leading jet (c) for the  $Z \rightarrow \mu^+ \mu^- + \text{jets}$  channel from PYTHIA and ALPGEN Monte Carlo with NLO (LO) MCFM predictions. The MCFM predictions have been corrected to the hadron level.

even NLO MCFM for low jet  $p_T$ . But, while the shape of the jet  $p_T$  distribution predicted by ALPGEN agrees well with the NLO MCFM prediction, PYTHIA generates a clearly softer  $p_T$  spectrum, as expected.

#### 4.4.2 Statistical and Systematic Errors

In order to determine the expected precision of the analysis, the cross-section measurement is performed on the fully-simulated ALPGEN  $Z + \text{jets}$  data sets, which are corrected to the hadron level, following the prescription of Section 4.3. Systematic errors from the corrections are included. In the next step we evaluate the impact of the uncertainties expected for real ATLAS data taking. ATLAS expects a limited precision of the jet energy scale in the first years, starting from uncertainties at the level of 10% and converging eventually towards 1%. We obtain two benchmark scenarios by propagating jet energy scale uncertainties of 5% and 10% into the measured cross-sections. Several backgrounds will be estimated with data-driven methods, introducing additional systematic errors. We account for that in a first approach by adding an error of 20% on the fraction of the multi-jet background for each

jet multiplicity. The statistical uncertainties in the samples are scaled to the number of events expected to be selected for an integrated luminosity of  $1 \text{ fb}^{-1}$ .

Figure 4 compares, for the  $Z \rightarrow e^+e^- + \text{jets}$  channel, the inclusive jet multiplicity (a) and the  $p_T$  of the leading jet (b) for MCFM and the fully-simulated corrected ALPGEN sample. The errors on the MCFM predictions result from the PDF uncertainty and from the errors from the correction for the non-perturbative effects. The errors on the ALPGEN Monte Carlo data include all the statistical and systematic uncertainties described in this section with the jet energy scale uncertainty set to 5%.

An additional systematic uncertainty is introduced on the unfolding correction for the jet resolution due to the uncertainty on the jet resolution measurement and to the uncertainty on the shape of the  $p_T$  distribution which we use to derive the corrections. Using corrections from different event generators and varying the jet resolution within its uncertainty results in a systematic error on the cross section at the percent level.

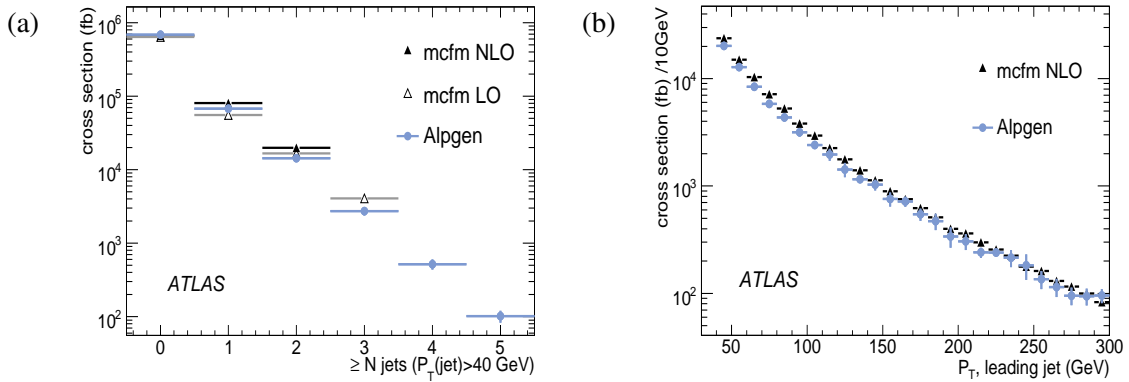

Figure 4: The inclusive jet cross-section (a) and the distribution of the  $p_T$  of the leading jet (b), as predicted by NLO (LO) MCFM (corrected to the hadron-level) and by ALPGEN for the  $Z \rightarrow e^+e^- + \text{jets}$  process.

The uncertainty on the theoretical predictions and on the measured cross section, as shown in Figure 4, are propagated on the data/theory ratio. Figure 5 shows the resulting uncertainty on a ratio of 1 for the inclusive cross-section and for the  $p_T$  of the leading jet. The systematic uncertainty on the inclusive cross-section from a jet energy scale uncertainty of 5% is twice as large as the sum of all the other statistical and systematic uncertainties. In this case, the overall precision on the data/theory ratio expected with the first  $\text{fb}^{-1}$  of data is at the level of 8-15% for topologies with 1-3 jets. A jet energy scale uncertainty of 10% results in the dominant error on the cross-section. In this case, the total uncertainty on the cross section is at the level of 15-30%, which is at the same order as the typical differences expected between LO and NLO predictions, or between predictions from PYTHIA, ALPGEN and MCFM. Statistical limitations become sizable for large jet  $p_T$  ( $\gg 200 \text{ GeV}$ ).

## 5 Conclusions

Final states containing  $Z + \text{jets}$  will serve as one of the Standard Model benchmarks for physics analyses at the LHC. We have simulated cross-section measurements for theoretically well-defined quantities such as the inclusive  $Z + \text{jets}$  cross-section, and the jet transverse momentum for the leading and next-to-leading jets. An unfolding technique from the detector to the hadron level has been

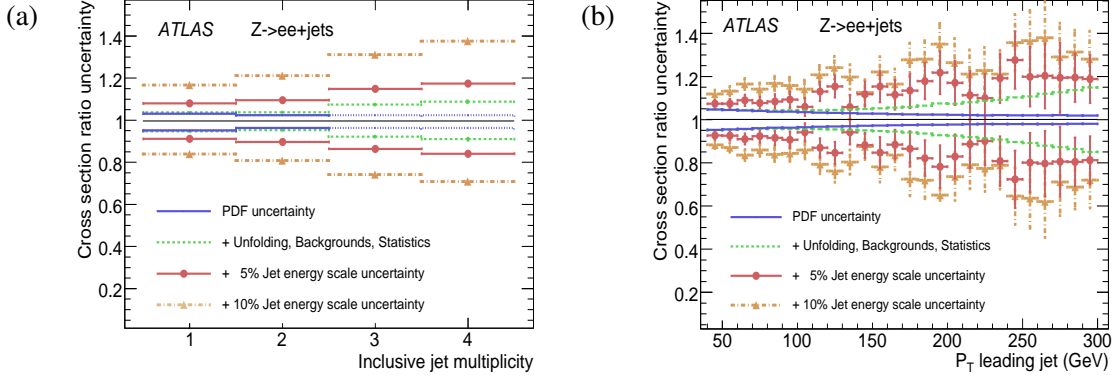

Figure 5: Uncertainty on the ratio of measurement and theory for the inclusive jet cross-section (a) and the  $p_T$  of the leading jet (b) for the  $Z \rightarrow e^+e^- + \text{jets}$  process.

developed, and results are presented at the hadron level. Theoretical corrections from parton to hadron level, necessary for comparisons of data to parton level predictions, are determined.

The main background sources are found to be QCD multi-jet processes for low jet multiplicities and  $t\bar{t}$  for large jet multiplicities and amount to the level of 5-20%, depending on the jet multiplicity. Predictions from the Monte Carlo generators PYTHIA and ALPGEN have been compared with MCFM NLO (LO) calculations. The inclusive cross-section predictions differ by 10-60%, with larger discrepancies for the PYTHIA parton shower prediction (with respect to MCFM and ALPGEN) with increasing jet  $p_T$ . Statistical and systematic uncertainties on the ratio data/theory have been determined. A jet energy scale uncertainty of 5% would be the dominant systematic uncertainty on the measured cross section, resulting in a total uncertainty of 8-15% for final states with 1-3 jets. A jet energy scale uncertainty of 10% results in an overall precision at the level of 15-30% which is at the same order as the typical differences expected between LO and NLO predictions or between predictions from PYTHIA, ALPGEN and MCFM.

# Measurement of the $W$ Boson Mass with Early Data

## Abstract

We present new methods for measuring the  $W$  mass at ATLAS, and show their performance on simulated data. The experimental systematic uncertainties and their impact on the  $m_W$  measurement are evaluated, with samples downscaled to  $15 \text{ pb}^{-1}$ . The electron transverse momentum analysis yields a precision of  $\delta m_W = 120(\text{stat}) \oplus 117(\text{syst}) \text{ MeV}$ . The systematic uncertainty is dominated by the energy scale. In the muon channel, the transverse mass analysis gives  $\delta m_W = 57(\text{stat}) \oplus 231(\text{syst}) \text{ MeV}$ , where the dominant contribution comes from the recoil calibration. PDF uncertainties contribute  $\delta m_W = 25 \text{ MeV}$ . Other theoretical uncertainties were not explicitly considered, but expected to be small in comparison to experimental uncertainties in early  $m_W$  measurements.

## 1 Introduction to the $W$ mass measurement at the LHC

The mass of the  $W$  boson is currently measured to be  $m_W = 80.399 \pm 0.025 \text{ GeV}$  [1]. Since the  $W$  boson mass and the top quark mass are the largest sources of uncertainty in the indirect determination of the Higgs boson mass, improved precision is desirable. The expected total inclusive  $W$  cross section at the LHC is about  $20.5 \text{ nb}$  for each lepton channel [2]. In  $10 \text{ fb}^{-1}$  of data, around  $30 \times 10^6$   $W$  events will be selected in each leptonic decay channel ( $W \rightarrow e\nu, \mu\nu$ ), providing a combined statistical sensitivity of about  $2 \text{ MeV}$ . Systematic errors will need to be controlled to comparable precision.

The present note is however concerned with the early ATLAS data ( $\mathcal{L} \sim 10 - 20 \text{ pb}^{-1}$ ), with an expected statistical precision of about  $100 \text{ MeV}$ . In this context, the main sources of systematic uncertainty are of experimental origin (energy and momentum scales, resolution, efficiency). Other sources, related to the theoretical description of  $W$  production, play a less significant role.

The aim of the following is to establish an unbiased  $W$  mass fit with templates, demonstrate that using  $Z$  events for calibration is valid, and show that the experimental sources of systematic uncertainties can be controlled to the level of the statistical sensitivity. In doing so, we test the readiness for the  $W$  mass measurement in the first years of data taking.

This note is structured as follows. First a general discussion in Section 2 gives the outline of the analysis, the ingredients involved in a  $W$  mass measurement, and the challenges in controlling them. Template based  $W$  mass fits are presented in Sections 3 to 5, exploiting the electron and muon channels. In a first step, all ingredients entering the templates are supposed perfectly known. We then evaluate the dependence of the fit results on each of them. Section 6 describes the calibration of the absolute lepton energy scale and resolution using  $Z$  decays. This section also discusses the effect of the lepton reconstruction efficiencies. Background uncertainties are treated in Section 7. Section 8 quantifies residual systematic uncertainties after *in situ* calibration. Finally, Section 9 summarizes the analysis and concludes.

## 2 Outline and strategy of the analysis

### 2.1 Simulation and data sets

The simulated  $W$  and  $Z$  samples on which this note is based are generated using the PYTHIA event generator [3]. Photon radiation is carried out by PHOTOS [4], and  $\tau$  decays are handled by TAUOLA [5]. Detector simulation is done using GEANT4 version 4.0 [6], and reconstruction with Athena version 12.0.6. These fully simulated events are reconstructed using the ATLAS software, and used as real data (“pseudo-data”). For the production of templates, we use the generator-level information only, together with estimated detector smearing corrections. Simulated statistics of our main signal samples are shown in Table 1. Our  $W$  signal samples correspond to roughly  $15 \text{ pb}^{-1}$ . In the following, all results will be normalized to this luminosity, i.e. downscaling results from the larger  $Z$  samples.

Channel	Nb. of events	Cross section [pb]	$\varepsilon$ of filter	Corresponding $\mathcal{L}$ [ $\text{pb}^{-1}$ ]
$W \rightarrow e\nu$	170143	20510	0.624	13.3
$W \rightarrow \mu\nu$	189903	20510	0.686	13.5
$Z \rightarrow ee$	377745	2015	0.857	218.7
$Z \rightarrow \mu\mu$	150650	2015	0.896	83.4

Table 1: Number of events, cross sections (at NNLO [2]), and corresponding luminosity of the simulated  $W$  and  $Z$  signal samples used in the analysis.

### 2.2 Event selection

Since the dijet cross section at hadron colliders is several orders of magnitude larger than the  $W$  boson cross section, the hadronic decay modes of  $W$  and  $Z$  bosons are not usable. Therefore, only the leptonic decay modes  $W \rightarrow \ell\nu$  and  $Z \rightarrow \ell\ell$  ( $\ell = e, \mu$ ) are considered. While the  $W$  and  $Z$  bosons are produced with a small transverse momentum on average (see Figure 2(a)), their longitudinal boost can be large. However, this boost leaves the lepton transverse momenta unchanged, which subsequently is a good distribution to study  $W$  boson decays.

$W$  events are required to have one isolated lepton with  $p_T$  above 20 GeV and missing transverse energy ( $\cancel{E}_T$ ) in excess of 20 GeV.  $Z$  events are required to have two isolated leptons with  $p_T$  above 20 GeV of opposite charge (see Figure 1). The triggers providing these events are an isolated 15 GeV electron trigger and a 20 GeV muon trigger. The electrons are required to pass tight identification criterion [7], and only combined muons (with reconstructed tracks in both the inner detector and the muon spectrometer [8]) are used. Both electrons and muons are required to lie within the tracking range  $|\eta| < 2.5$  (see Figure 2(b)). In addition, the calorimeter barrel-endcap transition range  $1.3 < |\eta| < 1.6$  is excluded for electrons.

In addition to this basic selection, some other requirements apply. To reject backgrounds from jet and  $t\bar{t}$  events, the signal events are required not to have large hadronic transverse activity. A summary of the requirements can be found in Table 2.

The expected numbers of events in  $15 \text{ pb}^{-1}$  from the above mentioned event selection are summarized in Table 3. Though the expected number of reconstructed  $Z$  events is an order of magnitude smaller

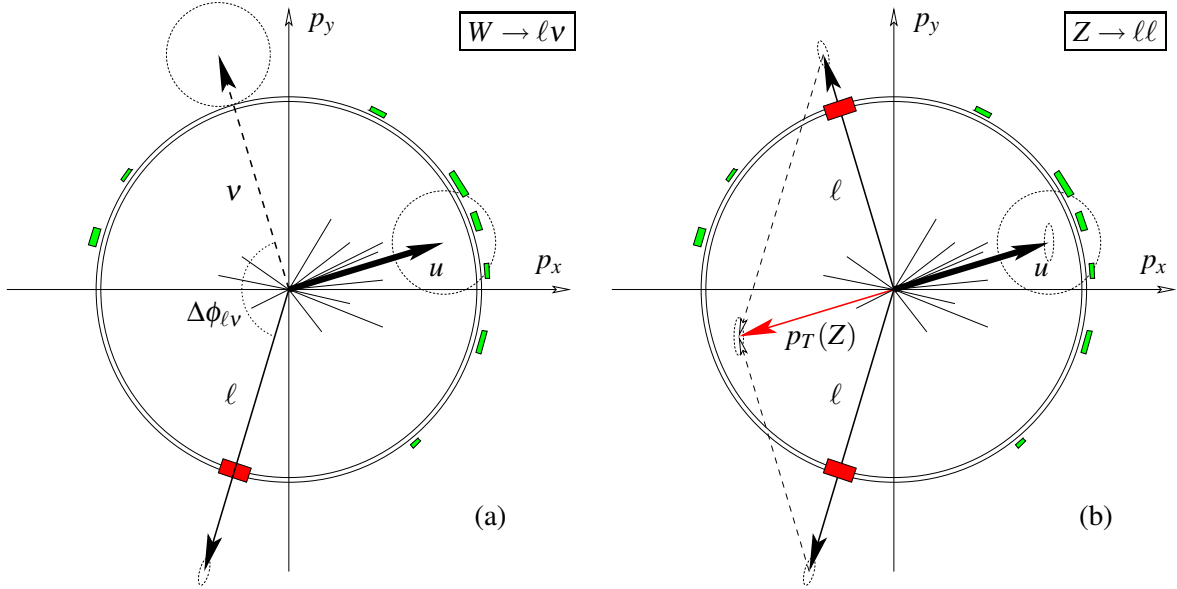

Figure 1: Transverse view of a  $W \rightarrow \ell \nu$  (a) and a  $Z \rightarrow \ell \ell$  (b) event. The combined transverse momentum of the recoil  $u$ , which should match that of the boson, is used to estimate the momentum of the undetected neutrino in the  $W \rightarrow \ell \nu$  decay. The dotted ellipses represent the uncertainties.

Requirement	$W \rightarrow e \nu$	$W \rightarrow \mu \nu$
Reconstructed lepton	$p_T > 20 \text{ GeV},  \eta  < 2.5$	$p_T > 20 \text{ GeV},  \eta  < 2.5$
Isolation	$E_T^{\text{cone}}/E_T < 0.2$	
Missing energy	$\cancel{E}_T > 20 \text{ GeV}$	$\cancel{E}_T > 20 \text{ GeV}$
Crack region	Remove $1.30 <  \eta  < 1.60$	
Recoil momentum	$p_T < 50 \text{ GeV}$	
Requirement	$Z \rightarrow ee$	$Z \rightarrow \mu\mu$
Reconstructed leptons	$p_T > 20 \text{ GeV},  \eta  < 2.5$	$p_T > 20 \text{ GeV},  \eta  < 2.5$
Isolation	$E_T^{\text{cone}}/E_T < 0.2$	
Crack region	Remove $1.30 <  \eta  < 1.60$	
Recoil momentum	$p_T < 50 \text{ GeV}$	

Table 2: Selection criteria for the  $W$  and  $Z$  decays. See text for details.

Figure 2: (a) Reconstructed transverse momentum of  $W$  and  $Z$  bosons. The larger resolution in the  $W$  events causes the wider peak at low  $p_T$ , while at higher  $p_T$  the  $Z$  spectrum slightly dominates. (b) Distribution in  $\eta$  of reconstructed muons from  $W$  and  $Z$  events.

than that of  $W$  events, the fact that  $Z$  events are fully reconstructed and thus have much better mass resolution compensates for this deficit.

Channel	$W \rightarrow e\nu$	$W \rightarrow \mu\nu$	$Z \rightarrow ee$	$Z \rightarrow \mu\mu$
Detector acceptance [%]	44.3	45.4	42.4	39.9
Reconstruction efficiency [%]	21.7	39.1	10.4	33.4
Nb. of events for $15 \text{ pb}^{-1}$ [ $10^3$ events]	66.7	120.2	3.2	10.1

Table 3: Acceptances, total reconstruction efficiencies, and resulting statistics for  $15 \text{ pb}^{-1}$  of data. The  $W$  cross sections are inclusive, while the  $Z$  cross sections are for invariant masses above 60 GeV. Both are at NNLO and contain the relevant branching fractions. The acceptance is the fraction of events which lies within the detector acceptance, while the total reconstruction efficiency is the overall efficiency for an event to pass all selection criteria including the acceptance.

### 2.3 Input to $W$ mass fit

While the  $Z$  decay can be fully reconstructed, and its mass calculated from the invariant mass of the decay leptons, this is not the case for  $W$  decays, where the neutrino goes undetected. From the momentum imbalance one can infer the missing energy, but with limited precision and only in the transverse direction. This means that the invariant mass can not be determined, and one is forced to consider other variables sensitive to the  $W$  mass. In principle there are three sensitive variables:

- The lepton transverse momentum,  $p_T^\ell$ .
- The missing transverse momentum,  $p_T^\nu \equiv \cancel{E}_T$ .
- The  $W$  transverse mass, defined as:  $m_T^W \equiv \sqrt{2p_T^\ell p_T^\nu (1 - \cos(\phi^\ell - \phi^\nu))}$ .

The lepton transverse momentum is measured with an accuracy of about 2% for electrons and muons [7, 8] in the momentum range of interest (see Section 6.2). This is an order of magnitude better com-

pared to the accuracy of the missing transverse energy determination, which has a resolution of about 20-30% [9]. Finally, the  $W$  transverse mass combines the two momenta along with the azimuthal angle between them.

All of the above distributions have a Jacobian peak either at  $m_W/2$  ( $p_T^\ell$  and  $p_T^W$ ) or  $m_W$  ( $m_T^W$ ), which is sensitive to the  $W$  mass. The sharpness of the peak is affected both by the resolution and the boson  $p_T$ . While the lepton  $p_T$  has a very good resolution, the  $p_T$  of the boson smears this Jacobian edge. On the contrary,  $m_T^W$  is to first order insensitive to the  $p_T$  of the boson, but here the edge is smeared by the poor resolution of the missing transverse energy (see Figure 3). Finally,  $p_T^W$  suffers from both effects, and is therefore the poorest candidate for a fitting variable. Since  $m_T^W$  is formed from  $p_T^\ell$  and  $p_T^W$ , it is of course statistically correlated with  $p_T^\ell$ . However, the statistical correlation between  $m_T^W$  and  $p_T^\ell$  is only about 30%, and since they have different systematic errors, combining the measurements based on these observables could improve the sensitivity.

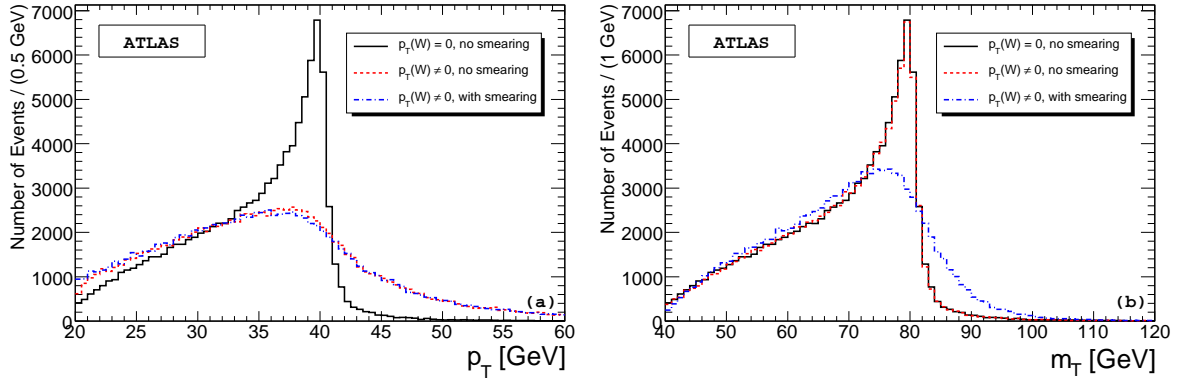

Figure 3: Fitted distributions of  $p_T^\ell$  (a) and  $m_T^W$  (b), showing the Jacobian peak, and the effects of finite detector resolution (i.e. smearing) and recoil (i.e.  $p_T$  of the  $W$ ). While  $p_T^\ell$  is more sensitive to the recoil than to the resolution, the converse is true for the  $m_T^W$  distribution.

## 2.4 Fitting the $W$ mass with templates

The lepton transverse momentum and  $W$  transverse mass distributions,  $p_T^\ell$  and  $m_T^W$ , shown in Figure 3, are the result of several non trivial effects. For this reason no analytical expression describes the distributions in detail, and one is forced to use numerical methods. One method for fitting these distributions is template fitting [10, 11]. Templates of the  $p_T^\ell$  and  $m_T^W$  distributions are produced with varying  $m_W$  values, and compared to the corresponding distribution observed in data (see Figure 6). The comparison is based on a binned  $\chi^2$  method.

To estimate the impact of a given effect on the  $W$  mass determination, templates unaware of the effect under consideration are produced and subsequently fitted to data, which includes this effect. Assuming an unbiased fit, when the effect is not included in the data (see Sections 3 and 4), the resulting shift in fit value measures the systematic error on the  $W$  mass from not including the effect. By gradually changing the size of an effect, the systematic error on the  $W$  mass as a function of this effect can be determined. As most effects are small, the dependencies are approximately linear. They are in general

different for the  $p_T^\ell$  and  $m_T^W$  fits. If an effect can be characterized by one parameter  $a$ , the systematic errors ( $\delta m_W$ ) can be calculated from the derivative  $\partial m_W / \partial a$  times the size of the uncertainty  $\delta a$ . If more parameters are required, the systematic uncertainty is calculated from all parameters  $a_i$  and their covariances  $\text{Cov}_{i,j}$ .

$$\delta m_W = \frac{\partial m_W}{\partial a} \delta a \quad (\text{Single parameter}) \qquad \delta m_W^2 = \sum_{i,j} \frac{\partial m_W}{\partial a_i} \frac{\partial m_W}{\partial a_j} \text{Cov}_{i,j} \quad (\text{Multi parameter})$$

In the following, the  $\delta a$  are to be understood as relative uncertainties, and the derivatives are with respect to these relative uncertainties. Our results for  $\partial m_W / \partial a$  are normalized in MeV/%.

## 2.5 Calibration procedure

The calibration of the absolute energy/momentum<sup>1</sup> lepton scale plays a central role, as it is the largest systematic uncertainty and the starting point of all other calibrations.

### 2.5.1 Average calibration

To first order, a single average lepton scale factor, defined as  $\alpha_E = E_{\text{rec}} / E_{\text{true}}$ , independently of  $\eta$  and  $p_T$ , can be obtained by demanding that the reconstructed  $Z$  peak matches its known mass. While this assures the correct lepton scale and resolution for  $Z$  events, the energy scale obtained in this way might not apply to  $W$  events. Because of non linearities and non uniformities, the different  $p_T$  and  $\eta$  distributions in  $W$  and  $Z$  events can possibly introduce significant bias.

### 2.5.2 Differential calibration

If needed, an upgrade to a differential calibration can be performed, which contrary to the average calibration includes variations of scale and resolution with energy/momentum,  $\eta$ , and/or  $\phi$ . The three key ingredients to such a calibration are the precise knowledge of the  $Z$  mass, width, and decay kinematics, the non zero transverse momentum of the  $Z$  bosons, and the very large sample of  $Z$  bosons produced at the LHC.

The calibration uses a large sample of reconstructed  $Z \rightarrow \ell\ell$  events along with corresponding templates, representing our knowledge of the  $Z$  lineshape, which we assume known. Through a comparison of the two in bins of the variables of interest (lepton  $p_T$ ,  $\eta$ , and  $\phi$ ) one can extract the scale and resolution in each of these bins [12].

Once the absolute scale is set for the leptons, the hadronic recoil scale can be determined by comparing it to the transverse momentum of the leptons from the  $Z$ . Again, this calibration can be done differentially, measuring the missing momentum response as a function of  $p_T(Z)$ , the recoil size, and the hadronic transverse activity ( $\sum E_T^{\text{hadrons}}$ ). While this calibration is naturally not as accurate as that of the lepton scale, due to the poorer resolution of the hadronic recoil, it fortunately turns out that the mass fit is less sensitive to the recoil scale (see Section 4.3).

<sup>1</sup>These two terms cover the same aspect, but will generally be used about electrons and muons, respectively. Angular uncertainties are omitted throughout this note, as they play an insignificant role.

### 2.5.3 Efficiency determination

The efficiency is determined using the “tag and probe” methods [13], again applied to  $Z \rightarrow \ell\ell$  events. The different spectra in  $W$  and  $Z$  events is accounted for by determining the efficiency as a function of  $p_T$  and  $\eta$ , which has been found to yield efficiencies compatible between  $W$  and  $Z$  [7, 8].

The following sections attempts to quantify the above outline.

## 3 Fitting the $W$ mass with templates - electron channel

### 3.1 Modelling templates for $W$ mass fit

As no analytical expression matches the lepton transverse momentum and  $W$  transverse mass distributions  $p_T^\ell$  and  $m_T^W$ , we fit the  $W$  mass using the template method (see Section 2.4). For the templates of varying  $W$  mass to match the measured distribution well, all effects influencing these distributions must be included when producing the templates. The principle influences are scale, resolution, non gaussian tails, efficiency and background effects, which are (with the exception of background) primarily obtained from the similar but more constrained  $Z \rightarrow \ell\ell$  events, as discussed in Section 6.

Two assumptions have to be validated first, namely the lack of bias of the fit in itself, and the portability of the calibration from the  $Z$  to the  $W$ . The lack of bias is tested by assuming perfectly known physics and detector response. In practice, the detector response is determined at this stage from direct comparisons of the lepton reconstruction to the generator level kinematics, using the  $W$  sample that is used in the mass fits. Then the fit is repeated using templates with the detector response estimated from the  $Z$  sample, still comparing reconstructed to simulated kinematics. An unbiased result validates the portability, i.e. that detector parameters can indeed be ported from  $Z$  to  $W$  events, justifying an *in situ* determination of these parameters using  $Z$  events.

In addition it has to be tested that the template components can be included without biasing the fit, and thus that a subsequent calibration, which matches the truth, will yield unbiased templates. This is tested in the following. The statistical sensitivity of our  $W \rightarrow e\nu$  sample, corresponding to  $15 \text{ pb}^{-1}$  of data, is about 120 MeV, and we provide an estimate of the required precision on the detector response parameters to keep the systematic uncertainty within this limit.

### 3.2 Fits to $m_W$ using templates: Validation of the method

In this section, the detector parameters are determined from fits to  $E_{\text{rec}}/E_{\text{true}}$ , the ratio of reconstructed to true energy of the decay electrons. The fits are done using the so-called “Crystal Ball” PDF [14], which aims at describing the result of calorimetric resolution together with upstream energy loss in a single function. It has four parameters and displays a gaussian core, and a power-law tail at low energy. Its expression is, up to normalization factors:

$$CB(x) = \begin{cases} e^{-\left(\frac{x-\alpha_E}{\sigma_E}\right)^2}, & x > \alpha_E - n\sigma_E \\ (\beta/n - |n| - x)^{-\beta}, & x < \alpha_E - n\sigma_E \end{cases} \quad (1)$$

where  $x = E_{\text{rec}}/E_{\text{true}}$ ,  $\alpha_E$  is the position of the peak,  $\sigma_E$  the gaussian width;  $n$  gives, in units of  $\sigma_E$ , the point of transition between the gaussian and power-law descriptions, and  $\beta$  is the exponent controlling the tails. The relative normalization of the two components preserves continuity at  $\alpha_E - n\sigma_E$ , up

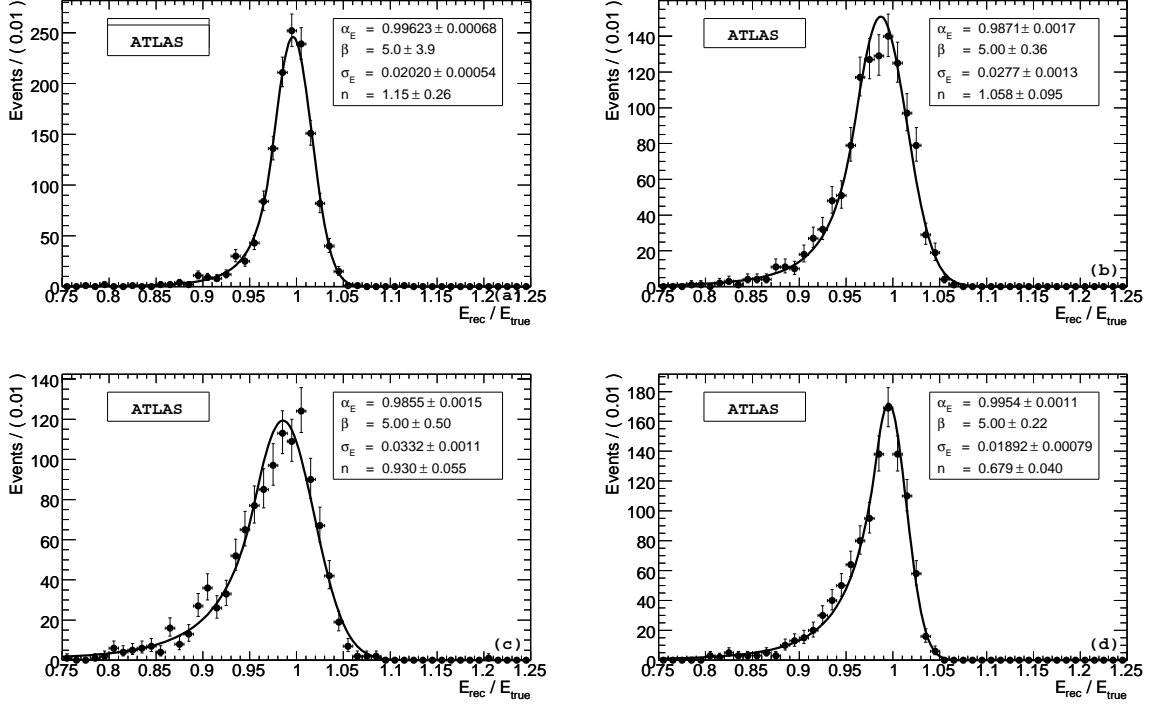

Figure 4: Examples of detector response functions fitted to  $E_{\text{rec}}/E_{\text{true}}$ , for  $30 < p_T^e < 40$  GeV. From upper left to lower right:  $0.4 < |\eta| < 0.5$  (a),  $0.8 < |\eta| < 0.9$  (b),  $1.3 < |\eta| < 1.4$  (c), and  $1.9 < |\eta| < 2.0$  (d).

to the first derivative. While not fully satisfactory from a theoretical point of view (the combination of resolution effects and radiation should in principle be given by a proper convolution), it is very effective in describing the observed response.

The fits are performed vs.  $\eta$  and  $p_T$ . The angular range  $0 < |\eta| < 2.5$  is divided in intervals of size  $\Delta\eta = 0.1$ . In each interval, fits are done for  $10 < p_T < 70$  GeV, in intervals  $\Delta p_T = 10$  GeV. Figure 4 shows a number of examples, at different values of  $\eta$  and  $p_T$ . The  $\eta$  dependence of the parameters, for  $30 < p_T < 40$  GeV, are displayed in Figure 5, where the shaded regions correspond to the excluded  $|\eta|$  region described in Section 2.2.

In our fits the  $\beta$  parameter was constrained to the range  $0 < \beta < 5$ . As the examples in Figure 4 illustrate, the  $\beta$  parameter appears to systematically choose values close to its upper bound, while satisfactory fits are still obtained. Therefore, we fix  $\beta = 5$  in the remaining of the analysis, and treat the response functions in terms of  $\alpha_E$ ,  $\sigma_E$  and  $n$  only. The  $p_T$  spectrum templates are produced from generator level  $W \rightarrow e\nu$  events, where the electrons are smeared using the above function and parameters according to their kinematic variables. Three example template distributions are shown in Figure 6(a), corresponding to three values of  $m_W$ . The number of events used to produce the templates is increased by repeatedly smearing generator level particles. Although this limits the impact of statistical fluctuations in the templates on the result, template fluctuations are still visible. Distributions on Figures 6 are plotted on a wide range to assure that the entire  $p_T$  spectrum is under control. The fitting range

Figure 5:  $\eta$  dependence of  $\alpha_E$  (a),  $\sigma_E$  (b) and  $n$  (c), for  $30 < p_T^e < 40$  GeV. The shaded regions correspond to the excluded  $|\eta|$  region described in the event selection (Section 2.2).

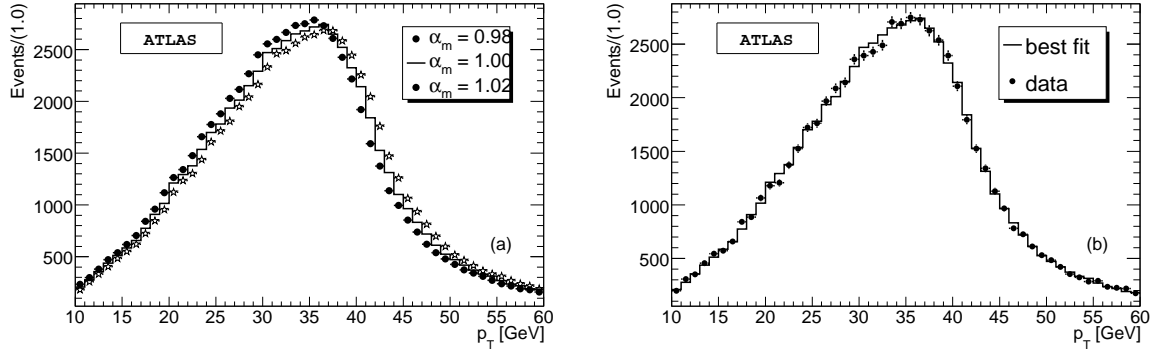

Figure 6: (a) Templates obtained at three example mass points, namely  $\alpha_m = m_W/m_W^{true} = 0.98, 1, 1.02$ . (b) Best fit template (histogram), compared to the pseudo-data (points).

is chosen to be between 30 and 60 GeV to avoid edge effects and to reject backgrounds (see Section 7).

The mass fit is performed using binned  $\chi^2$  comparisons between the pseudo-data and the template histograms. Given that all  $p_T$  bins contain at least several hundred events, the  $\chi^2$  of a given comparison can be defined as:

$$\chi^2 = \sum_{i=1}^N \frac{(n_{i,data} - n_{i,template})^2}{\sigma_{i,data}^2 + \sigma_{i,template}^2}, \quad (2)$$

where the sum is over the histogram bins, and  $n$  and  $\sigma$  are the bin contents and their errors, respectively. Computed as a function of  $\alpha_m = m_W/m_W^{true}$ , the  $\chi^2$  follows the parabola illustrated in Figure 7, which can be used to determine the  $m_W^{fit}$  and its error. The obtained parabola is satisfactory despite the fluctuations of the  $\chi^2$  points with respect to the fitted curve, which are due to the finite statistics of the templates. We obtain  $m_W^{fit} = 80.468 \pm 0.117$  GeV, to be compared to the input value  $m_W^{true} = 80.405$  GeV. The best fit template is shown in Figure 6(b). The stability of this result is verified by repeating this exercise a number of times, with the detector smearing applied independently

Figure 7:  $\chi^2$  vs.  $\alpha_m = m_W / m_W^{true}$ , for the comparisons of pseudo-data and templates described in the text.

in each exercise (i.e, producing independent sets of templates). The distribution of  $m_W^{fit}$  has a spread well compatible with the estimated fit uncertainty.

We thus conclude that within the statistical sensitivity of the  $W \rightarrow e\nu$  sample, the current procedure provides an unbiased estimate of  $m_W$ . We now proceed to relax our main assumptions and quantify the dependence of the fit on the detector response parameters.

### 3.3 Sensitivity of $m_W^{fit}$ to the template components

This section quantifies the stability of  $m_W^{fit}$  under variations of the assumptions used to produce the templates. As stated earlier, we leave phenomenological considerations aside and concentrate on experimental effects. We study explicitly the effect of non gaussian tails in the detector response function, reconstruction and identification efficiency, and backgrounds. The dependence of  $m_W^{fit}$  on the detector scale and resolution was studied in [15], and reviewed here. The bias  $\delta m_W = m_W^{fit} - m_W$  as a function of the fractional error on the lepton scale ( $\alpha_E$ ) and resolution ( $\sigma_E$ ) is found to be:

$$\partial m_W / \partial \alpha_E = 800 \text{ MeV}/\%, \quad \partial m_W / \partial \sigma_E = 0.8 \text{ MeV}/\%. \quad (3)$$

The impact of non gaussian tails is studied as follows. Starting from the detector response parametrization described in Section 3.2, we suppress the tails of the distribution and assume a pure gaussian response. The parameters describing scale and resolution are kept to their previous value. We then produce templates and perform the fit as above. The procedure is illustrated in Figure 8. The response distribution can be compared to Figure 4 to assess the impact of neglecting the non gaussian part of the distribution. As can be seen, the corresponding templates are biased towards higher  $p_T$ ; we thus anticipate, as otherwise expected, that an underestimation of the tails should imply a negative  $\delta m_W$ .

We obtain a bias  $\delta m_W = -555 \text{ MeV}$ , corresponding to an underestimation of the non gaussian tails by 100%. Denoting  $\tau$  the non gaussian fraction of the response function, we thus estimate the bias as a function of the relative error on the tails as:

$$\partial m_W / \partial \tau = -5.5 \text{ MeV}/\%. \quad (4)$$

Figure 8: (a) Response function at  $0.2 < \eta < 0.3$ ,  $20 < p_T < 30$  GeV, removing the non gaussian part of the distribution. (b) Pseudo-data (points), compared to templates produced assuming  $m_W = m_W^{\text{true}}$ , with non gaussian tails included (full line) or not (dashed line).

Figure 9: Electron reconstruction efficiency as a function of  $p_T$ , for different regions in  $\eta$ .

Distortions in the  $p_T$  distribution can also be caused by the lepton reconstruction efficiency, as soon as it has a non trivial  $p_T$  dependence, i.e.  $\varepsilon_\ell = \varepsilon_\ell(p_T)$ . This is the case in the electron channel, as illustrated in Figure 9.

As above, we quantify the impact of this  $p_T$  dependence by taking the pseudo-data as they are, but assuming a flat efficiency in the templates. Since  $\varepsilon_\ell(p_T)$  is an increasing function of  $p_T$ , we expect that the templates will be biased towards lower  $p_T$  values, inducing a positive shift in  $m_W^{\text{fit}}$ . Performing the mass fit indeed yields  $\delta m_W = 360$  MeV (this bias corresponds to a perfectly flat efficiency assumption). We estimate the bias per percent relative error on the  $p_T$  dependence of  $\varepsilon_\ell$  to be:

$$\partial m_W / \partial \varepsilon_\ell = 3.6 \text{ MeV} / \%. \quad (5)$$

Note that the present analysis only relies on the  $p_T$  dependence of  $\varepsilon_\ell$  and not on its absolute value.

Figure 10: Ratio of the fitted values of  $\alpha_E$ ,  $\sigma_E$  and  $n$ , between  $W$  and  $Z$  events. Each histogram represents the  $\eta$  dependence of the parameter  $\alpha_E$  (a),  $\sigma_E$  (b) and  $n$  (c), for  $30 < p_T^e < 40$  GeV.

### 3.4 Comparison of $W$ and $Z$ events

Before explicitly calibrating detector parameters from  $Z$  events and applying them in the  $m_W$  fit, we verify that this procedure is indeed justified. To this end, we perform the detector response fits as described in Section 3.2 on our  $Z \rightarrow ee$  sample, obtaining a map of the response parameters  $\alpha_E$ ,  $\sigma_E$  and  $n$  as a function of  $\eta$  and  $p_T$  of the electrons.

A first check is to compare the obtained values to those extracted from the  $W$  sample. This is illustrated in Figure 10. For all parameters, agreement is found within the statistical sensitivity throughout the analysed electron phase space, except for the resolution parameter in the shaded  $\eta$  region, excluded in the study as explained in Section 2.2. We thus expect that templates produced using detector response to  $Z$  events will provide an adequate description of  $W$  events.

A  $m_W$  fit is performed next. Templates are produced from generator level  $W \rightarrow e\nu$  events, smeared according to detector performance found on  $Z$  events. The resulting distributions are shown in Figure 11(a) together with their ratio in Figure 11(b); good agreement is observed. Fitted with a straight line, Figure 11(b) shows a slope of  $(3 \pm 2) \cdot 10^{-4}$ , compatible with 0, but which yields a small bias towards higher masses. Accordingly, the result of the fit is  $m_W^{fit} = 80.567 \pm 0.118$  GeV, to be compared to  $m_W^{fit} = 80.468 \pm 0.117$  GeV obtained with detector performance found on  $W$  events. The result is compatible with the input value  $m_W^{true} = 80.405$  GeV.

## 4 Fitting the $W$ mass with templates - muon channel

This section repeats the discussion of Section 3 for the muons channel. In addition, a template fit of the  $m_T^W$  distribution is described.

### 4.1 Template fits to the muon transverse momentum

Repeating the analysis from Section 3 for the muon channel yields  $m_W^{fit} = 80.538 \pm 0.106$  GeV, obtained with detector performance found on  $W$  events, and  $m_W^{fit} = 80.508 \pm 0.106$  GeV, with detector

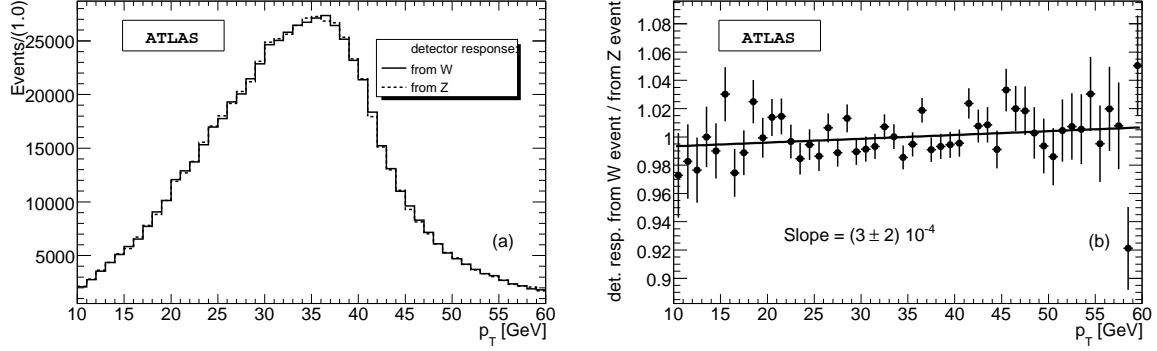

Figure 11: (a) Templates obtained for  $\alpha_m = m_W/m_W^{true} = 1$ , with detector performance obtained from  $W$  events (full line) and from  $Z$  events (dashes). (b) Ratio of the previous histograms, fitted with a straight line.

performance found on  $Z$  events. The differences with the electron channel are described in the following.

The dependence of the template fit on the scale and resolution is the same in the muon channel as in the electron channel. The muon momentum resolution is generally slightly worse, and whereas the electron resolution improves with  $p_T$ , the converse is true for the muon resolution. Figure 12 shows four examples of the momentum ratio distributions  $p_T^{rec}/p_T^{true}$  for muons – two from  $W$  events and two from  $Z$  events. As can be seen, the shapes can be modeled well with a core gaussian distribution describing the general muon bias and resolution complemented by an outlier gaussian distribution accounting for the muons, which are encountering parts of the detector with poor muon spectrometer coverage and increased material, resulting in a slightly degraded resolution.

To check the portability, the fitted constants are again compared between the  $W$  and the  $Z$  events, as can be seen in Figure 13. The correspondance between the fitted parameters is satisfactory. According to Figures 13(b) and 13(d), the resolution parameters are systematically smaller in  $W$  events. The difference between the resolutions in  $W$  and  $Z$  events averaged over  $\eta$  is 3.6%, which combined to Eq. 3 leads to a bias of 3 MeV. As will be seen in Section 6, this bias can be neglected given the precision of the *in situ* scale and resolution determination.

Unlike the electron case, the muon reconstruction efficiency does not vary significantly over the momentum range of interest. As can be seen from Figure 14, the efficiency is quite constant above 10 GeV, varying only slightly between barrel ( $\epsilon = 95.8\%$ ) and endcap ( $\epsilon = 94.3\%$ ) region, due to increase in material. As the reconstructed muons are required to have a momentum above 20 GeV, the efficiency is essentially constant.

The flatness of the efficiency is not expected to change until at several hundred GeV, where radiative losses grow larger than those due to ionization [1]. Using the “tag-and-probe” method, the hypothesis of a flat muon efficiency will be tested. The uncertainty in the linear fit translates for  $15 \text{ pb}^{-1}$  into a systematic error of 16 MeV, which is much less than in the electron channel, as expected.

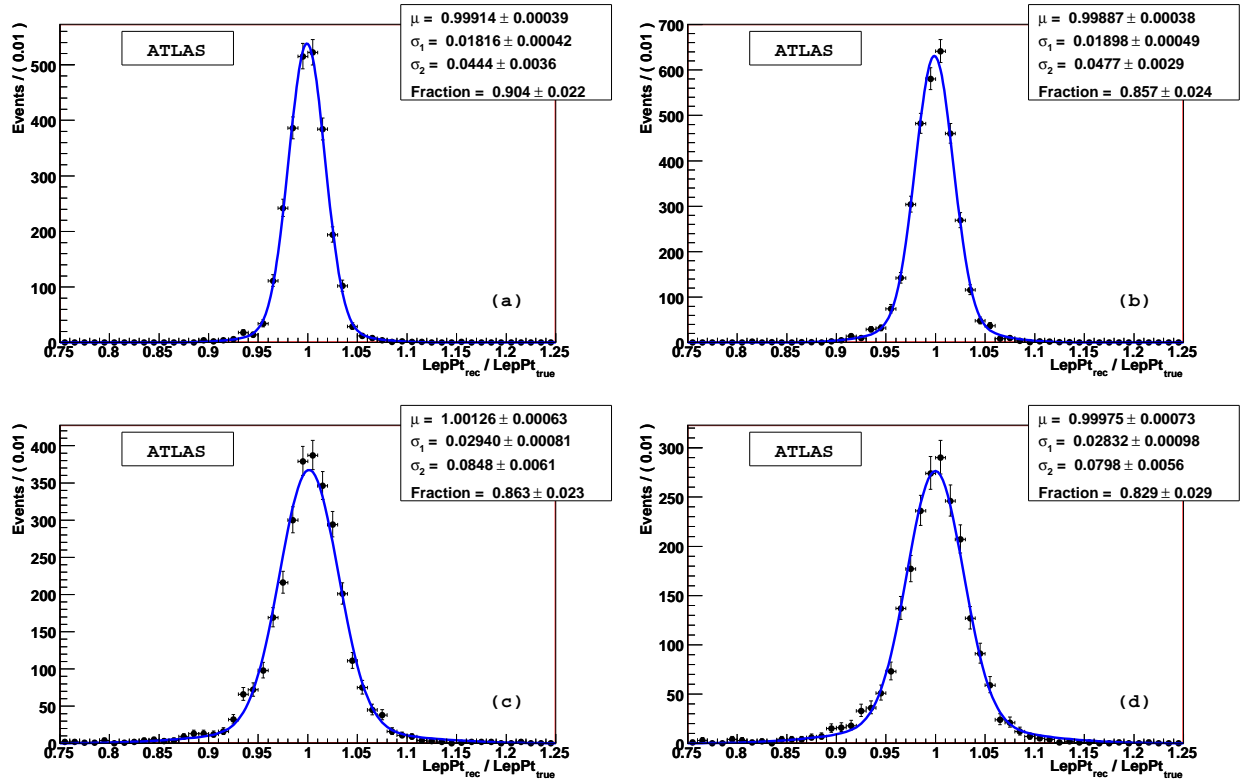

Figure 12: Distributions of transverse momentum ratios  $p_T^{\text{rec}} / p_T^{\text{true}}$  for muons from  $W$  ((a) and (c)) and  $Z$  ((b) and (d)) decays at  $|\eta| < 0.36$  ((a) and (b)) and  $1.79 < |\eta| < 2.14$  ((c) and (d)) in the momentum range 35-40 GeV.

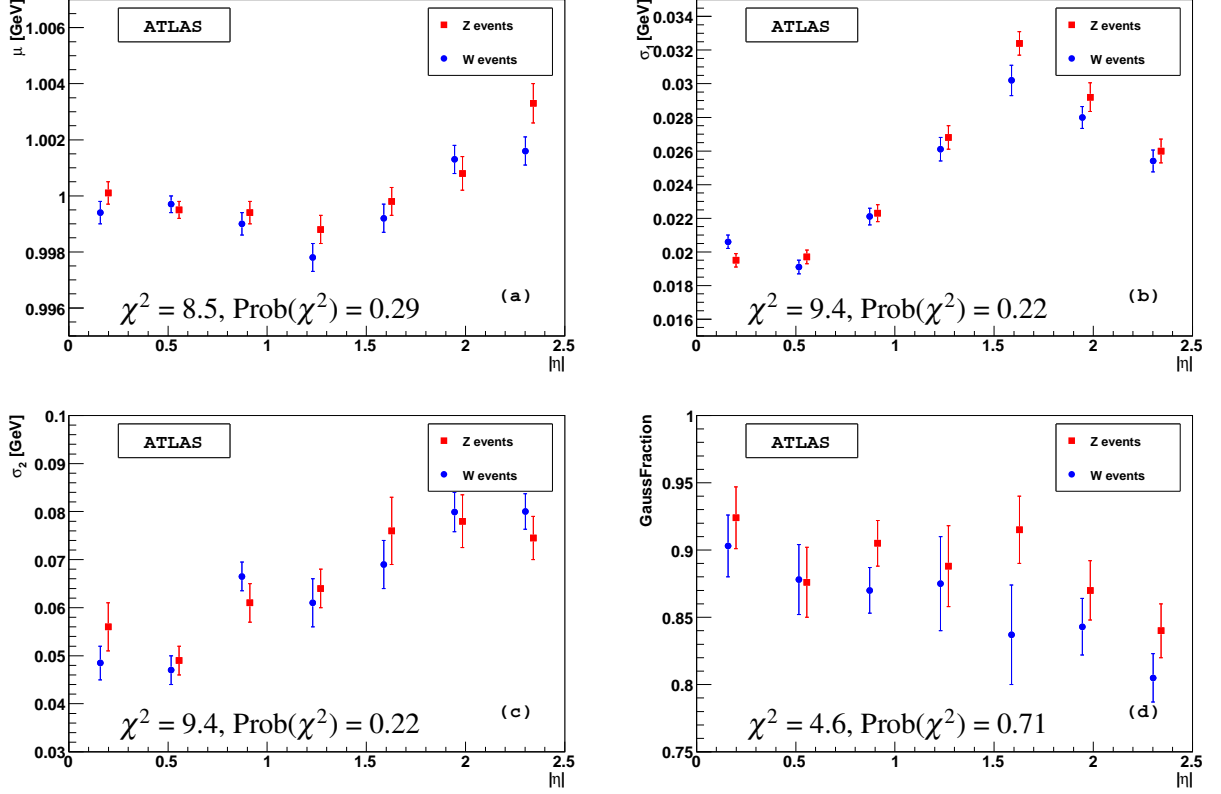

Figure 13: Comparison of fitted mean (a), core resolution (b), outlier resolution (c), and outlier fraction (d) between  $W$  (circles) and  $Z$  (squares) events for muons in the momentum range  $30 < p_T < 35$  GeV in seven bins of  $|\eta|$ . The markers have been artificially shifted, left ( $W$ ) and right ( $Z$ ), in  $|\eta|$  to increase readability.

Figure 14: (a) Muon efficiency as a function of  $p_T$  for  $W$  (circles) and  $Z$  (squares) events. Insert shows a zoomed view on the range of interest along with a constant fit to each of the graphs. The hypothesis of a flat probability in the range 10-70 GeV has been tested to be valid. (b) Muon efficiency ratio between  $W$  and  $Z$  events. No  $p_T$  dependence is seen, and a linear fit yields a slope of  $(6.3 \pm 6.5) \times 10^{-5}$ , consistent with zero.

## 4.2 Fitting the transverse $W$ mass

Having tested the template fitting of the  $p_T^\ell$  distribution, we now move to the  $m_T^W$  distribution. In addition to the lepton residuals, this fit requires residuals for the missing momentum. Since the missing momentum is a transverse quantity, it does not depend on the  $\eta$  of the lepton(s) in the event. However, the detector response depends on the total transverse hadronic activity  $\Sigma E_T$  and the recoil momentum perpendicular to the direction of the leptons (cf. Figure 1).

To describe the response,  $\Sigma E_T$  is divided in 10 bins in the range [0,200] GeV and recoil momentum into 10 bins in the range [0,40] GeV, each with an additional overflow bin. In each bin, the distributions are well described by two gaussian distributions with a common mean, as the missing momentum residuals are not expected to have any asymmetric tails.

To study the response, it is useful to project the  $\cancel{E}_T$  momentum components onto two axes, defined event by event in the transverse plane. The parallel axis is defined such that the azimuthal angles between the leptons ( $\ell$  and  $\nu$ ) and this axis are minimized and equal, and the perpendicular axis is defined as perpendicular to the parallel axis. This reference system adapts better to the individual event topology than fixed axes. Examples of the residual distributions projected on these axes are shown in Figure 15.

Figure 15: Distribution of  $\cancel{E}_T$  residuals  $\cancel{E}_T^{\text{rec}} - \cancel{E}_T^{\text{true}}$  for  $W$  decays. The  $\cancel{E}_T$  momentum components along the parallel (a) and perpendicular (b) axes are shown, for a recoil momentum in the range [8,12] GeV, and  $\Sigma E_T$  in the range [20,30] GeV. The fitting function describes the distributions well.

Using the above modelling of the missing momentum response, we produce  $m_T^W$  templates and test if the fit is unbiased or not. Unlike the lepton case, no additional efficiency curve has to be included, as the missing momentum is calculated for every event. As can be seen from Figure 16, the  $m_T^W$  templates match the reconstructed distribution, and the fit is unbiased, giving a fitted value of  $80.421 \pm 0.059$  GeV compared to an input value of 80.405 GeV.

Figure 16: (a) Reconstructed  $m_T^W$  distribution (middle curve) along with templates produced with the  $W$  mass hypothesis 78.792 GeV (left curve) and 82.008 GeV (right curve), before any kinematic selections. (b)  $\chi^2$  value of fitting templates to the reconstructed distribution as a function of the template's (fraction of)  $W$  mass hypothesis (compared to the nominal mass). The fit yields  $80.421 \pm 0.059$  GeV in agreement with the input value of 80.405 GeV.

#### 4.3 Fitting the transverse $W$ mass using the $Z$ events for calibration

The dependence of the  $m_W^{fit}$  on the relative recoil scale and resolution uncertainty was determined to be [15]:

$$\partial m_W / \partial \alpha_{recoil} = -200 \text{ MeV} / \%, \quad \partial m_W / \partial \sigma_{recoil} = -25 \text{ MeV} / \%. \quad (6)$$

These parameters can again be measured on  $Z$  events. To test the portability from the  $W$  to the  $Z$  of the  $m_T^W$  fit, we model the missing momentum using the  $Z$  events and compare this to the one obtained from the  $W$  events. However, unlike the lepton case, the detector response is not exactly the same for  $W$  and  $Z$  events. The difference is caused by the  $\cancel{E}_T$  reconstruction algorithm, which in its current state does not correctly subtract lepton calorimetric signals from the hadronic recoil. This results in a difference between  $W$  events where only one lepton is present, and  $Z$  events containing two leptons.

To illustrate this point, consider again the parallel and perpendicular axes defined in the previous section. The residuals of the recoil momentum components are projected on both axes, and the response in  $W$  and  $Z$  events is compared, cf. Figure 17. Along the parallel axis, the average difference between the residuals is  $\Delta_{W-Z} = 17 \pm 35$  MeV. Along the perpendicular axis, the difference is larger,  $\Delta_{W-Z} = 1964 \pm 35$  MeV. Using a  $Z$ -based calibration in the  $W$  mass fit is thus expected to be biased; performing this exercise indeed yields  $m_W^{fit} = 79.752 \pm 0.062$  GeV compared to the input value of 80.405 GeV. The  $Z$  based recoil calibration is thus not exploitable at present.

Instead, we assume that the needed improvements to the  $\cancel{E}_T$  reconstruction algorithm will be done in time for the measurement, providing equal response between  $W$  and  $Z$  events. The statistical sensitivity based on the  $Z$ -based calibration is about 50 MeV for  $15 \text{ pb}^{-1}$ , serving as a lower bound. Given the present uncertainties and the performance of similar analysis [16], we assume that the *in situ* calibration can be performed with a precision of 1 % with an associated uncertainty  $\delta m_W = 200$  MeV, according to Equation 6. The effect of pile-up on the missing momentum has not been studied.

Figure 17: Distribution of  $\cancel{E}_T$  residuals  $\cancel{E}_T^{\text{rec}} - \cancel{E}_T^{\text{true}}$  parallel (a) and perpendicular (b) to the lepton axis for  $W$  and  $Z$  decays.

## 5 Statistical uncertainty as a function of fitting range

As previously stated, the sensitivity to the  $W$  mass comes from the Jacobian edge in the fitting distribution. Generally the Jacobian edge is slightly sharper for the  $m_T^W$  distribution (see Figure 3), yielding a smaller statistical uncertainty. To test the influence of the fitting range, three different fitting ranges has been tested for the  $p_T^\ell$  and  $m_T^W$  distributions for the  $W \rightarrow \mu\nu$  sample. Since the typical  $m_T^W$  values are twice as large as the  $p_T^\ell$  values, the range size has been chosen accordingly. The result can be seen in Table 4.

Transverse lepton momentum, $p_T^\ell$		Transverse $W$ mass, $m_T^W$	
Fitting range [GeV]	$\sigma_{\text{stat.}}$ [MeV]	Fitting range [GeV]	$\sigma_{\text{stat.}}$ [MeV]
10-80	87	20-160	54
20-70	93	40-140	55
30-60	106	60-120	57

Table 4: Statistical uncertainty as a function of fitting range for  $p_T^\ell$  and  $m_T^W$  fits. The uncertainties in the  $p_T^\ell$  fit are larger, because the Jacobian edge is less sharp than in the  $m_T^W$  fit (see Figure 3).

As can be seen from Table 4, the  $p_T^\ell$  statistical uncertainty changes of about 30% with fitting range, while the  $m_T^W$  statistical uncertainty is essentially insensitive to the range, and generally somewhat lower as expected. Considering that most systematic effects (such as backgrounds, electron calibration and efficiency, etc.) are largest at low momenta, a loss in  $p_T^\ell$  statistical uncertainty will be countered by a gain in systematic uncertainty. For the  $m_T^W$  fit a narrow range is surely preferable. However, it is not possible to quantify this gain until all systematic uncertainties have been calculated.

## 6 Lepton performance determination *in situ*

In this section we review algorithms to calibrate the lepton response using  $Z$  events, and feed back the results to the  $m_W$  fit.

Figure 18: Fully simulated  $Z$  pseudo-data (dots with error bars), compared to an example  $Z$  resonance template with  $\alpha_E = 1$ ,  $\sigma_E = 0.02$ , and to the best fit.

### 6.1 Average scale and resolution

We first perform a global scale analysis, to verify whether neglecting possible non linearities in the response can be expected to induce a significant bias. We restrain ourselves to the electron channel. Fixing the non gaussian tail parameters to  $n = 0.8$  and  $\beta = 5$ , as expected from the studies performed in Section 3.3, we produce templates of the  $Z$  resonance by varying the electron scale and resolution. These response parameters are applied to generator level electrons as before.

The templates are then fitted to the fully simulated  $Z$  peak. A very good fit is obtained, as shown in Figure 18. An average scaling factor of  $\alpha_E = 0.9958 \pm 0.0003$ , and an average relative resolution of  $\sigma_E = 0.0207 \pm 0.0003$  provide a satisfactory description of the resonance. The precision of the fit corresponds to the complete  $Z$  event sample, i.e.  $\mathcal{L} = 200 \text{ pb}^{-1}$ . Scaling to our default luminosity  $\mathcal{L} = 15 \text{ pb}^{-1}$ , the precision becomes  $\delta\alpha_E = 0.0013$  and  $\delta\sigma_E = 0.0013$ .

### 6.2 Differential scale and resolution

The calibration uses a (large) sample of reconstructed  $Z \rightarrow \ell\ell$  events and a corresponding simulated sample (representing our knowledge of the  $Z$  lineshape). For each event the two leptons are assigned to bins  $i$  and  $j$  (choosing  $i \geq j$ ) according to energy/momentum,  $\eta$ , and/or  $\phi$ . Based on the lepton bins, events are divided into categories  $(i, j)$ , as shown in Figure 19.

For each category  $(i, j)$ , the reconstructed sample is compared to the known  $Z$  lineshape (obtained from the corresponding simulated sample), and a  $Z$  mass resolution function  $R_{ij}$  is obtained from requiring that its convolution with the theoretical lineshape matches the reconstructed distribution (see Equation 7). Each of these  $Z$  mass resolutions  $R_{ij}$  is the direct result of combining two lepton

Mapping of leptons to bins:

Data:				
Event	$p_T$	$\eta$	$\phi$	Bin
1: $\ell_1$	44.1	2.21	-2.98	11
$\ell_2$	28.4	1.78	0.43	8
2: $\ell_1$	34.2	1.67	-0.93	9
$\ell_2$	38.7	-0.92	2.66	2
...				
Simulation:				
Event	$p_T$	$\eta$	$\phi$	Bin
1: $\ell_1$	41.9	-1.01	-1.58	3
$\ell_2$	37.6	-1.26	1.52	2
2: $\ell_1$	58.5	0.79	-2.31	6
$\ell_2$	27.8	0.45	1.44	0
...				

Mapping of events to categories:

$$N \text{ lepton bins} \Rightarrow N \times (N + 1)/2 \text{ classes}$$

Figure 19: Illustration of scheme to categorize  $Z \rightarrow \ell\ell$  events. Each lepton is assigned a bin according to its  $p_T$  and  $|\eta|$ , here eight  $p_T$  bins and two  $|\eta|$  bins (barrel (**B**) and endcap (**E**)) thus  $8 \times 2 = 16$  bins total, as demonstrated (left).  $Z \rightarrow \ell\ell$  events from data/simulation (middle box) are then divided into categories (squares right) according to the reconstructed/truth  $p_T$  and  $|\eta|$  bin of both leptons.

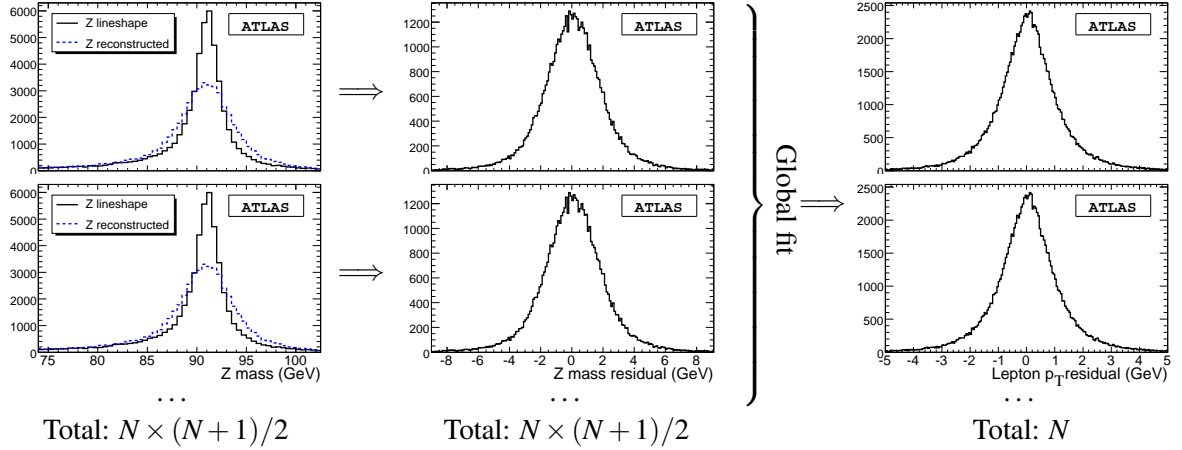

Figure 20: For each category a  $Z$  mass resolution function (middle) is determined from folding it with the simulated distribution to match the reconstructed one (left). The lepton bias and resolution parameters are determined for each of the 16 lepton bins, by globally fitting the  $16 \times 17/2 = 136$   $Z$  mass resolutions, which each is a result of two individual lepton resolutions (right).

 momentum resolutions  $R_i$  and  $R_j$ :

$$f(m_Z)_{ij}^{\text{Reco}} = f(m_Z)_{ij}^{\text{Truth}} \otimes R_{ij}, \quad R_{ij} = R_i \otimes R_j \quad (7)$$

The complicated lepton scale and resolution calibration can thus be split into two parts, which both saves computing time and allows for intermediate checks and changes.

Given  $N$  lepton bins and thus lepton resolution functions to determine, there are  $N \times (N + 1)/2$   $Z$  mass resolution functions, and thus the overconstrained system can be solved by a global  $\chi^2$  fit. This calibration procedure is illustrated in Figure 20, and allows for a determination of the detector response for all combinations of  $p_T$  and  $\eta$ .

Figure 21: Lepton scale constants for electrons (a) and muons (b) as obtained from simplified calibration to the  $Z$  peak (squares) and from truth (circles) using full  $Z$  samples (see Table 1). The first eight bins are scale constants for leptons of increasing  $p_T$  reconstructed in the barrel, while the last eight are for those in the endcap (see text). The result is in good agreement with average scale of  $0.9958 \pm 0.0003$  (indicated by the line in plot (a)) found in Section 6.1.

A simplified version of the above analysis has been performed, with the aim of obtaining only the scales. In this simplified procedure, the resolution functions  $R$  in Equation 7 reduces to calibration constants. The result of the calibration using the full  $Z$  samples (see Table 1) is shown for both electrons and muons in Figure 21, along with the scales obtained from the truth information.

As can be seen from the figure, the simplified calibration yields the correct behaviour of the scales in general. Some fluctuations around the expected values are observed induced by the above simplifications. Scaled to  $15 \text{ pb}^{-1}$ , the uncertainties are to be increased by a factor 3.8 and 2.4 for electrons and muons, respectively.

### 6.3 Lepton reconstruction efficiency

The  $p_T^\ell$  and  $m_T^W$  distributions of  $W$  events are also influenced by any  $p_T$  and  $\eta$  dependence of the lepton reconstruction efficiency. Any difference between the data and the simulation used to produce the templates will induce a difference in the distribution and cause a bias in the  $W$  mass fit.

Though the method to obtain the (differential) efficiency is conceptually the same for electrons and muons, the two cases are different in that electron reconstruction is generally more dependent on  $p_T$  and  $\eta$  than the muon reconstruction. For this reason, we have chosen to consider the electron reconstruction efficiency in the following. The electron reconstruction efficiency can be determined from the data with  $Z$  events, using the so-called “tag and probe” method [10], which we briefly summarize here. Events are selected with one well-identified electron, and an additional high  $p_T$  object. The invariant mass of these two objects is required to be within 10 GeV of the nominal  $Z$  boson mass. Assuming that this selects  $Z$  events with enough purity, the identification efficiency is then simply obtained by computing the fraction of events where the second object is indeed identified as an electron. The efficiency of the isolation criterion is obtained in a similar way.

The studies reported in [17] indicate that for an integrated luminosity of  $100 \text{ pb}^{-1}$ , the electron efficiency can be reconstructed with a precision of 1.5% in the range  $20 < p_T^e < 70 \text{ GeV}$ . The uncertainty is statistically dominated. Scaling this number down to  $\mathcal{L} = 15 \text{ pb}^{-1}$ , we anticipate a precision of 3.9%.

## 7 Background uncertainties

The leptonic  $W$  channel does not suffer from large backgrounds, due to the high cross section and the cleanness of the signal. The backgrounds are mostly from similar vector boson decays, such as  $W \rightarrow \tau(\rightarrow \ell\nu\nu)\nu$ ,  $Z \rightarrow \ell\ell$  (missing one lepton), and  $Z \rightarrow \tau(\rightarrow \ell\nu\nu)\tau$ . With the good particle identification capabilities of the ATLAS detector [13], jet events will despite their large cross section not be dominant. The backgrounds from  $t\bar{t}$  and  $W^+W^-$  events are negligible. The backgrounds and the uncertainties in their sizes are estimated below.

**$W \rightarrow \tau(\rightarrow \ell\nu\nu)\nu$  events:** A large background (largest in the electron channel) is from  $W \rightarrow \tau\nu$  events, where the  $\tau$  decays into a lepton. This background is irreducible, as the final state is identical to the signal; however, its  $p_T^\ell$  and  $m_T^W$  distributions are generally below the fitting range, as both the lepton and missing momentum are much reduced, leaving only a tail into the fitting range. Though a quite significant background, its uncertainty is small, as only the  $\tau \rightarrow \ell X$  branching ratio (1.0%) and the acceptance relative to the signal (2.5%) enter.

**$Z \rightarrow \ell\ell$  events:** Another large background (largest in the muon channel) comes from  $Z \rightarrow \ell\ell$  events, where one lepton is either undetected or not identified. A loose lepton identification for the second lepton can reduce this background, and possibly further reduction can be obtained with a  $Z$  veto, should the associated uncertainty still be significant. We do not apply this veto in the present analysis. The  $Z \rightarrow \ell\ell$  background extends significantly into the  $p_T^\ell$  and  $m_T^W$  distributions, except in the  $m_T^W$  electron channel, where the missed electron cluster still reduces the missing momentum, effectively lowering the apparent  $m_T^W$ . The size of this background has uncertainties from the  $W$  to  $Z$  cross section ratio  $R_{WZ}$  (1.8%),  $Z$  veto efficiency (2.0%), and the acceptance (2.5%).

**$Z \rightarrow \tau(\rightarrow \ell\nu\nu)\tau$  events:** A small background originates from  $Z \rightarrow \tau\tau$  events, where one  $\tau$  decays leptonically, while the other is not identified. While the cross section for such a process is small, it can fake missing momentum. The largest uncertainty in the size of this background comes from the  $\tau$  detector response (5.0%), along with cross section ratio  $R_{WZ}$  (1.8%), and acceptance (2.5%).

**Jet events:** This background is not studied here, because it can not be evaluated reliably using simulation only. Relying on Tevatron experience [16], we will assume it is small and it will not be discussed in this note.

**Impact of backgrounds:** If the size and shape of the backgrounds were perfectly known, then they would not affect the  $W$  mass measurement, as they could be included in the templates. It is thus the uncertainty on the size and shape of the backgrounds, in the fitting range of the  $p_T^\ell$  and  $m_T^W$  spectra, which gives rise to systematic errors. The uncertainties on the size of backgrounds arise from uncertainties relative to those of the signal events in cross sections, branching ratios and acceptances. These

Electron channel			Muon channel		
Process	Evts / $15\text{pb}^{-1}$	Fraction [%]	Process	Evts / $15\text{pb}^{-1}$	Fraction [%]
$W \rightarrow e\nu$	45468	97.8	$W \rightarrow \mu\nu$	83263	93.9
$W \rightarrow \tau\nu$	666	1.4	$W \rightarrow \tau\nu$	1238	1.4
$Z \rightarrow ee$	305	0.7	$Z \rightarrow \mu\mu$	3483	3.9
$Z \rightarrow \tau\tau$	30	0.1	$Z \rightarrow \tau\tau$	153	0.2

Table 5: Signal and expected backgrounds in  $15 \text{ pb}^{-1}$  after the event selection described in Section 2.2 and in the  $p_T^\ell$  range  $[30,60] \text{ GeV}$ .

are obtained from PDG [1] and efficiency studies (see Section 6.3).

The background shapes are determined from simulation. They are essentially unaffected by variations in the production, decay and resolution model. For jet events background, which was ignored in the present study, both normalisation and shape will have to be measured directly from the data.

We first assess the overall impact of the backgrounds. The backgrounds remaining after the selection described in Section 2.2 are given in Table 5, and the  $p_T$  spectrum of each process is shown in Figure 22.

Figure 22:  $p_T$  distribution for signal and backgrounds for electrons (a) and muons (b) after the selections described in Section 2.2. The  $p_T$  range used in the mass fit is  $30 < p_T < 60 \text{ GeV}$ .

Ignoring the background altogether in the templates leads to a bias  $\delta m_W = -10 \text{ MeV}$ . This is however the result of a conspiracy : the  $W \rightarrow \tau\nu$  background alone gives a bias of  $-80 \text{ MeV}$ , while the  $Z \rightarrow \ell\ell$  background gives a bias of  $+70 \text{ MeV}$ ; both sources of background can vary independently within the uncertainties given above. The other backgrounds have negligible impact. We thus estimate the bias per percent relative error on the background normalization (checked to scale linearly with the size of the background) to be:

$$\partial m_W / \partial N_{\tau\nu-\text{bkg}} = -0.8 \text{ MeV}/\%, \quad (8)$$

$$\partial m_W / \partial N_{\ell\ell-\text{bkg}} = 0.7 \text{ MeV}/\%. \quad (9)$$

We remind that the above does not include the jet events study.

## 8 Summary of uncertainties for $\mathcal{L} = 15 \text{ pb}^{-1}$

The response parameters determined *in situ* using  $Z$  events (cf. Section 6.1) are used to produce templates of the  $p_T^\ell$  spectrum in  $W$  events, as shown in Figure 23, for the electron channel. The resulting fit yields  $m_W = 80.466 \pm 0.110 \text{ GeV}$ , with no bias with respect to the true value. This results shows that for  $\mathcal{L} = 15 \text{ pb}^{-1}$ , propagating a global scale determined on  $Z$  events does not induce a significant bias in the analysis. Given that the global scale calibration had a precision of 0.13% and Equation 3, the scale-induced systematic uncertainty is  $\delta m_W(\alpha_E) = 110 \text{ MeV}$ . Likewise, the resolution uncertainty contributes  $\delta m_W(\sigma_E) = 5 \text{ MeV}$ .

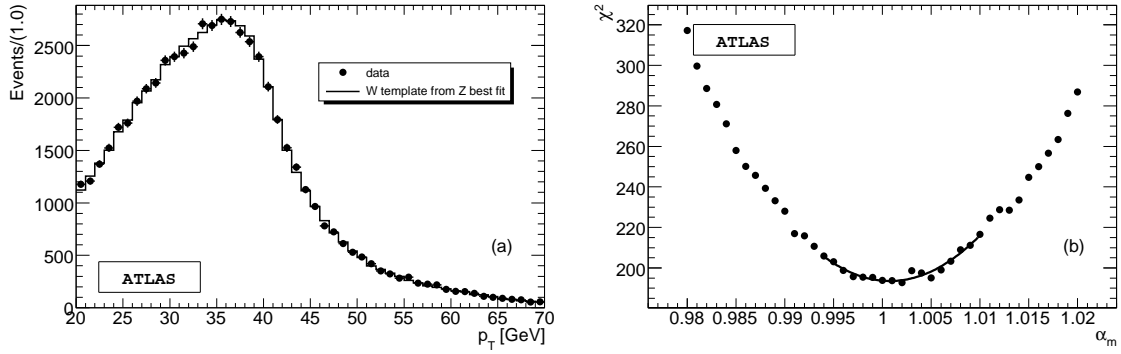

Figure 23: (a)  $p_T^\ell$  spectrum from fully simulated  $W$  decays (dots with error bars), and  $p_T^\ell$  template obtained assuming the  $Z$  based scale and resolution and the true value of  $m_W$ . (b) Template fit to  $m_W$ .

We did not attempt to control the non gaussian tails *in situ*. We assume that this contribution can be determined to 5% with  $15 \text{ pb}^{-1}$ , yielding a contribution of 28 MeV to the systematic uncertainty. As can be seen by comparing Figure 4 and Figure 12, the effect is smaller in the muon channel.

The expected precision of the *in situ* efficiency measurement (Section 6.3) and Equation 5 imply a systematic uncertainty on the fit result of about  $\delta m_W = 14 \text{ MeV}$ . This result holds for the electron channel. Given the flatness of the muon reconstruction efficiency, the systematic uncertainty in the muon channel is expected to be much smaller.

It was not attempted to determine the recoil calibration *in situ*. We assume that this calibration can be performed to 1%, yielding a systematic contribution of 200 MeV from Equation 6. This contribution affects the transverse mass analysis only.

The background uncertainty is discussed in the electron channel, and assumed identical in the muon channel. The  $Z \rightarrow \tau\tau$  background is negligible. Given the current knowledge of the  $W$  and  $\tau$  branching ratios [1], a realistic estimate of the  $\tau$  background uncertainty is 2.5%. Injecting the nominal background in the templates, then varying them within this range, we find a systematic uncertainty  $\delta m_W(\text{bkg}) = 2 \text{ MeV}$ . Similarly, the contribution from the  $Z \rightarrow ee$  background is found to be 2 MeV.

The total background contribution to the systematic uncertainty is thus expected to be 3 MeV.

A detailed discussion of theoretical uncertainties is provided in [15]. At the start-up of LHC, the dominant theoretical contribution comes from the proton parton density functions, which contribute 25 MeV.

In summary, for an integrated luminosity of  $15 \text{ pb}^{-1}$ , we found that the analysis of the  $p_T^\ell$  spectrum gives a statistical sensitivity of about  $\delta m_W = 110 \text{ MeV}$  per channel, while the transverse mass provides  $\delta m_W = 60 \text{ MeV}$ . These numbers have experimental systematic uncertainties of 114 MeV in the  $p_T^\ell$  analysis, and 230 MeV in the transverse mass analysis. The uncertainty on the lepton and recoil scales dominate these numbers. Finally, the uncertainty from PDFs is about 25 MeV and comparatively small. Our numbers are summarized in Table 6.

Method	$p_T(e)$ [MeV]	$p_T(\mu)$ [MeV]	$M_T(e)$ [MeV]	$M_T(\mu)$ [MeV]
$\delta m_W$ (stat)	120	106	61	57
$\delta m_W$ ( $\alpha_E$ )	110	110	110	110
$\delta m_W$ ( $\sigma_E$ )	5	5	5	5
$\delta m_W$ (tails)	28	< 28	28	< 28
$\delta m_W$ ( $\epsilon$ )	14	–	14	–
$\delta m_W$ (recoil)	–	–	200	200
$\delta m_W$ (bkg)	3	3	3	3
$\delta m_W$ (exp)	114	114	230	230
$\delta m_W$ (PDF)	25	25	25	25
Total	167	158	239	238

Table 6: Summary of contributions to  $\delta m_W$ , for the different fitting methods described in the text. From top to bottom: statistical uncertainty; systematic uncertainties related to the absolute scale, resolution, non gaussian tails, reconstruction efficiency, recoil calibration, and backgrounds; total experimental systematic uncertainty; uncertainty from PDF; total systematic uncertainty.

## 9 Conclusions

This note presents a first attempt towards  $m_W$  fits, confronting distributions obtained from fully simulated  $W \rightarrow e\nu, \mu\nu$  events to templates produced using a simplified detector model.

The simplified detector model used here relies on empirical functions to describe the energy and momentum scale, resolution, and non-gaussian tails, as well as the lepton selection efficiency. These functions are first determined, as a function of  $p_T$  and  $\eta$ , using simulated  $W$  events, i.e. the signal itself; the resulting fit, unbiased, provides a technical validation of the method.

In a second step, the model parameters are used as extracted *in situ*, from the analysis of  $Z$  events. The  $Z$  peak provides the detector scale and resolution; the tag-and-probe method [10], applied to its decay leptons, is used to estimate the efficiency. A fit of the  $Z$ -based templates to the  $W$  data again

shows no significant bias.

Our current approach can thus be considered valid, within a statistical sensitivity of about 60 MeV, for the transverse mass-based fit in the muon channel, and of 120 MeV for the transverse momentum-based fit in the electron channel.

This note has focused on experimental issues. Phenomenological uncertainties, related to QED, QCD and parton density functions are discussed in detail in [15].

# Forward-Backward Asymmetry in $pp \rightarrow Z/\gamma^* X \rightarrow e^+ e^- X$ Events

## Abstract

This paper describes a study on the measurement of the forward-backward asymmetry in  $pp \rightarrow Z/\gamma^* X \rightarrow e^+ e^- X$  events with the ATLAS detector for an integrated luminosity of  $100 \text{ fb}^{-1}$ . Such a measurement can be used to determine the effective weak mixing angle,  $\sin^2 \theta_{eff}^{lept}$ . We will demonstrate that a very high accuracy on the weak mixing angle,  $\delta \sin^2 \theta_{eff}^{lept} = (1.5(\text{stat}) \pm 0.3(\text{exp}) \pm 2.4(\text{PDF})) \times 10^{-4}$ , can be reached. This is possible due to the large cross-section for the production of Z bosons at the LHC and by using electron reconstruction in the forward calorimeters of ATLAS ( $2.5 < |\eta| < 4.9$ ).

## 1 Introduction

The forward-backward asymmetry,  $A_{FB}$ , measurement is one of the important precision measurements that can be done at the Large Hadron Collider (LHC). It will improve the knowledge of Standard Model parameters and test the existence of physics beyond the Standard Model.

The Z boson events in  $pp$  collisions originate from the annihilation of valence quarks with sea anti-quarks or from the annihilation of sea quarks with sea antiquarks. Since the valence quarks carry on average a larger momentum fraction than the sea quarks, the boost direction of the dilepton system can indicate the quark direction. However, dilepton events which originate from the annihilation of sea quarks with sea antiquarks do not contribute to the observed asymmetry.

$A_{FB}$  measurements with quarks and leptons at the Z peak provide a precise determination of the weak mixing angle  $\sin^2 \theta_{eff}^{lept}$ . The weak mixing angle is an important parameter in the electroweak theory that describes the mixing between weak and electromagnetic interactions. In the global fit of the Standard Model, the weak mixing angle has an impact on indirect constraints on Higgs mass.

With the experimental capabilities of the ATLAS experiment at the LHC and an expected integrated luminosity of up to  $100 \text{ fb}^{-1}$  it becomes interesting to perform a study on the measurement of the asymmetry,  $A_{FB}$ . In order to improve the measurement precision, it will be necessary to detect leptons in the very forward pseudo-rapidity region, which favors electrons over muons at ATLAS. In  $100 \text{ fb}^{-1}$  data around  $1.5 \times 10^8$  Z events will be produced, of which  $\sim 5 \times 10^6$  decay to an electron-positron pair, providing the measurement of  $A_{FB}$  (and  $\sin^2 \theta_{eff}^{lept}$ ) with a competitive precision to the current world average value [1],  $\delta \sin^2 \theta_{eff}^{lept} = 0.00016$ .

This paper is organized as follows. In section 2 we present a short introduction of the theoretical aspects of the measurement. An overview of the ATLAS detector is given in section 3. In section 4 the electron measurement in ATLAS is presented, both in the central and forward regions the latter being necessary for a precise measurement of the forward-backward asymmetry. We then present the simulated data samples used in section 5 and the definition of the electron polar angle in section 6. The event selection cuts are discussed in section 7. The charge misidentification is given in section 8. The pile-up effect is discussed in section 9. The systematic uncertainties are summarized in section 10. The expected precision on the asymmetry around the Z mass is shown in section 11.

## 2 Forward-backward asymmetry

In proton-proton collisions,  $e^+e^-$  pairs are predominantly produced via the annihilation of a quark  $q$  and an antiquark  $\bar{q}$ . In the Standard Model, quark-antiquark annihilations proceed via an intermediate  $[2, 3]$   $\gamma^*$  at low invariant mass  $M_{(e^+e^-)}$  or via a  $\gamma^*/Z$  interference at  $M_{(e^+e^-)}$  around the  $Z$  mass. The electroweak neutral current in the Standard Model lagrangian violates parity (due to the presence of vector and axial-vector couplings of the quarks and leptons to the  $Z$ -boson) and leads to an asymmetry in the polar emission angle of the electron in the rest frame of the electron-positron pair. The asymmetry can only be extracted with respect to the boost direction of the di-electron system since the quark direction is not known (see Sec. 6).

The differential cross-section for the production of an electron-positron pair in  $q\bar{q}$  annihilation via the  $s$ -channel can be written, in the electron-positron rest frame [4, 5], as:

$$\frac{d\sigma}{d\cos\theta} = N_c[(1 + \cos^2\theta)F_0(s) + 2\cos\theta F_1(s)] \quad (1)$$

where  $\theta$  is the emission angle of the  $e^-$  relative to the momentum vector of the quark in the  $e^+e^-$  rest frame and  $s$  is the center-of-mass energy squared.  $F_0(s)$ ,  $F_1(s)$  are form factors and  $N_c$  (1/3) is the colour factor:

$$F_0(s) = \frac{\pi\alpha^2}{2s}(q_q^2 q_l^2 + 2\text{Re}\chi(s)q_q q_l C_V^q C_V^l + |\chi(s)|^2((C_V^q)^2 + (C_A^q)^2)((C_V^l)^2 + (C_A^l)^2)) \quad (2)$$

$$F_1(s) = \frac{\pi\alpha^2}{2s}(2\text{Re}\chi(s)q_q q_l C_A^q C_A^l + |\chi(s)|^2 2C_V^q C_V^l 2C_A^q C_A^l), \quad (3)$$

with

$$\chi(s) = \frac{s}{s - M_Z^2 + is\Gamma_Z/M_Z} \quad (4)$$

where  $q_{q,l}$  is the electric charge of the quark or lepton and  $C_V$ ,  $C_A$  are the vector and axial-vector coupling to the  $Z$ .

The angular dependence of the various terms is either  $\cos\theta$  or  $(1+\cos^2\theta)$ . Only the  $(1+\cos^2\theta)$  term contributes to the total cross-section, as the  $\cos\theta$  term integrates to zero. However, it induces a forward-backward asymmetry. Thus, the differential cross-section can be written in a simple expression:

$$\frac{1}{\sigma} \frac{d\sigma}{d\cos\theta} = \left[ \frac{3}{8}(1 + \cos^2\theta) + A_{FB}(s)\cos\theta \right] \quad (5)$$

where  $\sigma = \frac{8}{3}F_0(s) \times N_c$  and

$$A_{FB}(s) = \frac{1}{\sigma}[\sigma(\cos\theta > 0) - \sigma(\cos\theta < 0)] \quad (6)$$

$$= \frac{3}{4} \frac{F_1(s)}{F_0(s)} \quad (7)$$

$$A_{FB}(s = M_Z^2) \sim \frac{3}{4} \frac{2C_V^q C_A^q}{(C_V^q)^2 + (C_A^q)^2} \frac{2C_V^l C_A^l}{(C_V^l)^2 + (C_A^l)^2} \quad (8)$$

The forward-backward asymmetry is commonly defined using the number of forward produced ( $\cos\theta > 0$ ) events ( $N_F$ ) and backward-produced ( $\cos\theta < 0$ ) events ( $N_B$ )

$$A_{FB} = \frac{N_F - N_B}{N_F + N_B} \quad (9)$$

Figure 1: SM prediction of the forward-backward charge asymmetry  $A_{FB}$  in the electron pair channel versus the di-electron invariant mass  $M_{e^+e^-}$  for  $|y_{e^+e^-}| > 1$  and for at least one electron in the central region ( $|\eta| < 2.5$ ).

where

$$F = \int_0^1 \frac{d\sigma}{d\cos\theta} d\cos\theta, \quad B = \int_{-1}^0 \frac{d\sigma}{d\cos\theta} d\cos\theta \quad (10)$$

### 2.1 Dependence of $A_{FB}$ on $M_{e^+e^-}$

In Figure 1 we show the Standard Model prediction, using MRST PDF [6], of the forward-backward charge asymmetry as function of the di-electron invariant mass. At the  $Z$ -pole we see a small asymmetry (as expected) which is dominated by a small vector coupling in  $Z \rightarrow e^+e^-$  with the dominant axial coupling. Around the  $Z$  mass the asymmetry is linear with the weak mixing angle  $\sin^2 \theta_{eff}^{lept}$ . It was estimated that (in a good approximation) the weak mixing angle can be determined from the measurement of the forward-backward asymmetry (this is the raw forward backward asymmetry measured at detector level) when averaged over the rapidity of the electron pair as follow [7, 8, 9]:

$$A_{FB} = b(a - \sin^2 \theta_{eff}^{lept}) \quad (11)$$

the parameters  $a$  and  $b$  depend on the parton distribution functions (PDFs).

At large invariant mass,  $A_{FB}$  is dominated by the properties of the interference between the propagators of the  $\gamma^*$  and the  $Z$  and is almost constant at a large positive value, close to 0.6, independent of the invariant mass.

## 3 Detector overview

The ATLAS detector has been described in detail in [10]. It consists of an inner tracking system, with pseudo-rapidity coverage of  $|\eta| < 2.5$ , inside a 2 T solenoidal magnetic field, followed by the calorimeters, and an outer muon spectrometer, with pseudo-rapidity coverage of  $|\eta| < 2.7$ , installed in a large toroidal magnet system. We briefly describe the parts of the detector relevant to this analysis.

Figure 2 shows a schematic transversal view of the ATLAS calorimeter system. It has been designed to be hermetic to  $|\eta| < 4.9$  with a fine lateral and longitudinal segmentation. A liquid argon (LAr) sampling calorimeter in a barrel-endcap geometry provides the electromagnetic and hadronic calorimetry. At  $|\eta| < 1.2$  the hadronic calorimetry is completed by a tile (Iron/scintillator) hadronic calorimeter.

Figure 2: Schematic transversal view (r-z view) of the calorimeters in the ATLAS detector. The cylindrical coordinate system is used with the z axis along the proton-beam direction and r is the transverse coordinate.

The electromagnetic barrel calorimeter, covering a pseudo-rapidity range of  $|\eta| < 1.475$ , shares its cryostat with the superconducting solenoid, the calorimeter being behind the solenoid. Each electromagnetic calorimeter end-cap (EMEC) covers the pseudo-rapidity range 1.4-3.2. To correct for the energy lost in the material in front of the calorimeters, both end-caps and barrel are preceded with pre-sampler detectors in the region  $|\eta| < 1.8$ . The performance expected gives for the energy resolution a sampling term of  $10\%/\sqrt{E(\text{GeV})}$  and a constant term better than 0.7%. The hadronic end-cap calorimeter (HEC) and the forward calorimeter (FCal) share the same cryostat with the EMEC and cover the pseudo-rapidity range 1.5-3.2 and 3.1-4.9 respectively. The design of the FCal was constrained by the high radiation level in the very forward region. It consists of three consecutive modules along the beam line: one electromagnetic module (FCal1) and two hadronic modules (FCal2 and FCal3). To optimize the resolution, copper was chosen as the absorber for FCal1, while tungsten was used in FCal2 and FCal3, to provide containment and minimize the lateral spread of hadronic showers.

The electron energy can be measured either in the central electromagnetic calorimeter ( $|\eta| < 2.5$ ) and/or in the forward calorimeters ( $2.5 < |\eta| < 4.9$ ). The  $|\eta| < 2.5$  region corresponds to the EM barrel and the EMEC outer wheel.

## 4 Electron identification

### 4.1 Central electrons

An electron candidate is reconstructed in the central calorimeters if there is a cluster with energy  $E$  and a charged track matched to the cluster with the condition of  $E/p < 7$  and  $|\Delta\eta| < 0.05$  and  $|\Delta\phi| < 0.1$ .  $\Delta\eta$  ( $\Delta\phi$ ) is the difference between the  $\eta$  ( $\phi$ ) position of the track and the position of the cluster. The track is then extrapolated to the cluster. The energy of the electron is determined by the total energy it deposits in the EM calorimeter. The transverse momentum ( $p_T$ ) of the electron is determined by the energy measured in the calorimeter and by the track angle at the nominal interaction point. The charge of the electron ( $q_e$ ) is determined from the sign of the curvature of the track.

The development of electromagnetic and hadronic showers is quite different so that shower shape information can be used to differentiate between electrons and hadrons. Electrons deposit almost all their energy in the electromagnetic section of the calorimeter, while hadrons are typically much more

Figure 3: Central Electron ID efficiency vs electron  $p_T$  for events with  $|\eta| < 1.3$  and  $|\eta| > 1.6$ .

Figure 4: Central Electron ID efficiency vs electron  $\eta$ . The efficiency is integrated over  $p_T > 20$  GeV.

penetrating. To obtain the best discrimination against hadrons, we use both longitudinal and transverse shower shapes. For example, for electrons passing tight identification criteria, the hadronic leakage and the lateral shower shape in the first and second sampling of the calorimeter are used. After the selections based on calorimeter information, we also take into account the inner detector information. We ask for a good track pointing to the calorimeter and fulfilling the consistency of the spatial and energy matching between the calorimeter and the inner detector.

Figure 3 and Figure 4 show the electron identification efficiency,  $62.0 \pm 1.0$  % on average, as a function of the electron transverse momentum and pseudo-rapidity  $\eta$  using electrons (and positrons) from  $Z \rightarrow e^+e^-$  events (the samples used are described in section 5). Tight cuts have been applied to identify the central electrons. We observe an expected increase in the efficiency as function of  $p_T$ . This dependence (in particular at low  $p_T$ ) is due to the lower performance for low  $p_T$  electrons. The drop in the efficiency versus  $\eta$  happens at the transition region between barrel and end-cap calorimeters,  $1.37 < |\eta| < 1.52$ . A more detailed description of the electron identification in the central calorimeters is given elsewhere [11].

## 4.2 Forward electrons

In contrast to the central region, forward electron reconstruction can use only calorimeter information as the tracking system is limited to the central region ( $|\eta| < 2.5$ ). In this case we can not distinguish between an electron, positron or photon. The electron candidate in the forward calorimeter<sup>1</sup> is reconstructed if there is a cluster with  $E_T > 20$  GeV. The direction of the electron is defined by the barycenter of the cells belonging to the cluster in the calorimeter.

To discriminate between electron and hadron a multivariate analysis [12] is used. Variables are defined using cluster moments or a combination of them.

The cluster moment of degree  $n$  for a variable  $x$  is defined as:

$$\langle x^n \rangle = \frac{1}{E_{\text{norm}}} \times \sum_i E_i x_i^n, \quad (12)$$

where  $E_{\text{norm}} = \sum_i E_i$ ,  $E_i$  is the cell energy and  $i$  is the cell index of the cluster.

<sup>1</sup>the EM forward calorimeters are the EMEC inner wheel ( $2.5 < |\eta| < 3.2$ ) and the front compartment of the FCal. These EM calorimeters are completed by the HEC and the last 2 compartments of the FCal ( $3.2 < |\eta| < 4.9$ ).

We use the following five discriminants in the electron ID:

- $r_i = |(\vec{x}_i - \vec{c}) \times \vec{u}|$ :

Electromagnetic and hadronic showers have different shapes in both the transverse and the longitudinal directions. To evaluate the shower shapes in the transverse direction we use the second moment of the distance  $r_i$  of each cell  $i$  ( $\vec{x}_i$ ) to the shower axis ( $\vec{c}$ ).  $\vec{u}$  is the shower axis.

- $lat_2/(lat_2 + lat_{max})$ :

A modified lateral moment is derived as above. It takes into account the two most energetic cells (shower core). So,  $lat_2$  is the second moment of the variable  $r_i$  for which we impose that the distance  $r = 0$  for the two most energetic cells. For  $lat_{max}$  we impose that  $r = 4$  cm for the two most energetic cells and  $r = 0$  for the remaining cells.

- $long_2/(long_2 + long_{max})$ :

To evaluate the shower shapes in the longitudinal direction we use an equivalent variable to the previous one where the distance of the each cell to the shower centre is used.

- $\frac{1}{E_{norm}} \times \sum_i E_i (E_i/V_i)$ :

where  $V_i$  is the volume of the cell  $i$ . The electromagnetic shower is narrow and deposits energy more locally than a hadronic shower.

- $f_{max}$

Fraction of the energy in the most energetic cell of the cluster. By measuring the energy fractions deposited in the cells of a segmented calorimeter it is usually possible to distinguish incident hadrons from electrons and photons.

In order to combine the electron identification information from the various discriminants into a single quantity that provides optimal discrimination power, we calculate the likelihood for each discriminant based on probability density functions. For each discriminant, the signal likelihood ( $p_s$ ) and the background likelihood ( $p_B$ ) are separately calculated and combined using the likelihood ratio:

$$R_L = \frac{\prod_{j=1}^{N_{var}} p_s(j)}{\prod_{j=1}^{N_{var}} p_s(j) + \prod_{j=1}^{N_{var}} p_B(j)} \quad (13)$$

where  $j$  runs over each discriminant. Figure 5 shows the distribution of  $R_L$  using all the discriminants described above. Both electrons (signal) and background are shown. As can be seen, good separation is achieved with this variable. The electron identification efficiency determined using  $Z \rightarrow e^+e^-$  events as function of the electron  $p_T$  and  $\eta$  as shown in Figures 6 and 7. The drop in the efficiency plot versus  $\eta$  happens at the transition region between inner wheel of the electromagnetic end-cap and the FCal.

Figure 5: The likelihood ratio  $R_L$  for the signal (yellow) and background (solid line). Due to the fact that the likelihood ratio is strongly peaked at 0 and 1, in the plot, a transformation is applied that zooms into the peaks.

Figure 6: Forward Electron ID efficiency vs electron  $p_T$  for events with  $2.5 < |\eta| < 4.9$ .

Figure 7: Forward Electron ID efficiency vs electron  $\eta$  for events with  $p_T > 20$  GeV.

## 5 Monte-Carlo samples

The Monte Carlo events are generated at a centre of mass of  $\sqrt{s} = 14$  TeV using PYTHIA [13] (version 6.3) for the signal  $pp \rightarrow Z/\gamma^* \rightarrow e^+e^-$  and the background  $pp \rightarrow jj$  with the CTEQ6LL [14] parton distribution functions. Table 1 shows the summary of the cross-sections, number of events and the equivalent luminosity for the signal and background simulated events.

### 5.1 Signal

The  $pp \rightarrow Z/\gamma^*X \rightarrow e^+e^-X$  events generated are filtered requiring at least one electron with  $|\eta| < 2.7$  and with transverse momentum  $p_T > 10$  GeV and a dilepton mass,  $\hat{m}$ , greater than 60 GeV. Figures 8 and 9 show the  $p_T$  distribution of electrons and the invariant mass of the electron pairs in the signal events.

### 5.2 Background

The dominant sources of background to the signal process  $pp \rightarrow Z/\gamma^*X \rightarrow e^+e^-X$  are:

Figure 8: The electron  $E_T$  distribution normalized to unit for events with  $|\eta| < 1.3$  and  $|\eta| > 1.6$ .

Figure 9: Di-electron invariant mass distribution for events with  $|\eta| < 1.3$  and  $|\eta| > 1.6$ .

- dijet production: this is the largest background when two jets fake an electron. The cross-section of this process is greater by several orders of magnitude than the signal one, and dominates at low transverse momentum.
- $pp \rightarrow t\bar{t}X \rightarrow e^+e^-X$ : The top quark decays into the  $W$  boson and a  $b$  quark, followed by the  $W$  decay into electron and neutrino ( $t \rightarrow Wb, W \rightarrow e\nu$ ). It has the same signature as the signal one as the two electrons of the final state can simulate the two electrons from  $Z$ .
- $pp \rightarrow W + X \rightarrow e\nu_e + X$ : where  $X$  is a photon or a jet misidentified as an electron

These events are passed through a detector simulation program to model detector response. Two detector simulation tools are used: a full detector simulation tool, based on GEANT4 [15], and a fast simulation program, ATLFAST [16] which simulates the detector response using efficiencies and smearing parameters measured from detailed simulation data. ATLFAST was used due to the high di-jet cross-section, the high rejection power of the selections and the available Monte Carlo statistics of fully simulated events which is not sufficient to evaluate the background. The Monte Carlo samples processed with the fast detector simulation were used only for estimation of the background contributions.

Physics process	Cross section (nb)	$\epsilon_{filter}$	Number of events	Equivalent luminosity ( $\text{pb}^{-1}$ )
$Z \rightarrow e^+e^-$	2.015	0.126	$5.10^5$	248.14
Inclusive jets	$21.10^4$	0.09	$3.10^7$	0.15
$t\bar{t}$	0.833		$6.10^5$	720.3
$W + X$	38.2		$1.10^6$	26.2

Table 1: List of signal and background samples.

Ref. [17] discusses expectation for electron triggers at different luminosities. The  $Z/\gamma^*$  events used in this measurement are selected by high transverse momentum triggers on one or two electrons. This selection requires at least one isolated electron with  $p_T > 20$  GeV or at least two isolated electrons with  $p_T > 12$  GeV. At Level 1, electrons are selected by the presence of an energy deposition in an EM calorimeter tower. The Level 2 decision, which is based on the result of the Level 1 trigger, can take into account the information from all ATLAS subdetector systems in the regions of interest (ROIs) and the event filter (EF) performs its task only after the complete event has been assembled in the event builder (EB).

## 6 Angular distribution

The  $Z$  production can be either from the annihilation of valence quarks with sea antiquarks or from the annihilation of sea quarks with sea antiquarks. Since the original quark direction is unknown in proton-proton collisions (it can originate with equal probability from either proton), the sign of  $\cos\theta$  is not directly measurable.

As the valence quarks have, on average, a much larger momentum than the sea quarks, in valence-sea quark collisions, the longitudinal motion of the dilepton system approximates the quark direction and the angle between the lepton and the quark in the  $e^+e^-$  rest frame can be extracted with respect to the beam axis. A lepton asymmetry can thus be expected with respect to the boost direction. For sea-sea quark collisions no such asymmetry is expected, diluting the overall effect.

To minimize the effect of the unknown transverse momenta of the incoming quarks in the measurement of the forward and backward cross-sections, we use the Collins-Soper reference frame [18]. This reference frame reduces the uncertainty in electron polar angle due to the finite transverse momentum of the incoming quarks. The particle four-vectors are transformed to the  $e^+e^-$  rest frame and the polar angle  $\theta^*$  is measured with respect to the axis, which bisects the two quark momentum vectors.

$$\cos\theta^* = \frac{2}{m(e^+e^-)\sqrt{m^2(e^+e^-) + p_T^2(e^+e^-)}} [p^+(e^-)p^-(e^+) - p^+(e^+)p^-(e^-)] \quad (14)$$

where  $p^\pm = \frac{1}{\sqrt{2}}(E \pm p_z)$ ,  $E$  is the energy and  $p_z$  is the longitudinal component of the momentum. To take into account our supposition that the  $Z$  boost and the quark direction are the same we add the sign of the  $Z$  boost to the definition:

$$\cos\theta^* = \frac{|p_z(e^+e^-)|}{p_z(e^+e^-)} \times \cos\theta^* \quad (15)$$

Figure 10 shows the resulting distributions of events for which the  $e^+e^-$  invariant mass is close to the  $Z$  mass. We should note that the detector itself doesn't introduce false asymmetries with the geometry used in the MC samples.

Figure 10: Distribution in  $\cos\theta^*$  for reconstructed events in the  $Z$  pole region.

## 7 Analysis method

### 7.1 Event selection

In this analysis we search for events with two electrons. An electron must fulfill certain quality and kinematic requirements. It must first satisfy the tight electron criteria outlined in Section 4.1. In addition the following cuts were applied:

- **C1**

We require an electron transverse momentum higher than 20 GeV ( $p_T > 20$  GeV) to emulate the energy threshold of the electron trigger

- **C2**

We require the  $e^+e^-$  invariant mass,  $M_{(e^+e^-)}$ , to be within a window of 12 GeV around the Z mass,  $85.2 \text{ GeV} < M_{(e^+e^-)} < 97.2 \text{ GeV}$  (Z pole)

- **C3**  $|y_{e^+e^-}| > 1$

In contrast to Tevatron  $p\bar{p}$  collisions, sea quark effects dominate at the LHC. At central rapidity,  $y_{e^+e^-}$ , the probability that the valence quark direction and the dielectron boost coincide is lower due the smallness of the valence quark distribution. This reduces the forward backward asymmetry. Since the valence quark dominates at high values of  $x$ , the events where one parton carries a large fraction of the proton momentum are more sensitive and they give a large rapidity to the dilepton system. In this region the most significant measurements can be performed, as shown in Figure 11. A purer, though smaller, signal sample can thus be obtained by introducing a rapidity cut. For the following studies we will impose a  $|y_{e^+e^-}| > 1$  cut.

- **C4**  $E_t^{miss} < 20 \text{ GeV}$

We require the missing transverse momentum to be less than 20 GeV. This cut rejects efficiently the background coming from  $pp \rightarrow t\bar{t}X$  channel where both top quarks decay semileptonically.

### 7.2 Analysis cases

A study using fast simulated events [19] showed that the use of forward electrons improves the precision of the forward-backward asymmetry measurement (and the weak mixing angle). As can be seen in Figure 12, a very high electron identification performance in the forward calorimeters is not needed, as already with a rejection of 100 against jets the influence of the remaining QCD background is negligible. Figure 12 shows only the statistical uncertainty on  $A_{FB}$  versus the jet rejection in the forward calorimeters (with a fixed electron efficiency of 50%). Thus, it is required that one of the two electrons lies in the central region ( $|\eta| < 2.5$ ), while the other electron may be either in the central region or in the forward region up to  $|\eta| = 4.9$ :

- $|\eta| < 2.5$  for both electrons (C-C), or
- $|\eta| < 2.5$  for one of the two electrons and  $|\eta| < 4.9$  for the other (C-F).

Figure 11: Di-electron rapidity distribution for all events (upper line) and for the events with correct quark direction (lower line).

Figure 12: Forward-Backward asymmetry statistical accuracy versus the forward jet rejection in the events where at least one electron is in the central region and keeping the efficiency of the electron in the forward region at 50%.

In the region  $2.5 < |\eta| < 3.2$  the calorimeters used are the EMEC and the HEC and for  $|\eta| > 3.2$  the forward calorimeter (FCal) is used. Note that we can not reconstruct the electron track in the forward region ( $2.5 < |\eta| < 4.9$ ) as the tracking system of ATLAS is limited to the region  $|\eta| < 2.5$ . In addition, the forward calorimeters have a coarser granularity than the central ones (a factor 2 in both eta and phi directions). Figure 13 shows the the  $E_T$  distribution of electron for events with at least one electron in the central region.

Figure 13: The electron  $E_T$  distribution for the central-forward events, normalized to unity.

Figure 14: Di-electron  $p_T$  distribution for the central-central events (C-C) and the central-forward events (C-F).

Using the forward electrons we gain about 30% in the statistics as shown in figure 14, where we compare the di-electron  $p_T$  distribution in the two analysis cases, C-C and C-F. Furthermore the value of the asymmetry is higher in the C-F events. The expected numbers of the signal and background events of each process are shown in table 2 in the two analysis regions, C-C and C-F.

Event statistics corresponding to a  $100 \text{ fb}^{-1}$  would be required for this analysis to reach a very high precision on the determination of the weak mixing angle from the forward-backward asymmetry measurement. Nevertheless the measurement can be also made at low luminosity in order to test the

consistency with the Standard Model. This can be done as function of  $M_{e^+e^-}$  to enhance sensitivity to possible deviations at high mass scales.

### 7.3 $A_{FB}$ calculation

The forward-backward asymmetry is calculated according to Eqs 9 and 10.

If we assume that the distribution of  $N_F$  and  $N_B$  follows a binomial distribution, then the uncertainty on the two quantities can be written as follows (which is valid only for small asymmetries):  $\sigma_{N_F} = \sigma_{N_B} = \sqrt{N_F N_B} / \sqrt{N_F + N_B}$ , and the  $A_{FB}$  uncertainty is  $\sigma_{A_{FB}} = \sqrt{\frac{1-A_{FB}^2}{N}}$ .

Selection cut	Signal	dijet	W+X	$t\bar{t}$
C-C				
<b>C1</b>	$2.39802 \times 10^7$	4741	73312	315178
<b>C2</b>	$1.87808 \times 10^7$	404	6048	28204
<b>C3</b>	$7.31282 \times 10^6$	144	2212	9937
<b>C4</b>	$7.30496 \times 10^6$	142	205	741
C-F				
<b>C1</b>	$3.09742 \times 10^7$	447408	2764790	336714
<b>C2</b>	$2.41535 \times 10^7$	35920	172321	29824
<b>C3</b>	$1.26855 \times 10^7$	35340	168486	11556
<b>C4</b>	$1.25967 \times 10^7$	35128	15868	864

Table 2: Summary of expected number of C-C and C-F signal and background events for  $100 \text{ fb}^{-1}$  of integrated luminosity. Results are given after the application of cuts **C1-C4**.

## 8 Electron charge identification

Any misidentification of the electron charge dilutes the asymmetry. Where possible, the charge of both electrons is measured and it is required that the signs differ. When both electrons are in the central region both charges can be measured and the condition that they have opposite charges removes the events where the charge of one of the two electrons is misidentified. In this case the forward-backward asymmetry is not significantly affected by charge misidentification.

The situation is different when one electron is forward and the other central. Only the charge of the central electron can be measured. A misidentification of the charge of the electron changes the sign of  $\cos \theta^*$  and a forward event may be taken as a backward one. This effect can be corrected for if the charge misidentification fraction is known.

To measure the charge misidentification we use two methods:

- MC method

We use the two electrons coming from Z and we count the number of events where the generated charge ( $q_{gen}$ ) and reconstructed charge ( $q_{reco}$ ) of the individual electrons differ. We define the charge misidentification fraction as follow:

$$r = \frac{N(q_{reco} \neq q_{gen})}{N_{tot}}. \quad (16)$$

- Tag and probe method

This method is used with the tag electron  $e_1$  having the tight electron requirements,  $p_T > 20$  GeV and  $|\eta| < 1.5$ . The tag and probe electron pair must have a dielectron mass within  $\pm 6$  GeV of  $M_Z$ . The rate at which the second electron  $e_2$  has the same charge gives an estimation of the charge misidentification fraction.

The true asymmetry can be deduced from the raw asymmetry using the relation:

$$A_{FB_{true}} = \frac{A_{FB} - r_+ + r_-}{1 - r_+ - r_-}. \quad (17)$$

where  $r_-$  is the fraction of true  $e^-$  misidentified as  $e^+$  and  $r_+$  is the fraction of true  $e^+$  misidentified as  $e^-$ .

Figure 15 shows the misidentification fraction as function of the electron pseudo-rapidity obtained with these two methods. The misidentification fraction is small. The difference between the misidentification fraction for  $e^+$  and  $e^-$  is shown in figure 16.

Figure 15: Electron charge misidentification fraction versus the electron pseudo-rapidity: Data method of tag-and-probe measuring the charge misidentification fraction (open points), and Monte Carlo driven charge misidentification fraction (full points).

Figure 16: The difference in charge misidentification fraction of positrons and electrons versus the electron pseudo-rapidity.

## 9 Effect of pile-up

Pile-up originates from the fact that several  $pp$  collisions can occur during the same bunch crossing. This causes extra activity in the detector and therefore influences the event selection. The effect of pile-up is assessed by superimposing additional events on top of the signal when events are simulated; hits from several bunch crossings are overlaid. In this study, pile-up events corresponding to  $10^{33} \text{ cm}^{-2} \text{ s}^{-1}$  were investigated.

The pile-up affects the electron selection efficiency due to the presence of additional activity in the events. Figure 17 displays the electron identification efficiency with and without pile-up. We can see also in Table 3 the summary of the results for the C-C and C-F events, after all selection cuts. The results show a loss of about 3% of signal events.

	C-C	C-F
No pile-up	7,304,960	$1.25967 \times 10^7$
With pile-up	7,026,653	$1.217696 \times 10^7$

Table 3: Number of expected events, at  $100 \text{ fb}^{-1}$ , after all cuts, for the signal, and for C-C and C-F events. The numbers are shown for the two cases: with and without pile-up. The reference pile-up luminosity used is  $10^{33} \text{ cm}^{-2} \text{ s}^{-1}$ .

Figure 17: Effect of pile-up on the electron identification efficiency. The reference pile-up luminosity used is  $10^{33} \text{ cm}^{-2} \text{ s}^{-1}$ .

## 10 Systematic Uncertainties

We have considered several sources of systematic uncertainties. There are PDF uncertainties and experimental ones including the energy scale, energy resolution, reconstruction efficiency and the background estimation.

### 10.1 Parton Distribution Functions

Since the vector and axial vector couplings of the  $u$  and  $d$  quarks to the  $Z$  boson are different, the forward-backward asymmetry is expected to depend on the ratio of the  $u$  and  $d$  quark parton distribution function. Thus, the choice of the parton distribution functions (PDFs) will affect the measured lepton forward-backward asymmetry.

The MRST PDF parametrization [6] is used to assess the uncertainty arising from the PDFs. Thirty eigenvectors are used in this parametrization to indicate the effect of  $\pm 1\sigma$  variations. Figure 18 shows the  $e^+e^-$  asymmetry for each eigenvector. The deviation of  $A_{FB}$  from the central value is of the same order of magnitude as the statistical accuracy.

To study the effect of the PDFs on the asymmetry, a PDF reweighting technique is used to reduce the need for Monte Carlo generations and simulation. Thus, we generate the events with the best fit central value ( $PDF_0$ ) and then we reweight to  $PDF_i$  of the set  $i$  by weighting each event via:

$$\frac{f_{PDF_i}(x_1, Q^2, flav_1) \cdot f_{PDF_i}(x_2, Q^2, flav_2)}{f_{PDF_0}(x_1, Q^2, flav_1) \cdot f_{PDF_0}(x_2, Q^2, flav_2)} \quad (18)$$

where  $x f_{PDF}(x, Q^2, flav)$  is the parton momentum distribution for flavour,  $flav$ , at scale,  $Q^2$ , and mo-

momentum fraction,  $x$ .

Figure 18: The forward-backward asymmetry for each MRST eigenvector; the red star is the central value.

## 10.2 Background subtraction

The determination of  $A_{FB}$  (with real data) requires knowledge of the number of background events and the forward-backward charge asymmetry of the background events. Thus the central value of  $A_{FB}$  we showed above can be obtained from the data events by subtracting the background events in the forward and backward regions separately from the *raw* forward-backward asymmetry. The number of background events estimated thus gives rise to a source of systematic uncertainties on  $A_{FB}$ .

The systematic uncertainty is evaluated by varying the estimated numbers of background events by 30%. The uncertainty value is taken as the shift in  $A_{FB}$ . The largest shift is less than 0.01%.

## 10.3 Detector performance

Various effects due to uncertainties on the knowledge of the detector performance have to be taken into account:

**Energy scale** The electron energy scale uncertainty, which arises from calorimeter calibration uncertainties, affects the forward-backward asymmetry by causing a shift in the  $e^+e^-$  invariant mass over which we integrate  $A_{FB}$ . The effect is significant in the Z-pole region as can be seen in Figure 1. To take these effects into account, the central calorimeter scale is varied by 0.1% and the forward calorimeter scale is varied by 0.5% to estimate the systematic uncertainties. The positive and negative variations are considered separately and the largest shift is taken as the uncertainty.

**Reconstruction efficiency** The impact of the uncertainties on the electron reconstruction in the  $A_{FB}$  measurement can be estimated by removing 0.2% and 0.5% fraction of the reconstructed electrons in the central region and forward region respectively. These values used here are based on our study on the forward calorimeters reconstruction.

**Energy resolution** The forward backward asymmetry is sensitive to the variations in the energy resolution. These variations are mainly due to the dead material distribution, known with an insufficient accuracy. To evaluate the impact of this contribution the central electron energy is degraded by an extra-term  $0.01 E_T$  and the forward calorimeter energy by  $0.05 E_T$ .

**Charge identification** A systematic variation in charge misidentification fraction would directly translate into uncertainties of the forward-backward asymmetry. The systematic uncertainty is estimated by comparing the measurement as performed as in the data (tag and probe method), to that using the true Monte Carlo. As it is shown in figure 15 a difference of about 0.1% is observed.

Table 4 reports all the systematic uncertainties at  $100 \text{ fb}^{-1}$ . As expected, the dominant contribution to the overall uncertainty is from the PDF uncertainties.

Source	$\delta A_{FB}$ (abs)	$\delta \sin^2 \theta_{eff}^{lept}$ (abs)
Energy scale	$2.7 \times 10^{-5}$	$1.5 \times 10^{-5}$
Reco. Eff.	$3.4 \times 10^{-5}$	$1.9 \times 10^{-5}$
Energy resol.	$1.9 \times 10^{-6}$	$1.1 \times 10^{-6}$
Charge ID	$2.6 \times 10^{-5}$	$1.4 \times 10^{-5}$
Background subtraction.	$< 10^{-5}$	$< 10^{-5}$
PDFs	-	$-2.4 \times 10^{-4}$ $+1.3 \times 10^{-4}$
$a$ and $b$ parameters	-	$3 \times 10^{-5}$
Statistical error	$2.7 \times 10^{-4}$	$1.5 \times 10^{-4}$

Table 4: Summary of the systematic and statistical uncertainties on  $A_{FB}$  and  $\sin^2 \theta_{eff}^{lept}$  for events with at least one electron in the central region (C-F). The uncertainty on  $\sin^2 \theta_{eff}^{lept}$  is determined using Eqs. 11 and  $a$  and  $b$  parameters from figure 21.

## 11 Results

Figure 19 shows the dielectron invariant mass spectrum expected in terms of the number of events per GeV for an integrated luminosity of  $100 \text{ fb}^{-1}$  after the application of cuts **C1**, **C3** and **C4**. The yellow histogram corresponds to the signal contribution. The light blue displays the contributions from dijet events. The green and violet histograms display the contribution of  $W + X$  and  $t\bar{t}$  backgrounds respectively. The background contributions were obtained with MC samples with a fast detector simulation. The signal contribution was obtained with a full detector simulation.

Table 2 shows the expected number of background and signal events for  $100 \text{ fb}^{-1}$  of integrated luminosity after the application of cuts **C1-C4**. It indicates that the contribution from background events is at the level of 0.2%.

In Figure 20 we display the variation of the charge asymmetry versus the rapidity of the two electrons. It is observed that the asymmetry increases when allowing the second electron to be up to  $|\eta| = 4.9$ . Using  $|y_{e^+e^-}| > 1$  and going from C-C to C-F events, the integrated asymmetry increases from 1.3% to 2.7%. The precision on the forward-backward asymmetry improves from  $3.7 \times 10^{-4}$  to  $2.7 \times 10^{-4}$ .

Using the parameters  $a = 0.23 \pm 0.03$  and  $b = 1.832 \pm 0.255$ , of Eqs. 11, derived from the linear fit of the figure 21, we can estimate the error expected for  $\sin^2 \theta_{eff}^{lept}$  from a measurement of the forward-

Figure 19: Dielectron invariant mass distribution for the signal and background events normalized to  $100 \text{ fb}^{-1}$ , with the final selection except that the cut **C2** is removed.

Figure 20: Forward-backward asymmetry versus dielectron rapidity in the C-C events (open points) and in the C-F events (full points).

backward asymmetry at the Z pole, for an integrated luminosity of  $100 \text{ fb}^{-1}$ :

$$\delta \sin^2 \theta_{eff}^{lept} = (1.5(\text{stat}) \pm 0.3(\text{exp}) \pm 2.4(\text{PDF})) \times 10^{-4} \quad (19)$$

## 12 Conclusion

We report on a detailed study of the forward-backward charge asymmetry  $A_{FB}$ , at LHC with the ATLAS detector, of electron pairs resulting from the process  $pp \rightarrow Z/\gamma^* X \rightarrow e^+e^-X$ . This measurement provides a test of the Standard Model. In the vicinity of the Z-pole this measurement can be used to determine the effective weak mixing angle  $\sin^2 \theta_{eff}^{lept}$ . The precision on  $\sin^2 \theta_{eff}^{lept}$  obtained is  $\delta \sin^2 \theta_{eff}^{lept} = (1.5(\text{stat}) \pm 0.3(\text{exp}) \pm 2.4(\text{PDF})) \times 10^{-4}$  for a 12 GeV mass window around the Z mass, and  $100 \text{ fb}^{-1}$  of integrated luminosity. Electron identification in the forward region ( $2.5 < |\eta| < 4.9$ ) of

Figure 21: Forward backward asymmetry  $A_{FB}$  versus the weak mixing angle  $\sin^2 \theta_{eff}^{lept}$  at the  $Z$  pole. The straight line is a  $\chi^2$  fit to the points shown. Fast simulated events are used.

the ATLAS detector is very important for the measurement. In this region an electron ID efficiency of 80% is achieved with less than 3% QCD background.

The main systematic effects relevant for forward-backward asymmetry measurements with  $100 \text{ fb}^{-1}$  of data are addressed, including systematic uncertainties on detector effects and MRST PDF uncertainty. An advanced technique was developed and used to estimate the error due to the PDF uncertainties. This study showed that the uncertainty in the weak mixing angle determination due to PDF's is of the same order as the measurement statistical error, which means that the precision on the weak mixing angle at LHC can be competitive to the current world average. In addition we expect that in the future the knowledge of the PDF's will improve from the constraints imposed by Tevatron, HERA and first LHC measurements (e.g. using  $W$  asymmetry), and the systematic uncertainty due the uncertainty in the PDF's should decrease by the time ATLAS high luminosity data is available. If this is not the case, the asymmetry measurements can be used, conversely, to constrain the parton distribution functions.

# Diboson Physics Studies

## Abstract

This note presents studies of the sensitivity of the ATLAS experiment to Standard Model diboson ( $W^+W^-$ ,  $W^\pm Z$ ,  $ZZ$ ,  $W^\pm\gamma$ , and  $Z\gamma$ ) production in pp collisions at  $\sqrt{s} = 14$  TeV, using final states containing electrons, muons and photons. The studies use ATLAS simulated data, which include trigger information and detector calibration and alignment corrections. The influence of backgrounds on diboson detection is assessed using large samples of fully simulated background events. The cross-section measurement uncertainties (both statistical and systematic) are estimated as a function of integrated luminosity (from 0.1 to 30 fb<sup>-1</sup>). The studies show that the Standard Model  $W^+W^-$ ,  $W^\pm Z$ ,  $W^\pm\gamma$ , and  $Z\gamma$  signals can be established with significance better than  $5\sigma$  for the first 0.1 fb<sup>-1</sup> of integrated luminosity, and the  $ZZ$  signal can be established with 1 fb<sup>-1</sup> of integrated luminosity. The ATLAS experiment's sensitivity to anomalous triple gauge boson couplings is also estimated. The anomalous triple gauge boson coupling sensitivities can be significantly improved, even with 0.1 fb<sup>-1</sup> of data, over the results from the Tevatron that use 1 fb<sup>-1</sup> of data.

## 1 Introduction

This paper presents studies of the ATLAS experiment's sensitivity to diboson ( $W^+W^-$ ,  $W^\pm Z$ ,  $ZZ$ ,  $W^\pm\gamma$ ,  $Z\gamma$ ) production using lepton and photon final states, and the corresponding ability to set limits on anomalous triple gauge boson couplings (TGC). The analysis of diboson production at the LHC provides an important test of the high energy behavior of electroweak interactions. Vector boson self-couplings are fundamental predictions of the Standard Model [1], resulting from the non-Abelian nature of the  $SU(2)_L \times U(1)_Y$  gauge symmetry theory, which was demonstrated by precision measurements of  $W^+W^-$  and  $ZZ$  pair production at LEP II [2].

Any theory predicting physics beyond the Standard Model while maintaining the Standard Model as a low-energy limit may introduce deviations in the gauge couplings at some high energy scale. Precise measurements of the couplings will not only provide stringent tests of the Standard Model, but will also probe for new physics in the bosonic sector. These tests will provide complementary information to other direct searches for new physics at the LHC. Many models predict deviations of vector boson self-couplings from the Standard Model at the  $10^{-3} - 10^{-4}$  level [3]. Experiments that can reach this sensitivity could provide powerful constraints on these models. The signature for such anomalous couplings is enhanced diboson production cross-sections, particularly at high transverse momentum ( $p_T$ ) of the bosons. Experimental limits on non-Standard Model TGC's can be obtained by comparing the shape of the measured  $p_T$  or mass distributions (or transverse mass,  $M_T$ , for final states involving  $W$ ) with predictions, provided that the signal is not overwhelmed by background.

The analysis uses over 30 million fully simulated and reconstructed events, with a detector layout and trigger system that reflects the ATLAS experiment as it will operate at LHC turn-on at 14 TeV center of mass energy, thus providing a realistic understanding of the detection of these diboson final states. A *Boosted Decision Tree* [4] technique is applied to selected channels, significantly enhancing measurement sensitivities. These are among the ways this study improves on our understanding and the results of the previous ATLAS diboson studies [5]- [10].

### 1.1 Diboson production cross-sections

Tree-level Feynman diagrams for electroweak diboson production at hadron colliders are shown in Figure 1. The  $s$ -channel diagram contains the vector-boson self-interaction vertices of interest here. The cross-sections are calculated to next-to-leading-order (NLO) in [11]- [13]. The Standard Model diboson production cross-sections are listed in Table 1.

Figure 1: The generic Standard Model tree-level Feynman diagrams for diboson production at hadron colliders;  $V, V_1, V_2 = \{W, Z, \gamma\}$ . The  $s$ -channel diagram contains the trilinear gauge boson vertex. In the Standard Model, only  $WW\gamma$  and  $WWZ$  vertices are allowed.

Table 1: The Standard Model diboson production total cross-sections, calculated to the NLO, at the Tevatron ( $\sqrt{s} = 1.96$  TeV) and the LHC ( $\sqrt{s} = 14$  TeV). The references in the first column indicate the MC generators used for the calculations, with parton density function (PDF) CTEQ6M and the electroweak parameters [14]. The theoretical uncertainty from the PDF and the QCD scale factor is typically 5%.

Diboson mode	Conditions	$\sqrt{s} = 1.96$ TeV	$\sqrt{s} = 14$ TeV
		$\sigma[pb]$	$\sigma[pb]$
$W^+W^-$ [15]	$W$ -boson width included	12.4	111.6
$W^\pm Z$ [15]	$Z$ and $W$ on mass shell	3.7	47.8
$ZZ$ [15]	$Z$ 's on mass shell	1.43	14.8
$W^\pm\gamma$ [16]	$E_T^\gamma > 7$ GeV, $\Delta R(\ell, \gamma) > 0.7$	19.3	451
$Z\gamma$ [17]	$E_T^\gamma > 7$ GeV, $\Delta R(\ell, \gamma) > 0.7$	4.74	219

The LHC diboson production rates will exceed those of the Tevatron by at least a factor 100 (10 times higher in cross-sections and at least 10 times higher in luminosity). Furthermore, because the energy reach at the LHC will be 7 times higher than at the Tevatron, the LHC sensitivity to anomalous TGC's is expected to be improved by orders of magnitude over that which can be reached at the Tevatron or LEP.

### 1.2 Effective Lagrangian for charged TGC's

The most general effective Lagrangian, that conserves  $C$  and  $P$  separately, for charged triple gauge boson interactions is [19]:

$$L/g_{WWV} = ig_1^V (W_{\mu\nu}^* W^\mu V^\nu - W_{\mu\nu} W^{*\mu} V^\nu) + i\kappa^V W_\mu^* W_\nu V^{\mu\nu} + \frac{\lambda^V}{M_W^2} W_{\rho\mu}^* W_\nu^\mu V^{\nu\rho}$$

where  $V$  refers to the neutral vector-bosons,  $Z$  or  $\gamma$ ,  $X_{\mu\nu} \equiv \partial_\mu X_\nu - \partial_\nu X_\mu$  and the overall coupling constants  $g_{WWV}$  are given by  $g_{WW\gamma} = -e$ ,  $g_{WWZ} = -e \cot \theta_W$ , with  $e$  the positive electron charge and  $\theta_W$  the weak mixing angle. The Standard Model triple gauge boson vertices are recovered by letting  $g_1^V = \kappa^V = 1$  and  $\lambda^V = 0$ . Experimentally, deviations from the Standard Model couplings is searched for; thus the anomalous coupling parameters are defined as

$$\Delta g_1^Z \equiv g_1^Z - 1, \quad \Delta \kappa_\gamma \equiv \kappa_\gamma - 1, \quad \Delta \kappa_Z \equiv \kappa_Z - 1, \quad \lambda_\gamma, \quad \text{and} \quad \lambda_Z.$$

Note that electromagnetic gauge invariance requires  $g_1^\gamma = 1$  or  $\Delta g_1^\gamma = 0$ .

Studies of three different diboson final states,  $W^+W^-$ ,  $W^\pm Z$  and  $W^\pm \gamma$  will provide complementary sensitivities to the charged anomalous TGC's [17]. For example, the  $\Delta \kappa_V$  terms in  $W^+W^-$  production are proportional to  $\hat{s}$ , defined as the square of invariant mass of the vector-boson pair, whereas these terms are only proportional to  $\sqrt{\hat{s}}$  in  $W^\pm Z$  and  $W^\pm \gamma$  production.  $W^+W^-$  production is thus expected to be more sensitive to  $\Delta \kappa_V$  than  $W^\pm Z$  and  $W^\pm \gamma$  production. Conversely,  $W^\pm Z$  production is expected to be more sensitive to  $\Delta g_1^Z$  than  $W^+W^-$  production because terms in  $\Delta g_1^Z$  are proportional to  $\hat{s}$  in  $W^\pm Z$  production. The  $\lambda$ -type anomalous couplings have an  $\hat{s}$  dependence in all three cases, thus the sensitivities will be enhanced at the high center-of-mass energy of the LHC.

With non-Standard Model coupling parameters, the amplitudes for gauge boson pair production grow with energy, eventually violating tree-level unitarity. The unitarity violation is avoided by introducing an effective cutoff scale,  $\Lambda$  [18]. The anomalous couplings take a form, for example,

$$\Delta \kappa(\hat{s}) = \frac{\Delta \kappa}{(1 + \hat{s}/\Lambda^2)^n},$$

where  $\Delta \kappa$  is the coupling value in the low energy limit. The scale  $\Lambda$  is physically interpreted as the mass scale where the new phenomenon, which is responsible for the anomalous couplings, would be directly observable. The value of  $n = 2$  is used for charged anomalous TGC, and  $n = 3$  for neutral anomalous TGC.

### 1.3 Effective Lagrangian for neutral TGC's

In the Standard Model, neutral boson pairs,  $ZZ$  and  $Z\gamma$ , are produced via the  $t$ -channel diagrams shown in Figure 1. While the Standard Model  $ZZZ$  and  $ZZ\gamma$  triple gauge boson couplings are zero at tree level, anomalous couplings may contribute. This study considers the effect of anomalous couplings on the production of pairs of on-shell  $Z$  bosons only. In this case, the most general form of the  $Z^\alpha(q_1)Z^\beta(q_2)V^\mu(P)$  ( $V = Z, \gamma$ ) vertex function which respects Lorentz invariance and electromagnetic gauge invariance may be written as [20]

$$g_{ZZV}\Gamma_{ZZV}^{\alpha\beta\mu} = e \frac{P^2 - M_V^2}{M_Z^2} [if_4^V(P^\alpha g^{\mu\beta} + P^\beta g^{\mu\alpha}) + if_5^V \epsilon^{\mu\alpha\beta\rho}(q_1 - q_2)_\rho]$$

where  $M_Z$  is the  $Z$ -boson mass and  $e$  is the positive electron charge;  $q_1, q_2$  and  $P$  are the 4-momenta of the two on-shell  $Z$  bosons and the  $s$ -channel propagator, respectively. The effective Lagrangian generating the  $g_{ZZV}$  vertex function is

$$L = -\frac{e}{M_Z^2} [f_4^V (\partial_\mu V^{\mu\beta}) Z_\alpha (\partial^\alpha Z_\beta) + f_5^V (\partial^\sigma V_{\sigma\mu}) \tilde{Z}^{\mu\beta} Z_\beta],$$

where  $V_{\mu\nu} = \partial_\mu V_\nu - \partial_\nu V_\mu$  and  $\tilde{Z}^{\mu\beta} = \frac{1}{2} \epsilon_{\mu\nu\rho\sigma} Z^{\rho\sigma}$ . The couplings  $f_i^V$  ( $i = 4, 5$ ) are dimensionless complex functions of  $q_1^2$ ,  $q_2^2$  and  $P^2$  and are zero at tree level. All couplings are  $C$  odd;  $CP$  invariance forbids  $f_4^V$ , while parity conservation requires that  $f_5^V$  vanishes. Because  $f_4^Z$  and  $f_4^\gamma$  are  $CP$ -odd, contributions

to the helicity amplitudes proportional to these couplings will not interfere with the Standard Model terms, and hence  $ZZ$  production is not sensitive to the sign of these couplings. The  $CP$  conserving couplings  $f_5^V$  contribute to the Standard Model cross-section at the one-loop level, but this contribution is  $\mathcal{O}(10^{-4})$  [20].

#### 1.4 Current Tevatron results on diboson physics

Diboson production measurements and studies of anomalous TGC's have been performed at the Tevatron with the CDF and D0 experiments, using up to  $2 \text{ fb}^{-1}$  of integrated  $p\bar{p}$  luminosity. Diboson cross-section measurements using  $e/\mu$  decay modes, and their event statistics, measurement precision, and background events are summarized in Table 2. The measurements from Tevatron experiments are consistent with the Standard Model predictions based upon NLO matrix element calculations.

Table 2: Summary of Tevatron  $p\bar{p} \rightarrow$  diboson cross-sections. For the  $W^+W^-$ ,  $W^\pm Z$ , and  $ZZ$  channels total production cross-sections are quoted.

Process	Source	L $\text{fb}^{-1}$	observed events	background events	$\sigma(\text{data})$ [pb] $\pm (\text{stat}) \pm (\text{sys}) \pm (\text{lum})$	$\sigma(\text{theory})$ [pb]

The Tevatron's  $p\bar{p}$  collisions produce the charged states of  $W^\pm Z$  and  $W^\pm \gamma$ . These states can be used to study the  $W^+W^-Z$  and the  $W^+W^- \gamma$  couplings independently, which is in contrast with the anomalous TGC measurements made at LEP [32] from the  $W^+W^-$  final state, where certain assumptions relating the  $W^+W^-Z$  and the  $W^+W^- \gamma$  couplings were made. The Tevatron limits for the  $WW\gamma$  and  $WWZ$  anomalous TGC's are summarized in Table 3. These limits will improve significantly by combining the constraints from the  $W^\pm \gamma$ ,  $W^\pm Z$  and  $W^+W^-$  channels, and by increasing the datasets using the expected integrated luminosity of  $6 \text{ fb}^{-1}$  at the end of the Tevatron running.

## 2 Signal and background modeling and simulated data samples

### 2.1 MC generators used to produce fully simulated events

The diboson physics analyses focus on leptonic decay channels of the boson pairs ( $W^+W^-$ ,  $W^\pm Z$ ,  $ZZ$ ,  $W^\pm \gamma$ , and  $Z\gamma$ ) produced in the proton-proton collisions at the LHC.

Diboson productions of the  $W^+W^-$ ,  $W^\pm Z$ , and  $ZZ$  final states, as well as the subsequent pure leptonic decays, are modeled by the MC@NLO [15] Monte Carlo generator. The generator incorporates the next-to-leading-order (NLO) QCD matrix elements into the parton shower by interfacing to the HERWIG/Jimmy [33] programs. A branching ratio of 0.0336 for  $Z \rightarrow \ell^+ \ell^-$  and 0.108 for  $W^+ \rightarrow \ell^+ \nu$  is used

Table 3: Anomalous gauge coupling limits (95% C.L.) for  $WW\gamma$  and  $WWZ$  from the Tevatron experiments, with  $\Lambda = 2$  TeV.

Coupling	Source	L (fb <sup>-1</sup> )	$\lambda_Z$	$\Delta\kappa_Z$	$\Delta\kappa_\gamma$	$\lambda_\gamma$
$WW\gamma$ from $W^\pm\gamma$	D0 [27]	0.16			[-0.88, 0.96]	[-0.2, 0.2]
$WWZ$ from $W^\pm Z$	D0 [24]	1.0	[-0.17, 0.21]	[-0.12, 0.29]		
$WWZ$ from $W^\pm Z$	CDF	1.9	[-0.13, 0.14]	[-0.82, 1.27]		
$WWZ = WW\gamma$						
from $W^+W^-$	D0 [30]	0.25	[-0.31, 0.33]	[-0.36, 0.33]		
from $W^+W^-, W^\pm Z$	CDF [31]	0.35	[-0.18, 0.17]	[-0.46, 0.39]		

for each lepton flavor ( $e, \mu, \tau$ ). The gauge-boson decays into tau leptons are included in the MC event generator and these tau leptons decay to all the possible final states. Hard emission is treated as in NLO computations and soft/collinear emission is treated as in a regular parton shower MC. The matching between these two regions is smooth (no double-counting).  $W$ -boson width and spin-spin correlations are included in the generator. However, ‘zero-width’ approximations are used in  $W^\pm Z$  and  $ZZ$  calculations, and no  $Z/\gamma^*$  interference terms are included. MC@NLO does not include anomalous triple gauge boson couplings. The process of  $W^+W^-$  production via gluon-gluon fusion and the leptonic decays of the  $W$ ,  $gg \rightarrow W^+W^- \rightarrow \ell\nu\ell'\nu$ , is modeled by the MC generator `gg2ww` [34]. The  $W^\pm\gamma$  and the  $Z\gamma$  production processes and subsequent leptonic decays of the  $W^\pm$  and the  $Z$  are modeled by the PYTHIA MC generator [35], which only incorporates the leading-order (LO) QCD matrix elements into the parton shower. To include the off-shell  $Z$  and  $\gamma^*$  into the  $ZZ$  analysis, we have also used PYTHIA to generate the  $Z/\gamma^* + Z/\gamma^* \rightarrow \ell^+\ell^-\ell'^+\ell'^-$  events. The  $Z/\gamma^*$  mass threshold is set to 12 GeV in PYTHIA. Table 4 list all the diboson signal samples used in this paper.

Major physics backgrounds for diboson signal detection come from top pairs and hadronic jets associated with  $W$  or  $Z$  gauge bosons. We have used MC@NLO to model  $t\bar{t} \rightarrow \ell + X$  production (700k events). The inclusive  $W + X$  and  $Z + X$  ( $X = \text{jets, or } \gamma$ ) processes are modeled by the PYTHIA (30M events) and ALPGEN [36] (1.1M events).

Whenever LO event generators are used, the cross-sections are corrected to NLO by using k-factors from NLO matrix element calculations to normalize the expected signal and background events.

## 2.2 MC generators for TGC studies

Monte Carlo generators BosoMC [16] and BHO [17] are used for anomalous TGC studies. These MC programs are numerical parton level generators. They are used to calculate both LO and NLO cross-sections for all five diboson final states ( $W^+W^-$ ,  $W^\pm Z$ ,  $ZZ$ ,  $W^\pm\gamma$ ,  $Z\gamma$ ) with anomalous coupling parameters. However, they do not include parton showers automatically. We use the BHO MC to model the  $ZZ$ ,  $W^+W^-$ , and  $Z\gamma$  production cross-sections and kinematics with Standard Model and anomalous couplings. BosoMC is used for  $W^\pm Z$  and  $W^\pm\gamma$  diboson final-state TGC studies. The calculated diboson production rates from these generators are accurate to NLO. The  $W^+W^-$ ,  $W^\pm Z$  and  $ZZ$  production calculations with the Standard Model couplings are compared with the MC@NLO calculations using PDF CTEQ6M. We found that both cross-sections and kinematic distributions are in good agreement, as shown in Figure 2. The left plot shows the  $W^\pm Z$  production differential cross-section as a function of the transverse mass of the  $W^\pm Z$  system. The right plot shows the  $W^+W^-$  production differential cross-section as a function of the  $W$  transverse momentum. The discrepancies between MC@NLO and the BHO MC are within 2%.

Table 4: Diboson signal production processes, cross-sections including branching ratios of  $W/Z$  leptonic decays and fully simulated number of MC events. The MC simulation ‘filter’ is the event selection at the generator level. The corresponding filter efficiencies are given in the table. We also indicate the MC generators used to produce the MC events and to calculate the cross-sections given in this table.

Process	cross-section (fb)	$\epsilon_{\text{filter}}$	$N_{MC}$	Generator
$q\bar{q}' \rightarrow W^+W^- \rightarrow \ell^+\nu\ell^-\nu$	11718	1.0	180,000	MC@NLO
$gg \rightarrow W^+W^- \rightarrow \ell^+\nu\ell^-\nu$ ( $\ell = e, \mu, \tau$ )	540.0	0.96	180,000	gg2ww
$q\bar{q}' \rightarrow W^+Z \rightarrow \ell^+\nu\ell^+\ell^-$	441.7	1.0	50,000	MC@NLO
$q\bar{q}' \rightarrow W^-Z \rightarrow \ell^-\nu\ell^+\ell^-$ ( $\ell = e, \mu$ ; $Z$ on mass shell)	276.4	1.0	50,000	MC@NLO
$q\bar{q}' \rightarrow ZZ \rightarrow \ell^+\ell^-\ell^+\ell^-$	66.8	1.0	49,250	MC@NLO
$q\bar{q}' \rightarrow ZZ \rightarrow \ell^+\ell^-\nu\bar{\nu}$ ( $\ell = e, \mu$ ; $Z$ on mass shell)	397	1.0	118,000	MC@NLO
$q\bar{q}' \rightarrow ZZ \rightarrow \ell^+\ell^-\ell^+\ell^-$ ( $\ell = e, \mu, \tau$ ; $M_{Z/\gamma^*} > 12 \text{ GeV}$ ) (4 leptons ( $e, \mu$ ), $p_T^\ell > 5 \text{ GeV}$ , $ \eta^\ell  < 2.7$ )	159	0.219	43,000	PYTHIA
$q\bar{q}' \rightarrow W^+\gamma \rightarrow \ell^+\nu\gamma$	10220	1.0	38,400	PYTHIA
$q\bar{q}' \rightarrow W^-\gamma \rightarrow \ell^-\nu\gamma$ ( $\ell = e, \mu$ ; $E_T^\gamma > 10 \text{ GeV}$ )	6820	1.0	25,600	PYTHIA
$q\bar{q}' \rightarrow Z\gamma \rightarrow \ell^+\ell^-\gamma$ ( $\ell = e, \mu$ ; $E_T^\gamma > 10 \text{ GeV}$ )	5280	1.0	66,000	PYTHIA

A somewhat different procedure is used in the estimation of neutral triple gauge couplings from  $ZZ$  events. In this case, the signal expectation with anomalous couplings was determined from the leading order Monte Carlo calculation of BHO, corrected using a  $p_T$  dependent k-factor derived from MC@NLO.

### 3 Diboson event selection

This section discusses features of five diboson signals, ( $W^\pm Z$ ,  $W^\pm \gamma$ ,  $W^+W^-$ ,  $Z\gamma$ ,  $ZZ$ ), the major backgrounds and the analysis cuts required to discriminate between them. The varied event topology of each diboson signal precludes a common set of universal cuts. Two analysis approaches are employed. The first is based on a sequence of straight cuts on kinematic quantities. The second is a refined, multi-variate analysis based on *Boosted Decision Tree* (BDT) which is briefly described in Section 3.2. Some of the diboson analyses employ both techniques. The major results of these analyses are included here.

#### 3.1 Physics objects

The ATLAS detector and its performance is described in detail elsewhere [37]. A brief description of the physics objects used in diboson analysis is given below.

The major physics objects used in diboson physics analysis are electrons, photons, muons, missing  $E_T$  ( $\cancel{E}_T$ ), and hadronic jets. Electrons are identified by their distinctive pattern of energy deposition in the calorimeter and by the presence of a track in the inner tracker that can be extrapolated from the

Figure 2: Comparison of MC@NLO MC to BHO MC for  $W^\pm Z$  and  $W^+W^-$  production. The histograms are normalized to production cross-sections. Left plots: the  $W^\pm Z$   $M_T$  distribution from  $W^\pm Z$  production. Right plots: the  $W^+$   $p_T$  distribution from  $W^+W^-$  production.

interaction vertex to a cluster of energy in the calorimeter. To ensure high trigger efficiency, for events with a single electron, the transverse energy of a single electron must satisfy  $E_T > 25$  GeV. For events with dielectrons, both electrons are required to have  $E_T > 10$  GeV. The electrons must be isolated from other energy clusters. An electron is required to pass a set of cuts on shower shape, track quality and track to calorimeter cluster matching. Photon identification is similar to an electron in the EM calorimeter, but no charged tracks in the inner tracker should match the EM energy cluster. The average electron identification efficiency in the barrel is about 75% and in the endcaps about 60%.

Muons are reconstructed using information from the outer muon spectrometer (MDT chambers and trigger chambers), the inner tracking detectors and the calorimeters. Muons are identified with a tracking algorithm that associates a track found in the muon spectrometer with the corresponding inner detector track, after the former is corrected for energy loss in the calorimeter. The combined muon detection rapidity coverage is  $|\eta| < 2.5$ . The minimum  $p_T$  of reconstructed muon track is 5 GeV. The candidate muons are required to be isolated in the calorimeter and inner tracker to minimize the contributions of muons originating from hadronic jets. The average muon identification efficiency is about 95%.

The hadronic jets are reconstructed using the fixed-cone jet algorithm. The cone size used in this analysis is 0.7. The jet seed threshold on the transverse energy in a tower is set to  $E_s = 1$  GeV, and the final energy cut on a jet is  $E_T > 7$  GeV. With this cut the minimum measurable jet  $E_T$  should be 20 GeV.

Missing transverse energy,  $\cancel{E}_T$ , is calculated from the energy deposited in all calorimeter cells and from muons. A correction is applied for the energy lost in the cryostat. For diboson events with neutrinos in final states, the  $\cancel{E}_T$  resolution we found to be 6.5 GeV based on our studies using  $Z \rightarrow \ell^+ \ell^-$  MC events.

The ATLAS trigger consists of three levels of event selection: Level-1 (L1), Level-2 (L2) and the event filter (EF). The L2 and EF together form the High-Level Trigger (HLT). According to the present physics trigger menu for initial running, diboson candidate events with multi-lepton final states will be recorded with single muon, single electron, dielectron and dimuon triggers. The trigger efficiencies for diboson events, defined as the fraction of events accepted by the analysis cuts that have satisfied the trigger requirements, are expected to be in a range of 95% - 100%, with the exception of a lower efficiency ( $\sim 80\%$ ) for  $W\gamma$  events. The events that are accepted by the trigger are used for the analysis results.

### 3.2 Boosted Decision Trees

A rather new multivariate analysis technique, *Boosted Decision Tree*, has been used in our analysis to improve the detection sensitivity for diboson signals. BDTs have been used in HEP data analysis in recent years [38], and details can be found in the Ref. [4]. A further development, allowing for weighted events, is used in these diboson physics studies [39].

The BDT technique involves a fast ‘training’ procedure for event pattern recognition. It works with a set of data including both *signal* and *background*. Data are represented by a set of physics variable distributions. A *decision-tree* splits data recursively based on *cuts* on the input variables until a stopping criterion is reached. Every event ends up in a *signal* (score=1) or a *background* (score=-1) *leaf* of the decision-tree. Misclassified events will be given larger weights in the next tree (boosting). This procedure is repeated several hundreds to thousands of times until the performance is optimal. The *discriminator* from the BDT training is the sum of the weighted scores from all the decision-trees. If the total score for a given event is relatively high this event is most likely a signal event, and if the score is low it is likely a background event.

### 3.3 $W^\pm Z \rightarrow \ell^\pm \nu \ell^+ \ell^-$ selection

The  $W^\pm Z$  production at hadron colliders uniquely probes the  $WWZ$  trilinear gauge boson coupling as shown in Figure 1, the Standard Model tree-level Feynman diagrams.

$W^\pm Z$  candidate events have three charged lepton final states, referred to as trileptons, produced when  $Z \rightarrow \ell^+ \ell^-$  and  $W^\pm \rightarrow \ell^\pm \nu$ , where  $\ell^\pm$  are  $e^\pm$  or  $\mu^\pm$ . Standard Model backgrounds can be highly suppressed by requiring three isolated high  $p_T$  leptons and large missing transverse energies ( $\cancel{E}_T$ ). However, the pure leptonic decay mode of the  $W^\pm Z$  events only has a 1.5% branching ratio [2]. The total cross-sections times the branching ratio are 442 fb and 276 fb for  $W^+ Z$  and  $W^- Z$ , respectively. Event selection with high efficiency is important for early observations of this channel.

Major backgrounds to the  $W^\pm Z$  trilepton final states come from  $ZZ \rightarrow \ell^+ \ell^- \ell^+ \ell^-$  with one lepton undetected;  $Z + X \rightarrow \ell^+ \ell^- + X$  ( $X$ =jets, or photon) with a jet or a photon faking a lepton; and  $t\bar{t} \rightarrow W^+ W^- b\bar{b} \rightarrow \ell + \ell + \ell + X$ .

After a trigger,  $W^\pm Z$  events are selected in two stages: (1) pre-selection with relatively loose cuts, and (2) final selection with tightened cuts or with BDT multivariate discriminator. The overall trigger efficiency for  $W^\pm Z$  events with trileptons in the final state is  $(98.9 \pm 1.0)\%$  using a combination of single lepton and dilepton triggers.

The pre-selection of the  $W^\pm Z$  events is done by identifying three leptons (at least one lepton with  $p_T > 25$  GeV) and requiring  $\cancel{E}_T > 15$  GeV in an event with characteristics consistent with  $Z$  dilepton decays ( $M_{\ell\ell} = (91.18 \pm 20)$  GeV) and  $W$  leptonic decays ( $10 \text{ GeV} < M_T(\ell, \cancel{E}_T) < 400$  GeV). The overall pre-selection efficiency for  $W^+ Z$  events is 26%, and for  $W^- Z$  events is 29%. The acceptance difference is due to the differing  $\eta$  distributions of the leptons decaying from  $W^+$  and  $W^-$ . After the preselection, the known background is about 70 times larger than the signal.

To bring the background level below the signal, a rejection power better than 100 in the second stage of event selections is required. To achieve this, events with  $\cancel{E}_T < 25$  GeV and with significant hadronic jet activities are rejected. Events must contain no more than one hadronic jet with  $E_T^{\text{jet}} > 30$  GeV and  $|\eta^{\text{jet}}| < 3.0$ . The transverse recoil of the  $W^\pm Z$  system, calculated using the vector sum of the  $p_T$  of the charged leptons and  $\cancel{E}_T$ , is required to be less than 120 GeV and the sum of the hadronic transverse energy must be less than 200 GeV. These requirements effectively reject the  $t\bar{t}$  and hadronic jet events. To reject the  $Z + X$  background, the third lepton (not from the  $Z$  boson decay)  $p_T$  is required to be greater than 20 GeV and 25 GeV for muons and electrons, respectively. Any pair of leptons must satisfy  $\Delta R = \sqrt{(\Delta\eta^2 + \Delta\phi^2)} > 0.2$ . Leptons must be isolated from other energy clusters based on calorimeter and inner tracker measurements. All three leptons must be associated with isolated tracks that originate

Table 5: Number of expected  $W^\pm Z$  signal ( $N_{WZ}$ ) and background ( $N_B$ ) for  $1 \text{ fb}^{-1}$  data with cut-based analysis.

	WZ	ZZ	$t\bar{t}$	Z+jet	Z+ $\gamma$	Drell-Yan	Total bkg	$N_{WZ}/N_B$
$N$ events	<b>53</b>	2.7	.023	1.9	0.18	2.5	<b>7.3</b>	7.3
% of background	-	37	.32	26	2.5	35	-	-

from the same collision point. The dilepton invariant mass best matching the mass of  $Z$  must be within the  $Z$ -mass window of  $|M_Z - M_{\mu\mu}| < 12 \text{ GeV}$  or  $|M_Z - M_{ee}| < 9 \text{ GeV}$ . These mass windows are set by the mass resolutions. The  $M_T$  determined by the third lepton and the  $\cancel{E}_T$  must be within the transverse  $W$ -mass window:  $40 \text{ GeV} < M_T < 120 \text{ GeV}$ .

The total and selected number of the signal and the background events for each trilepton final state, and for  $1 \text{ fb}^{-1}$  of integrated luminosity, are listed in Table 5. The overall signal efficiency is 8.7% and 7.1% for  $W^- Z$  and  $W^+ Z$ , respectively. For  $1 \text{ fb}^{-1}$  of data, 53  $W^\pm Z$  signal events and 7 background events are expected. The dominant background contributions are from ZZ, Z+jet and Drell-Yan processes, while  $Z\gamma$  and  $t\bar{t}$  contribute a small fraction of the total background events.

Table 6: Number of expected  $W^\pm Z$  signal ( $N_{WZ}$ ), and background ( $N_B$ ) for  $1 \text{ fb}^{-1}$  of data with BDT analysis using the cut  $\text{BDT} > 200$ .

	WZ	ZZ	$t\bar{t}$	Z+jet	Z+ $\gamma$	Other	Total bkg	$N_{WZ}/N_B$
$N$ events	<b>128</b>	7.7	2.8	2.5	2.0	1.1	<b>16</b>	7.9
% of background		48	17	16	12	7.0	-	-

For  $0.1 \text{ fb}^{-1}$  of integrated luminosity, only 5 signal events ( $N_S$ ) with 0.7 background event ( $N_B$ ) contamination are expected. The  $W^\pm Z$  detection significance, defined as the probability from Poisson distribution with mean  $N_B$  to observe equal or greater than  $N_S + N_B$  events, converted in equivalent number of sigmas (standard deviations) of a Gaussian distribution, will be  $3.6\sigma$  only. To improve the detection sensitivity, the BDT analysis technique is employed. This BDT analysis is conducted with a total of 1000 trees with 20 tree-split nodes. Based on the variables used in the cut-based analysis, and the BDT training Gini-index (a measure of a variable effectiveness in separating signal from background), a total of 22 kinematic and topology variables are selected for the BDT training. About 12000 pre-selected signal events and 18000 pre-selected background events are used in this BDT-based analysis, where 50% of the signal and background events are used for the training, and another 50% of statistically independent events allocated to the BDT test sample sets. The BDT output discriminator from the testing sample, used to separate the signals from the background, is shown in Figure 8 (right), see Section 4.1. This spectrum will be used to determine (fit) the  $W^\pm Z$  production cross-section.

Results of the  $W^\pm Z$  event selection with the cut  $\text{BDT} > 200$  are shown in Table 6. Expected numbers of signal and background events are given for  $1 \text{ fb}^{-1}$  of integrated luminosity. The estimated background uncertainties are 15-20% due to the limited number of simulated events available. The overall  $W^\pm Z$  event selection efficiency is about 13.7% for signal, resulting in 12.8 signal and 1.6 background events for  $0.1 \text{ fb}^{-1}$ . The  $W^\pm Z$  detection significance is expected to be  $5.9\sigma$  (including both statistical and 20% systematic uncertainties) for  $0.1 \text{ fb}^{-1}$  of integrated luminosity.

### 3.4 $W^\pm\gamma \rightarrow \ell^\pm\nu\gamma$ selection

The  $W^\pm\gamma$  signal events are modeled with PYTHIA, which includes tree-level diagrams as shown in Figure 1 for  $W$  production with initial state radiation (ISR) (the  $t$ - and  $u$ -channels) and the  $s$ -channel production depending on the triple-gauge-coupling  $WW\gamma$  vertex. The  $WW\gamma$  vertex introduces a destructive interference of *zero amplitude* at  $\cos\theta_{\bar{q},\gamma} = \pm 1/3$  for  $W^\pm$  production, where  $\theta_{\bar{q},\gamma}$  is the photon scattering angle to the incoming anti-quarks.

The  $W^\pm\gamma$  diboson events are selected from  $pp$  collisions using pure  $W$  leptonic decays. The experimental signature is a final states with one high  $p_T$  lepton (electron or muon), one high  $p_T$  photon and large  $\cancel{E}_T$ . Major backgrounds are from the processes:

- Inclusive  $W + X$  production with  $W + X \rightarrow \ell\gamma\nu + X$ , where the  $\gamma$  is from final state radiation (FSR) from the lepton.
- Inclusive  $W + X \rightarrow \ell\nu + X$  productions, with  $X = \text{jets}$  and the jets faking a photon.
- Inclusive  $Z + X \rightarrow \ell\ell + X$  productions, with one lepton escaping detection, and with  $X = \gamma$  or jets faking a photon.

A photon isolation cut is effective in suppressing these backgrounds.

To study the  $W^\pm\gamma$  detection sensitivity about 1.3 million inclusive  $W$  events and about 100,000 inclusive  $Z$  events were generated with the PYTHIA MC generator. In these datasets, the photon transverse energy threshold is 10 GeV and the lepton and photon separation,  $\Delta R(\ell, \gamma)$  was required to be greater than 0.7.

The  $W^\pm\gamma$  candidates are inclusive  $e^\pm\gamma$  or  $\mu^\pm\gamma$  events having one electron or muon observed and the absence of the oppositely charged lepton of the same flavor. The photon selected is the most energetic one in the events. Efficiencies for three trigger types are investigated: isolated muon with  $p_T > 20$  GeV, isolated electron with  $p_T > 22$  GeV and photon with  $E_T(\gamma) > 55$  GeV. The overall  $W^\pm\gamma$  trigger efficiency is about 80% based on our study.

Background to the  $W^\pm\gamma$  signal is dominated by inclusive  $W^\pm$  events with radiated jets faking a photon. Contamination from inclusive  $Z$  events with an undetected lepton is also significant. Figure 3 shows the  $W^\pm\gamma$  signal (first column) scatter plots compared to those for major backgrounds: the inclusive  $W$  events with final state radiation (FSR) (the 2nd column), and with fake photon (the third column), and the  $Z$  events with one lepton escaping detection and a photon of any type reconstructed (the 4th column).

The BDT method is used to select the  $W^\pm\gamma$  signal events. Three trainings are done to separate: 1) The  $\ell\gamma\nu$  events with FSR photons from other sources, 2) The  $W^\pm\gamma$  signal photons from fake photons, and 3) The signal photons from the contamination of  $Z$  inclusive events. Nineteen variables are used in the BDT analysis. Cuts are applied to the BDT output spectra for the three trainings. The cuts chosen for signal selection correspond to a  $W^\pm\gamma$  selection efficiency of 65% with a signal to background ratio of 0.95 (0.98) for electron (muon) final states, respectively. The numbers of events selected with the BDT cuts are listed in Table 7. The selected events are further required to pass the trigger requirements as the final accepted events, which are listed in the Table as well.

The BDT discriminates signal photons effectively from FSR and fake photons in the high  $E_T(\gamma)$  region. This preserves a high detection efficiency in the region that is sensitive to discovery of phenomenon beyond Standard Model predictions.

### 3.5 $W^+W^- \rightarrow \ell^+\nu\ell^-\nu$ selection

The production of  $W$  pairs has been investigated extensively at LEP and at the Tevatron. The experimental  $W^+W^-$  signature is two high transverse momentum leptons with opposite charge associated with

Figure 3: Distributions of the  $W^\pm(\mu^\pm\nu)\gamma$  event variables, with a photon from the  $W^\pm\gamma$  signal (ISR), and from backgrounds, FSR, fake  $\gamma$ , and inclusive  $Z$  contamination.

large transverse missing energy.  $W^+W^-$  production involves both  $WWZ$  and  $WW\gamma$  triple gauge boson couplings and is most sensitive to the  $\Delta\kappa_V$  anomalous coupling parameters. Furthermore, the  $W$  pair production provides an important background to Higgs boson searches in the  $pp \rightarrow H \rightarrow WW^{(*)} \rightarrow \ell\nu\ell\nu$  channel at the LHC. In dileptonic  $W$ -decays no Higgs mass peak can be reconstructed, so this background cannot be estimated from the measured data via sideband interpolation. An understanding of the irreducible  $W$ -pair continuum background is therefore crucial.

At the LHC the major background processes ( $t\bar{t}$ , inclusive  $W$  and  $Z$ , and Drell-Yan) have much higher cross-sections than  $W^+W^-$ . It will be necessary to achieve very high background rejection power to suppress the events with mis-identified leptons (from jet, photon and instrumentation effects) and leptonic decays from heavy-flavor quark jets. In the Drell-Yan process the mis-measured  $\cancel{E}_T$  also contributes non-negligible background.

Event selection consists of the trigger, pre-selection (two high  $p_T$  leptons plus  $\cancel{E}_T$ ), and final selection with a set of conventional cuts or with BDT selection cuts. The  $W^+W^-$  events are required to pass one of two high-level trigger paths: a single, isolated electron with  $p_t > 25$  GeV or a single muon, with  $p_t > 20$  GeV. The trigger efficiencies for  $WW \rightarrow ee$ ,  $WW \rightarrow \mu\mu$  and  $WW \rightarrow e\mu$  events with two opposite sign isolated leptons ( $p_T > 20$  GeV,  $|\eta| < 2.5$ ) are estimated as follows: 98.2 %, 95.9%; and 97.4% respectively.

The cut-based analysis rejects background events with tight lepton identification criteria and isolation requirements as well as with event topology variables which clearly distinguish the signal and significantly suppress the main background processes  $t\bar{t}$  and  $Z + X$ . The  $W^+W^-$  leptonic decay events are selected by requiring two well identified isolated leptons with opposite charge, and with  $p_T^\ell > 20$  GeV and  $|\eta| < 2.5$ . A jet veto requirement rejects events with any jet ( $p_T^{jet} > 20$  GeV) in the rapid-

Table 7: The number of  $W^\pm\gamma$  signal and background events after pre-selection, BDT selection and trigger requirement, for an integrated luminosity of  $1 \text{ fb}^{-1}$ . The signal and total background are then scaled to NLO cross-sections with the k-factors indicated. For the signal, the k-factor is obtained using BosoMC. For background, the k-factors are obtained by comparing the cross-sections calculated with *MC@NLO* and PYTHIA generators.

		Signal $W^\pm\gamma$	Background			Total
			W+FSR_ $\gamma$	W+fake_ $\gamma$	$Z(\ell\ell)\gamma$	
$\ell = e$	Pre-selected	1710	11440	7890	32480	
	BDT selection	1145	242	791	101	
	Triggered	966	188	628	93	
	NLO scaled	1604 (k=1.66)				1183 (k=1.3)
$\ell = \mu$	Pre-selected	2680	28410	10250	3950	
	BDT selection	1793	413	961	409	
	Triggered	1305	177	595	260	
	NLO scaled	2166 (k=1.66)				1342 (k=1.3)

ity region  $|\eta| < 3$ . This cut is efficient in  $t\bar{t}$  suppression since  $t\bar{t}$  contains one or two energetic  $b$  jets in addition to the  $W^+W^-$  signature. An event with  $\cancel{E}_T < 50 \text{ GeV}$  is rejected to reduce the background arising from the event pileup and from  $Z/\gamma^*$  events in the Drell-Yan process. To reject the dilepton events from inclusive  $Z$  production, a  $Z$  mass veto is applied. Finally, angular variable cuts are imposed. For cross-section measurements, events must pass a cut:  $\phi_{\ell\ell} < 2 \text{ rad}$ , where  $\phi_{\ell\ell}$  is the angle between the transverse momentum of the two leptons. For anomalous TGC studies, this cut is replaced with:  $\Phi(\mathbf{p}_T^{\ell^+, \ell^-}, \mathbf{p}_T^{\text{miss}}) > 175 \text{ deg}$ , where  $\Phi$  is the angle between the transverse momenta of the lepton pair, and the missing transverse momentum. The first angular cut (selection-A) results in high signal detection efficiency, but it is not optimized for high  $p_T(\ell)$  and  $p_T(\ell\ell)$  event detection and thus could decrease the sensitivity to anomalous TGC's. The second angular cut (selection-B) results in lower signal detection efficiencies, but has higher efficiency for high  $p_T(\ell)$  and  $p_T(\ell\ell)$  events. The yields of the  $W^+W^-$  selection with the cut-based analysis are summarized in Table 8. Both signal and background events are normalized to  $1 \text{ fb}^{-1}$  of data. Figure 4 shows the transverse momentum distributions of leptons (left) and lepton pairs (right) after applying the kinematic cuts of Selection-B. The distributions are shown for sum of signal and various backgrounds, and for individual backgrounds, for an integrated luminosity of  $1 \text{ fb}^{-1}$  of data.

The  $W^+W^-$  overall signal detection efficiency is 1.4-3%, depending on the selection cuts and the final lepton states. The signal detection significance for  $0.1 \text{ fb}^{-1}$  of data is expected to be  $4.7\sigma$  (for Selection A), after taking into account a 20% background systematic uncertainty. The detection efficiencies can be improved by using the multivariate BDT technique. In this  $W^+W^-$  analysis one thousand decision trees, wherein one tree has 20 *splitting-nodes*, are used to separate signal from background based on the input variables. The input data for the BDT analysis must first pass the pre-selection cuts (two leptons with  $p_T^\ell > 10 \text{ GeV}$  and  $\cancel{E}_T > 15 \text{ GeV}$ ). The pre-selected simulated samples are divided into two equal parts: one sample is used for BDT training and the other to test event selection performance. The BDT output spectra for both signal and background are shown in Figure 8 (left). By varying the location of the cut along the BDT *scores* ( $x$ -axis), the signal to background ratio can be optimized. Table 9 presents the detection sensitivities with total integrated luminosity of  $1 \text{ fb}^{-1}$ : the selected number of signal events ( $N_{WW}$ ), the corresponding signal efficiency ( $\epsilon_{WW}$ ), the number of background ( $N_{bkg.}$ ) events, and signal to background ratio ( $N_{WW}/N_{bkg.}$ ) are shown. The breakdown of background contributions are also given

Table 8: Yield and total event detection efficiency of the WW selection for  $1 \text{ fb}^{-1}$  of data. The errors shown are statistical only.

Selection-A	efficiency		$N_{WW}$		$N_{\text{background}}$	$N_{\text{sig.}}/N_{\text{bkg.}}$
	$gg \rightarrow WW$	$q\bar{q} \rightarrow WW$	$gg \rightarrow WW$	$q\bar{q} \rightarrow WW$		
$ee$	2.1%	1.3%	$1.3 \pm 0.05$	$17.4 \pm 1.1$	$1.4 \pm 0.3$	$13.3 \pm 3.0$
$\mu\mu$	4.1%	2.8%	$2.4 \pm 0.08$	$36.4 \pm 2.2$	$10.7 \pm 2.1$	$3.6 \pm 0.8$
$e\mu$	2.8%	1.9%	$3.3 \pm 0.13$	$50.6 \pm 1.8$	$7.2 \pm 1.2$	$7.5 \pm 1.3$
$ll$	3.0%	2.0%	$7.0 \pm 0.16$	$104.4 \pm 2.4$	$19.3 \pm 2.4$	$5.8 \pm 0.8$
Selection-B						
$ee$	0.94%	0.92%	$0.6 \pm 0.04$	$12.0 \pm 0.9$	$2.8 \pm 1.2$	$4.5 \pm 1.9$
$\mu\mu$	2.1%	2.0%	$1.1 \pm 0.03$	$25.5 \pm 1.8$	$4.8 \pm 1.0$	$5.5 \pm 1.2$
$e\mu$	1.3%	1.4%	$1.5 \pm 0.09$	$35.3 \pm 1.5$	$7.4 \pm 1.3$	$5.0 \pm 0.9$
$ll$	1.4%	1.4%	$3.2 \pm 0.10$	$72.8 \pm 2.5$	$15.0 \pm 2.0$	$5.1 \pm 0.8$

Figure 4: Transverse momentum distributions of leptons (left) and lepton pairs (right) after applying kinematic cuts from Selection-B. The distributions are shown for sum of signal and various backgrounds, and for separated backgrounds for  $L=1 \text{ fb}^{-1}$ .

in this table. For initial measurements using early LHC data based on  $0.1 \text{ fb}^{-1}$  of integrated luminosity, the application of BDT is compelling. As inferred from Table 8, the initial data is expected to yield a total for all decay channels of  $\sim 10$  signal events using conventional cuts, whereas the BDT-based analysis, which gives a similar signal to background ratio as the conventional cuts is expect to yield total 47 signal events. With an estimated background contribution of 9.2 events the  $W^+W^-$  detection significance is about  $10\sigma$  (including 20% background systematic uncertainties).

### 3.6 $Z\gamma \rightarrow \ell^+\ell^-\gamma$ selection

$Z\gamma$  signals are produced through initial state radiation (ISR) of the photon from the quarks as illustrated by the  $t$ - and  $u$ -channel diagrams shown in Figure 1. The  $s$ -channel  $Z\gamma$  production contains the  $Z\gamma V$  ( $V = Z, \gamma$ ) vertex, which is forbidden at tree-level in the Standard Model. The cross-section measurement of the  $Z\gamma$  production would provide a sensitive probe to anomalous  $Z\gamma V$  couplings, which can be investigated through this channel by measuring the  $E_T(\gamma)$  distribution, especially at large values.

The cleanest  $Z\gamma$  experimental signature is two high  $p_T$  leptons from the decay of the  $Z$  boson and an

Table 9:  $WW \rightarrow$  leptons detection sensitivities of accepted signal and background events for  $1 \text{ fb}^{-1}$  of integrated luminosity. Results from the BDT analysis are shown with cuts that give similar signal to background ratio as the cut-based analysis. The quoted efficiencies in the table are the BDT selection efficiencies including the trigger requirements based on pre-selected events.

Modes	$\epsilon_{WW}(\%)$	$N_{WW}$	$N_{bkg}$	Background fraction			$N_{WW}/N_{bkg}$
				$t\bar{t}$	$W^\pm Z$	$Z + X$	
$e\nu\mu\nu$	32.7	$347 \pm 3$	$64 \pm 5$	47.7%	27.8%	21.8%	5.4
$\mu\nu\mu\nu$	12.1	$70 \pm 2$	$17 \pm 2$	54.1%	34.6%	11.3%	4.1
$e\nu e\nu$	13.7	$52 \pm 1$	$11 \pm 1$	81.4%	7.2%	11.4%	4.7

isolated high  $p_T$  photon (from ISR). The backgrounds to this  $Z\gamma$  signal are: 1) the  $Z$  boson production with a FSR photon from the leptons decay from the  $Z$ , 2) the  $Z$  boson production with a fake photon from jets, and 3) a small contamination from  $W + X$  production reconstructed as a  $\ell^+\ell^-\gamma$  final state. Some of the event variables for different photon sources are shown in Figure 5.

Events are pre-selected with  $E_T(\gamma) > 10 \text{ GeV}$ , a value chosen to be above the PYTHIA generator threshold and as low as is reasonably achievable by detector reconstruction. The FSR event rate is almost an order of magnitude higher than the ISR rate in the inclusive  $Z$  production process. Backgrounds with a  $Z$  boson and a fake photon are comparable to the  $Z\gamma$  signal photon rate.

The event selection is conducted with BDTs trained to separate  $Z\gamma$  events of different photon types. The training is in two stages: first to identify the FSR photon background events and then to distinguish the signal (ISR) photon from  $Z$  events with fake photons. Separate BDT training is done for the electron and muon  $Z$  decay channels.

The BDTs are trained with 19 variables in total. As one example, FSR photons can be identified from the opening angle from the nearest lepton. Fake photons originating from high  $p_T$  neutral mesons decaying to two photons can not be directly identified within the limits of the spatial resolution provided by the ECAL segmentation. However, they are often accompanied by jet secondaries or underlying remnant particles. By counting the charged tracks in a neighborhood (a cone of  $0.45 \text{ rad}$  in this case), or summing their energies, parameters useful for differentiating background from isolated ISR photons can be formed.

With the chosen BDT cuts the signal selection efficiency is 67%, and the signal to background ratio is 2.0 and 1.8 for the electron and muon  $Z$  decay channels, respectively. The estimated numbers of reconstructed  $Z\gamma$  candidates for an integrated luminosity of  $1 \text{ fb}^{-1}$  are listed in Table 10.

The FSR and fake photons contribute approximately equally to the total background but have important distinctions. The fake photons populate the low  $E_T(\gamma)$  region, and are differentiated from the signal photon (ISR) in the  $E_T(\gamma) > 20 \text{ GeV}$  region. The shape of the  $E_T$  distribution in the low energy region is important for calibration and measurement of the production cross-section with ISR photons. On the other hand, the FSR photons have an  $E_T(\gamma)$  distribution similar to the ISR photons which carry signatures of the coupling to the colliding quarks. Event rates in the high  $E_T(\gamma)$  region, where the background is primarily FSR, is an important probe of new physics phenomena.

### 3.7 $ZZ \rightarrow \ell^+\ell^-\ell^+\ell^-$ selection

The cleanest experimental signature for  $ZZ$  detection is through the four lepton decay channels:

$$pp \rightarrow ZZ \rightarrow e^+e^-e^+e^-, \mu^+\mu^-\mu^+\mu^-, e^+e^-\mu^+\mu^-.$$

Figure 5: Distributions of  $Z(ee)\gamma$  event variables for ISR (left column), FSR (middle column.) and fake photons (right column).

The  $ZZ \rightarrow 4\ell'$  ( $\ell' = e, \mu, \tau$ ) signal is modeled at LO by the PYTHIA event generator using the CTEQ6L PDF. The  $Z/\gamma^*$  interference terms are included in the generator. With the 12 GeV mass cut on the dileptons decay from  $Z/\gamma^*$ , the cross-section times the dilepton decay branching ratio,  $\sigma \times BR$  is 159 fb. A filter is applied to the simulated data to pre-select four lepton ( $e$  and  $\mu$  only) events by requiring that the lepton transverse momenta must be greater than 5 GeV, and the lepton rapidity,  $\eta_\ell$ , must be in a range  $|\eta_\ell| < 2.7$ . The overall filter efficiency is 0.219. The  $\tau$  lepton contribution to the four lepton channels ( $4e, 4\mu, 2e2\mu$ ) is less than 4% in the event sample after the filter. The fraction of the on-shell  $ZZ$  events (both lepton pair masses are between 70 GeV to 110 GeV) in the sample is about 73%. Next-to-leading-order calculations give higher production cross-sections. The k-factor is about 1.35 when both  $Z$ 's are on mass shell. However, when the  $Z/\gamma^*$  are off the  $Z$  mass shell, the k-factor varies from 1.15 to 1.52 for the  $(Z/\gamma^*)(Z/\gamma^*)$  mass range from 115 GeV to 405 GeV, which is determined by using the MCFM Monte Carlo calculations [11]. The k-factor is set constant at 1.35 to normalize the  $ZZ \rightarrow 4\ell$  signal events. The four-lepton events have high trigger efficiencies close to 100%.

Major background processes for four lepton final states are  $t\bar{t} \rightarrow WWb\bar{b} \rightarrow 4\ell + X$  and  $Zb\bar{b} \rightarrow 4\ell + X$ . The  $t\bar{t}$  background events, generated using *MC@NLO*, has a total production cross-section of 833 pb. The  $Zb\bar{b}$  background events are generated using *AcerMC*, with cross-section scaled to NLO by a k-

Table 10: The number of  $Z\gamma$  signal and background events after pre-selection and BDT selection is listed, for an integrated luminosity of  $1 \text{ fb}^{-1}$ . The signal and total background are then scaled to NLO cross-sections with the k-factors indicated. For the signal, the k-factor is obtained using BHO.

		Signal		Background		
		$Z\gamma$	$Z+\text{FSR}_\gamma$	$Z+\text{fake}_\gamma$	$W(l\nu)\gamma$	Total
$\ell = e$	Pre-selected	430	2760	490	44	
	BDT selection	288	70	74	0	
	Triggered	282	65	79	0	
	NLO scaled	367 (k=1.3)				187 (k=1.3)
$\ell = \mu$	Pre-selected	950	7500	790	930	
	BDT selection	636	173	186	0	
	Triggered	578	164	165	0	
	NLO scaled	751 (k=1.3)				429 (k=1.3)

Figure 6: The four-lepton invariant mass distributions of  $ZZ$  signal,  $Zb\bar{b}$  and  $t\bar{t}$  background events with tight (left) and loose (right)  $Z$  mass cut on the lepton pairs. The number of events correspond to an integrated luminosity of  $10 \text{ fb}^{-1}$ .

factor. Leptons from  $b$  quark decays in these processes are produced in association with hadrons. Their contributions can be highly suppressed by lepton isolation requirements. For muons, the ratio between the transverse energy deposited in a cone around the muon track of radius  $\Delta R = 0.4$  and the transverse energy of the muon  $E_T^\mu$  must be below 0.2. A similar isolation cut is applied to the electron selections. To reject background with leptons not originating from the  $Z$  decays, the two opposite sign lepton pairs must have at least one lepton with  $p_T$  greater than 20 GeV, and at least one lepton pair must have the invariant mass between 70 GeV- 110 GeV. This is referred to as the loose  $Z$  mass cut. A tight  $Z$  mass cut requires the second lepton pair also to have invariant mass between 70 GeV- 110 GeV. The separation between the two leptons must be  $\Delta R(\ell^+\ell^-) > 0.2$ . Table 11 lists the signal selection cut efficiencies for all the four lepton final states. Each cut efficiency value is relative to the previous selection. The quoted uncertainties of the selected numbers of events are statistical only.

The total selection efficiencies for the  $Zb\bar{b}$  background using these same tight cuts are  $0.13\% \pm 0.06\%$ ,  $0.61\% \pm 0.14\%$ , and  $0.51\% \pm 0.13\%$  for the  $4\mu$ ,  $4e$ , and  $2\mu 2e$  channels, respectively. For  $t\bar{t}$  these efficiencies are  $0.07\% \pm 0.07\%$  for all three channels. The expected number of signal and background events for  $L = 1 \text{ fb}^{-1}$  requiring tight  $Z$  mass cut are given in Table 12. The expected signal and

Table 11:  $ZZ \rightarrow \ell^+ \ell^- \ell^+ \ell^-$  signal selection cut efficiencies

background events with only one on-shell Z (Loose Z mass cut) are in Table 13. Uncertainties quoted in these tables are statistical only. Figure 6 shows the four-lepton invariant mass distributions for the  $ZZ$  signal,  $Zb\bar{b}$  and  $t\bar{t}$  background with tight and loose Z mass cut on the lepton pairs. Based on these results the ATLAS experiment will establish the  $ZZ \rightarrow 4\ell$  signal with a significance of  $6.8\sigma$  (after taking into account 20% background systematic errors) with the first  $1 \text{ fb}^{-1}$  of integrated luminosity.

### 3.8 $ZZ \rightarrow \ell^+ \ell^- \nu \bar{\nu}$ selection

The  $ZZ \rightarrow \ell^+ \ell^- \nu \bar{\nu}$  signature is two high- $p_T$  charged leptons with a large missing transverse energy ( $\cancel{E}_T$ ) due to the neutrino pair leaving the detector. The main backgrounds will either come from channels with large cross sections, such as  $t\bar{t}$  and  $Z \rightarrow \ell^+ \ell^-$ , or those with a similar signature to the signal, such as the  $W^\pm Z$  diboson channel. Both signal ( $ZZ \rightarrow \ell^+ \ell^- \nu \bar{\nu}$ ) and background ( $t\bar{t}$ ,  $W^\pm Z$ ,  $W^+ W^-$ , and Drell-Yan dileptons) are modeled by the generator *MC@NLO*, except for high  $p_T$   $Z$  ( $p_T(Z) > 100 \text{ GeV}$ ) events which are modeled by *PYTHIA*.

To reduce the backgrounds, a set of simple cuts on discriminating parameters is invoked. In general, each cut is used to suppress a particular background channel, as described below.

First, two oppositely charged good quality leptons with  $p_T > 20 \text{ GeV}$  are selected. This reduces much

Table 13: Expected  $ZZ \rightarrow \ell^+ \ell^- \ell^+ \ell^-$  signal and background events at  $L = 1 \text{ fb}^{-1}$  using the loose Z mass cut.

	$4\mu$ events	$4e$ events	$2\mu 2e$ events	Total
Signal	$5.7 \pm 0.06$	$3.2 \pm 0.04$	$7.6 \pm 0.07$	$16.5 \pm 0.1$
$Zb\bar{b}$	$0.1 \pm 0.01$	$0.5 \pm 0.02$	$0.3 \pm 0.02$	$0.9 \pm 0.1$
$t\bar{t}$	$0.1 \pm 0.06$	$0.5 \pm 0.14$	$0.4 \pm 0.13$	$1.0 \pm 0.2$
Total background	$0.2 \pm 0.06$	$1.0 \pm 0.14$	$0.7 \pm 0.13$	$1.9 \pm 0.2$

of the  $t\bar{t}$  background which contains softer leptons than the signal. This cut also reduces the background from  $Z \rightarrow \tau^+\tau^- \rightarrow \ell^+\ell^- \nu_\ell \bar{\nu}_\ell \nu_\tau \bar{\nu}_\tau$  as the electrons and muons are produced with reduced  $p_T$ . The leptons must also lie within the inner detector pseudorapidity range,  $|\eta| < 2.5$ .

The charged lepton pairs are required to have an invariant mass close to the  $Z$  mass, specifically  $|M_{\ell\ell} - 91.2 \text{ GeV}| < 10 \text{ GeV}$ . This is equivalent to  $\sim 5\sigma$  of the signal width, and helps to reduce background combinatorics where the lepton pair does not come directly from a  $Z$  decay. A lepton veto is imposed by combining the good quality and loose lepton selection to remove any events with more than two leptons in total. This reduces background from the  $W^\pm Z$  channel, whose  $Z$  has an almost identical signature to the signal, and the neutrino from  $W$  decay also appears as  $\cancel{E}_T$ . The third-lepton veto suppresses the  $W^\pm Z$  background by  $\sim 30\%$ . If the lepton from the  $W$  is not reconstructed, however, this background channel becomes almost indistinguishable from the signal.

A main characteristic of the signal decay is a large missing transverse energy ( $\cancel{E}_T$ ) from the  $Z \rightarrow \nu\bar{\nu}$  decay. An important background, due to its large cross section, comes from the  $Z \rightarrow \ell^+\ell^-$  Drell-Yan process, where jets are produced in addition to the leptons. If these jets are aligned with cracks in the detector, then they will fake  $\cancel{E}_T$  as they will not be fully accounted for in the calorimeters. This background can be significantly reduced by applying a 50 GeV  $\cancel{E}_T$  cut. The background from  $ZZ \rightarrow 4\ell$  is also reduced, but this is less significant as it has a much smaller cross-section. The  $W^\pm Z$  channel is suppressed by this cut as only one neutrino is produced, and hence the  $\cancel{E}_T$  distribution is slightly softer.

Figure 7: The  $\cancel{E}_T - p_T(Z)$  magnitude (left) and angle matching (right) distributions before cuts for  $ZZ \rightarrow 4\ell$  (solid),  $Z \rightarrow \ell^+\ell^-$  (dash) and  $W^\pm Z$  (dot). The plots are normalised to unit area for comparison of distribution shapes.

The signal is expected to have missing  $p_T$  equal and opposite to that of the reconstructed  $Z$ , when the  $ZZ$  pair is produced with no initial  $p_T$  and they decay back-to-back. Figure 7 (left and right) shows a clear peak in the signal for both magnitude and angle matches. The  $W^\pm Z$  background shows a worse magnitude match as some of the  $W$  momentum is lost to either an electron or muon on decay. This means that the missing  $p_T$  will not quite match up with that of the recoiling  $Z$ . The angular distribution shows a peak in both the  $W^\pm Z$  and  $Z \rightarrow \ell\ell$  channels. In the case of  $W^\pm Z$ , this is because the  $W$  and  $Z$  are produced in approximately opposite directions. When the  $W$  decays, the neutrino will be deflected and so the peak has a wider distribution. In a similar way, in  $Z \rightarrow \ell\ell$ , the  $Z$  is likely to be produced with some quarks recoiling against it. These will manifest themselves as jets which can fake  $\cancel{E}_T$ . Cuts at  $(|\cancel{E}_T - p_T(Z)|)/p_T(Z) < 0.35$  and  $145^\circ < \phi_{\cancel{E}_T} - \phi_Z < 215^\circ$ , reduce the  $W^\pm Z$  background.

A jet veto reduces backgrounds with large hadronic activity. For example, the predominant decay channel for the top quark in  $t\bar{t}$  is the  $t \rightarrow Wb$  final state, resulting in several high  $p_T$  jets. Its contribution can be reduced by applying a veto on events containing any jet with  $p_T^{\text{jet}} > 30 \text{ GeV}$  and  $|\eta^{\text{jet}}| < 3.0$ .

The final cut to be applied is on the  $p_T$  of the reconstructed  $Z$  boson. This reduces the background

Table 14: Cut flow table for  $ZZ \rightarrow \ell^+ \ell^- \nu \bar{\nu}$  signal and background after cuts for an integrated luminosity of  $1 \text{ fb}^{-1}$ . The values in brackets indicate the percentage of events passing each cut relative to the previous cut. Note that this  $Z \rightarrow ll$  MC sample already requires  $p_T(Z) > 100 \text{ GeV}$ .

Table 15: The expected  $ZZ \rightarrow \ell^+ \ell^- \nu \bar{\nu}$  signal yields and total signal selection efficiency for  $1 \text{ fb}^{-1}$  of integrated luminosity. The errors shown are statistical only.

$N_{\text{signal}}$	Signal efficiency	$N_{\text{background}}$	$N_S/N_B$
$10.2 \pm 0.2$	2.6%	$5.2 \pm 2.6$	$2.0 \pm 0.8$

from the single  $Z$  channel, whose  $p_T(Z)$  distribution drops much faster than the signal. A cut of  $p_T(Z) > 100 \text{ GeV}$  significantly reduces this background, and has a negligible effect on the sensitivity to anomalous couplings, which predominantly manifest at high  $p_T$ .

Using the single isolated electron trigger (effective  $E_T > 22 \text{ GeV}$ ) and the single isolated muon trigger (effective  $p_T > 20 \text{ GeV}$ ), the trigger efficiency for selected  $ZZ \rightarrow \ell^+ \ell^- \nu \bar{\nu}$  events is expected to be 97%.

Table 14 gives a summary of the cuts applied and presents the expected number of events passing the cuts. The final row in each column gives the statistical error. If no events pass cuts, the figure given is the number of expected events at the 90% confidence level. The dominant background is  $t\bar{t}$ . Table 15 summarizes the expected yield and sensitivity of the  $ZZ \rightarrow \ell^+ \ell^- \nu \bar{\nu}$  channel.

## 4 Total cross section measurements

A binned likelihood method is used to determine the most likely cross-sections. This likelihood method is also used to extract the sensitivities to the anomalous TGCs which will be described in Section 5. The likelihood is based on Poisson statistics convoluted with Gaussian probabilities to model the signal and background uncertainties. What follows is a more detailed description of the binned likelihood method followed by a description of the statistical and systematic uncertainties for the diboson cross-section measurements using the first  $1.0 \text{ fb}^{-1}$  of data.

#### 4.1 Binned likelihood

In the binned likelihood method, expected events are determined from high statistics Monte Carlo simulation, and observed events are also determined from Monte Carlo simulation for this work, but with appropriate statistical fluctuation according to the luminosity. The events are binned by one or more observables. As an example, in the case of the cross-section measurement the BDT output spectrum, an example of which is shown in Figure 8, could be used. In the TGC analysis described in Section 5 the  $M_T(VV)$  and  $p_T(V)$  spectra are chosen.

For each bin expected signal and background are compared to the observed number of events ( $n$  events in the bin) with a likelihood, which is based on Poisson statistics. We assume the systematic uncertainties of the signal and background are Gaussian and uncorrelated for each bin. Thus, two Gaussian distributions are convolved with the Poisson distribution to form the likelihood

$$L = \int_{1-3\sigma_b}^{1+3\sigma_b} \int_{1-3\sigma_s}^{1+3\sigma_s} g_s g_b \frac{(f_s v_s + f_b v_b)^n e^{-(f_s v_s + f_b v_b)}}{n!} df_s df_b \quad \text{with} \quad g_i = \frac{e^{(1-f_i)^2/2\sigma_i^2}}{\int_0^1 e^{(1-f_i)^2/2\sigma_i^2} (i=s,b)},$$

here the total systematic uncertainty of signal and background appear as  $\sigma_s$  and  $\sigma_b$ , respectively.

From these likelihoods a total log-likelihood is formed from all the bin likelihoods. Some processes may also be separated into multiple channels (such as the three decay combinations of  $WW \rightarrow ee, e\mu, \mu\mu$ ). Also, a factor of -2 is included to make this test statistic comparable to a chi-squared distribution. Thus, the negative log-likelihood is

$$-2\ln L = -2 \sum_{k=\text{channels}} \sum_{i=\text{bins}} \log(L_i^k).$$

In cross-section measurements, the likelihood is determined as a function of cross-section in each bin of a measured spectrum for each channel (e.g. the BDT output spectrum for the  $W^+W^- \rightarrow e\nu\mu\nu$  channel as shown on the left in Figure 8). The log-likelihoods are then combined and the minimum of the negative log-likelihood determines the most likely cross-section (or anomalous TGC). The 68% C.L. limits ( $\pm 1\sigma$ ) are taken from the minimum of the negative log-likelihood plus 1.0. To set the 95% confidence-level interval of the anomalous TGC limits, likelihood minimum+1.92 is taken when fitting one parameter, and the minimum+2.99 for a fit of two parameters (e.g. two independent anomalous couplings).

#### 4.2 Statistical uncertainties

Based on the diboson event selections described in Section 3, the expected number of signal and background events for  $1 \text{ fb}^{-1}$ , and the expected detection significance of observing the Standard Model signals, are summarized in Table 16, after taking into account the known background contributions and 20% systematic uncertainties of the background estimate. The expected signal statistical uncertainties are also given in the 5<sup>th</sup> column of the table. For  $1 \text{ fb}^{-1}$  they range from 2.1% to 31% depending on the channel.

For early LHC data with  $0.1 \text{ fb}^{-1}$  integrated luminosity, the statistical uncertainties are large. However, based on BDT analysis, with an assumption of a 20% systematic uncertainty, the signal detection significances could reach  $9.9\sigma$  and  $5.9\sigma$  for  $W^+W^-$  and  $W^\pm Z$ , respectively. The overall detection significance is expected to be greater than  $10\sigma$  for both  $W^\pm\gamma$  and  $Z\gamma$  signals with  $0.1 \text{ fb}^{-1}$  of data.

#### 4.3 Systematic uncertainties

The major theoretical uncertainties on the production cross-sections come from the PDF uncertainties and the QCD factorization scaling uncertainties (for NLO calculations). By varying the PDF's and scale values for  $W^+W^-$ ,  $W^\pm Z$ , and  $ZZ$  cross-section calculations, the differences of the calculated cross-sections are found to range from 3.4% to 6.2%.

Figure 8: BDT-output spectra from a Monte Carlo experiment for  $W^+W^-$  (left) and  $W^\pm Z$  (right) detection with  $1 \text{ fb}^{-1}$ . The dots in the plots are Monte Carlo ‘mock data’. The dashed histograms represent the signal and the dotted, background.

The major experimental systematic effects in the cross-section measurements arise from the uncertainties of the luminosity determination, the lepton identification efficiencies and energy/momentum resolutions, the jet energy scale and resolutions, and background model and estimate.

A promising possibility for the precise determination of the luminosity is to use the  $W$  and  $Z$  production and leptonic decays. The estimates show that in this way the luminosity uncertainties could be controlled to  $\sim 5\%$  [40]. It should be noted that a 6.5% luminosity uncertainty was quoted in Tevatron Run II physics papers.

The lepton acceptance uncertainty is about 2-3% mainly due to the isolation requirement which involves the hadronic jet energy uncertainties. The lepton trigger efficiency uncertainties also contribute. With large  $Z$  samples, this uncertainty could be minimized.  $Z$  decays can typically be triggered and identified using only one of the two decay leptons. This leaves the second lepton unbiased from the point of view of trigger and offline identification. The rate at which the unbiased lepton passes the trigger and ID requirements provides a measurement of the respective efficiencies.

In the studies using the ATLAS simulated events the background estimate dominates the systematics with uncertainties of 15-25% for all the diboson channels except for the  $ZZ \rightarrow \ell^+ \ell^- \ell^+ \ell^-$  channel, where the background uncertainty should be less than 2%. Even though more than 30 million fully simulated events are used to estimate the background, the analyses are still largely limited by  $W + \text{jets}$  event sample statistics in the diboson background estimate. Tevatron experiments have used data to estimate the background, and typical uncertainties for diboson physics analyses are around 10% for  $1 \text{ fb}^{-1}$  of data. With early LHC data ( $0.1 \text{ fb}^{-1}$ ), the background estimate uncertainty would be comparable to current Tevatron diboson background uncertainties, and with more data the uncertainties of the background estimate should decrease.

The lepton and jet energy resolution uncertainties will contribute to additional background estimate uncertainties which will further propagate to the cross-section measurement uncertainties. A study has been performed in  $W^\pm Z$  analysis to estimate the size of such uncertainties. In this study, the  $W^\pm Z$  BDTs are first trained with Monte Carlo signal and background events simulated with the ‘standard’ detector energy resolutions and calibrated energy scale. For independent test samples, 10% and 3% are added to the jet and lepton energy resolutions, respectively, and the reconstructed energy related quantities are

Table 16: Summary of signal and background of all diboson final states ( $\ell$  denotes  $e$  and  $\mu$ ) for  $1 \text{ fb}^{-1}$  of integrated luminosity. The 4th column indicates the overall signal selection efficiency and the type of analysis, The 5th column gives the signal statistical uncertainty. The last two columns indicate the  $p$ -value and the significance (in Gaussian standard deviations) where  $p$ -value is the probability of the background fluctuating to the expected total observation assuming 20% systematic uncertainties.

Diboson mode	Signal	Background	Signal eff.	$\sigma_{stat}^{signal}$	$p$ -value	Sig.
$W^+W^- \rightarrow e^\pm \nu \mu^\mp \nu$	$347 \pm 3$	$64 \pm 5$	12.6% (BDT)	5.4%	$3.6 \times 10^{-166}$	27.4

$W^+W^- \rightarrow e^\pm \nu e^\mp \nu$	$52 \pm 1$	$11 \pm 2$	4.9% (BDT)	13.9%	$1.9 \times 10^{-24}$	10.1
$W^+W^- \rightarrow \ell^\pm \nu \ell^\mp \nu$	$103 \pm 3$	$17 \pm 2$	2.0% (cuts)	9.9%	$1.4 \times 10^{-54}$	15.5
$W^\pm Z \rightarrow \ell^\pm \nu \ell^\pm \ell^-$	$128 \pm 2$	$16 \pm 3$	15.2% (BDT)	8.8%	$3.0 \times 10^{-76}$	18.4
	$53 \pm 2$	$8 \pm 1$	6.3% (cuts)	13.7%	$3.1 \times 10^{-30}$	11.4
$ZZ \rightarrow 4\ell$	$17 \pm 0.5$	$2 \pm 0.2$	7.7% (cuts)	24.6%	$6.0 \times 10^{-12}$	6.8
$ZZ \rightarrow \ell^+ \ell^- \nu \bar{\nu}$	$10 \pm 0.2$	$5 \pm 2$	2.6% (cuts)	31.3%	$7.7 \times 10^{-4}$	3.2
$W\gamma \rightarrow e\nu\gamma$	$1604 \pm 65$	$1180 \pm 120$	5.7% (BDT)	2.5%	significance > 30	
$W\gamma \rightarrow \mu\nu\gamma$	$2166 \pm 88$	$1340 \pm 130$	7.6% (BDT)	2.1%	significance > 30	
$Z\gamma \rightarrow e^+e^-\gamma$	$367 \pm 12$	$187 \pm 19$	5.4% (BDT)	5.2%	$1.2 \times 10^{-91}$	20.3
$Z\gamma \rightarrow \mu^+\mu^-\gamma$	$751 \pm 23$	$429 \pm 43$	11% (BDT)	3.6%	$5.9 \times 10^{-171}$	27.8

Table 17: Change of background acceptance in a test of BDT ( $W^\pm Z$  vs.  $ZZ$ ) performed by smearing jet energy,  $E_{jet}$ , and missing  $E_T$ ,  $\cancel{E}_T$ , by an additional 10%; and the lepton energy  $E_T^\ell$  by an additional 3%.

Signal Efficiency	Background Eff.	Background Eff.	Background Eff.
	No additional smearing	10% for $E_{jet}$ & $\cancel{E}_T$	10% for $E_{jet}$ & $\cancel{E}_T$ , 3% for $E_T^\ell$
40%	4.0%	4.2% (+5.7%)	4.2%(+6.7%)
50%	8.6%	8.9% (+3.7%)	9.0%(+4.8%)
60%	14.6%	14.9% (+2.2%)	15.1%(+3.7%)
70%	22.3%	22.7% (+2.0%)	23.0%(+3.4%)

‘smeared’ to reflect the uncertainties of the diboson detection sensitivity (signal to background ratio). In this study the signal efficiencies are fixed and changes to the background acceptance are gauged. The results are summarized in Table 17. As an example, for a BDT signal selection efficiency of 60%, the change of the signal to background ratio is 3.4%. For the  $W^\pm Z$  cross-section measurement with  $1 \text{ fb}^{-1}$  of integrated luminosity, the 3.4-6.7% background contribution uncertainty would result in additional cross-section measurement uncertainties of about 2-3%.

#### 4.4 Measurement uncertainties vs. selection cuts and luminosities

The cross-section measurement uncertainties are estimated for various event selection cuts and integrated luminosities in the  $W^+W^-$  and  $W^\pm Z$  BDT based analysis. The BDT output spectra are used to build the log-likelihood by using ‘mock data’, which is a sample of simulated events with appropriate statistics according to the luminosity and the Standard Model. For example, the BDT-output spectra for a Monte Carlo experiment with  $1 \text{ fb}^{-1}$  of data are shown in Figure 8 for  $W^+W^- \rightarrow e^\pm \nu \mu^\mp \nu$  detection (left) and for  $W^\pm Z \rightarrow \ell^\pm \nu \ell^+ \ell^-$  detection (right). The Standard Model ‘mock data’ (points) are compared to expected signal (dashed histogram) and background (dotted histogram).

Figure 9: The total relative uncertainties for  $W^+W^-$  (left) and for  $W^\pm Z$  (right) cross section measurements as the BDT cut is varied for different luminosities. The optimal BDT cut is between 200 and 300. An overall 9.2% systematic uncertainty was included in the fitting process.

To understand the optimal cut on the BDT spectra for cross-section measurements, the cuts on the BDT spectra are varied and the cross-section measurements are repeated. A total 9.2% systematic uncertainty is included in the fitting process. Figure 9 shows the cross-section measurement uncertainty as a function of the BDT cut for different integrated luminosities from the  $W^+W^-$  and the  $W^\pm Z$  analysis.

Figure 10 shows the relative cross-section uncertainties as a function of integrated luminosity (with BDT spectrum cut at 200) for  $W^+W^-$  (left) and  $W^\pm Z$  (right) cross-section measurements. From these plots it should be noted that the systematic uncertainty starts to dominate after  $5 \text{ fb}^{-1}$  of integrated luminosity for  $W^+W^-$  cross-section measurements, and after  $10 \text{ fb}^{-1}$  for  $W^\pm Z$ .

## 5 Sensitivity to anomalous couplings

The signature of anomalous couplings in diboson production is an increase in the cross-section at high values of gauge boson transverse momentum ( $p_T$ ) and diboson transverse mass ( $M_T$ ). The ATLAS

Figure 10: The  $W^+W^-$  (left) and the  $W^\pm Z$  (right) cross-section measurement uncertainties as a function of integrated luminosity (with BDT spectrum cut at 200). An overall 9.2% systematical uncertainty was included in the fitting process.

sensitivity to anomalous TGC's is investigated by comparing the 'measured' diboson production cross-sections and the vector boson  $p_T$  or diboson  $M_T$  distributions to models with anomalous TGC's. A binned likelihood fitting procedure using the  $M_T$  or  $p_T$  spectrum for each channel is followed to extract the 95% C.L. intervals of anomalous coupling parameters. The most dramatic effect is an increase in the high  $M_T$  or high  $p_T$  cross-sections, so it is important for the binned likelihood calculation to include events up to the highest values of the observables. Details of the binned likelihood method are described in Section 4.1. One- and two-dimensional limits are set on the charged CP-conserving coupling parameters from the  $W^+W^-$ ,  $W^\pm Z$ , and  $W^\pm \gamma$  final states. The  $ZZ$  final state is used to probe the neutral anomalous TGC sensitivity.

The values of the form factor scale  $\Lambda$  are chosen such that the extracted experimental anomalous coupling limit from data for a certain diboson production process is less than the unitarity limit [41]. For this study, with  $0.1\text{--}1.0\text{ fb}^{-1}$  of integrated luminosity at early LHC running,  $\Lambda$  values of 2-3 TeV are used. The same  $\Lambda$  values of 2-3 TeV are also used to estimate the anomalous coupling sensitivities for higher luminosities for simplicity. It should be noted that as the luminosity increases, the  $\Lambda$  value should have increased accordingly.

### 5.1 Re-weighting the fully simulated events

To avoid producing an impractically large number of fully simulated events in non-Standard Model anomalous coupling parameter space, a **re-weighting** method was invoked to study the ATLAS detector sensitivities to anomalous coupling parameters. The BHO and the BosoMC calculations are used with different anomalous coupling parameters to re-weight the fully simulated events generated by MC@NLO. As an example, Figure 11 shows the  $W^+W^-$  production differential cross-section distributions for Standard Model and some anomalous coupling parameters (left plot) and the corresponding differential cross-section ratio,  $\frac{d\sigma(\text{non-SM})/dM_T}{d\sigma(\text{SM})/dM_T}$  (right plot). These ratios have been used as *weights* to re-weight the fully simulated events to probe the anomalous TGC sensitivities. The *weights* are generated in one-dimensional and two-dimensional anomalous coupling space according to parton level kinematics using the BHO and the BosoMC programs. To produce the weights the step size in coupling parameter space ranges from  $0.1 \times 10^{-3}$  to  $1.0 \times 10^{-3}$ . For each point in the coupling parameter space 5 million

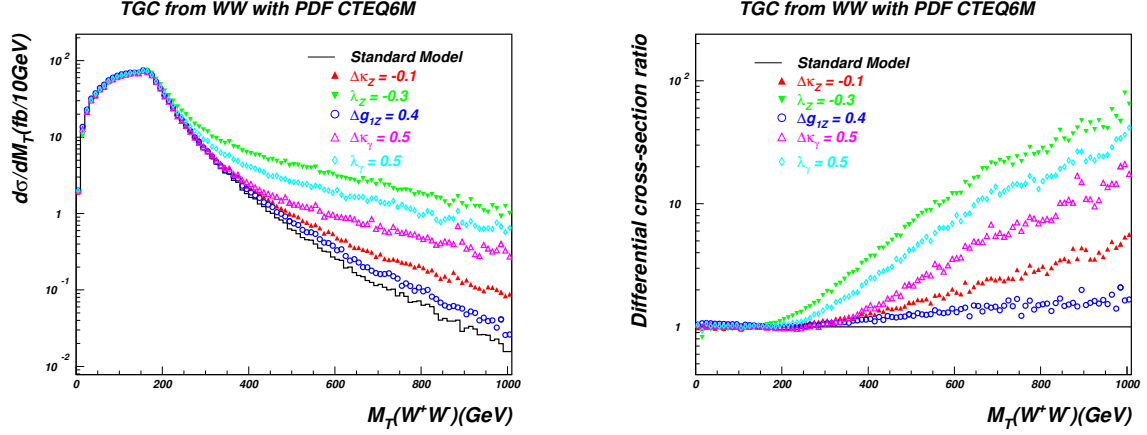

Figure 11: Left: WW transverse mass,  $M_T$ , distributions. Events are generated with the Standard Model coupling (black line) and anomalous couplings (colored symbols); Right: the corresponding differential cross-section ratio.

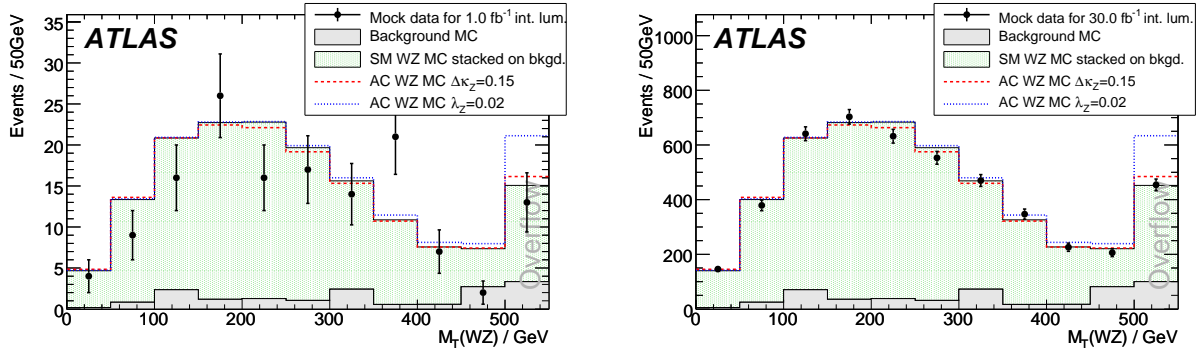

Figure 12: The expected signal+background of the Standard Model, superimposed with ‘mock data’ (points with error bars showing statistical uncertainty), and the non-Standard Model (anomalous couplings) predicted signal+background histograms (dashed and dotted histograms). The left plot is for  $1 \text{ fb}^{-1}$  of data and the right plot is for  $30 \text{ fb}^{-1}$  of data.

events were generated to obtain the theoretical ‘reference’ distributions. The fully simulated events with the Standard Model couplings are required to pass the event selection cuts, and then reweighted according to the parton level kinematics. The weighted events are equivalent to fully simulated events with the corresponding anomalous couplings. The distributions of variables, sensitive to the anomalous coupling, such as lepton  $p_T$ , of the data events, can be compared to those of simulated events with anomalous couplings included, to extract the limits on the anomalous couplings. In this study the Standard Model ‘mock data’ are used to probe the ATLAS detector sensitivities to anomalous triple gauge boson couplings.

## 5.2 WWZ anomalous TGC sensitivity in $W^\pm Z$ analysis

The  $W^\pm Z$  diboson production involves exclusively the  $WWZ$  coupling, in contrast to the  $W^+W^-$  diboson final state which contains both  $WWZ$  and  $WW\gamma$  couplings. To extract the 95% C.L. sensitivity intervals of the anomalous parameters,  $\Delta\kappa_Z$ ,  $\Delta g_1^Z$ , and  $\lambda_Z$ , from the  $W^\pm Z$  diboson final state, both the transverse mass of  $W^\pm Z$  ( $M_T(W^\pm Z)$ ) and the transverse momentum of  $Z$  ( $p_T(Z)$ ) spectra are used to fit the anomalous

Table 18: Summary of  $WWZ$  one-dimensional anomalous coupling parameter 95% CL sensitivities using the  $M_T(W^\pm Z)$  fitting for  $\Lambda = 2$  TeV and  $\Lambda = 3$  TeV for integrated luminosities of 0.1, 1, 10 and 30  $\text{fb}^{-1}$ .

Int. Lumi ( $\text{fb}^{-1}$ )	Cutoff $\Lambda$ (TeV)	$\Delta\kappa_Z$	$\lambda_Z$	$\Delta g_1^Z$
0.1	2.0	[-0.440, 0.609]	[-0.062, 0.056]	[-0.063, 0.119]
1.0	2.0	[-0.203, 0.339]	[-0.028, 0.024]	[-0.021, 0.054]
10.0	2.0	[-0.095, 0.222]	[-0.015, 0.013]	[-0.011, 0.034]
30.0	2.0	[-0.080, 0.169]	[-0.012, 0.008]	[-0.005, 0.023]
0.1	3.0	[-0.399, 0.547]	[-0.050, 0.046]	[-0.054, 0.094]
1.0	3.0	[-0.178, 0.281]	[-0.020, 0.018]	[-0.017, 0.038]
10.0	3.0	[-0.135, 0.201]	[-0.015, 0.013]	[-0.013, 0.018]
30.0	3.0	[-0.069, 0.131]	[-0.008, 0.005]	[-0.003, 0.016]

couplings.

Monte Carlo experiments are performed with 0.1, 1, 10, and 30  $\text{fb}^{-1}$  of integrated luminosities to study the anomalous coupling sensitivities. Figure 12 shows the expected signal+background of the Standard Model, superimposed with the ‘mock data’ (points with error bars), and the non-Standard Model (anomalous couplings) predicted signal+background distributions. Table 18 shows the summary of 1-dimensional 95% C.L. anomalous coupling parameter intervals based on the  $M_T(W^\pm Z)$  spectra fitting. Results corresponding to 0.1, 1, 10 and 30  $\text{fb}^{-1}$  of integrated luminosities for cutoff,  $\Lambda = 2$  TeV and  $\Lambda = 3$  TeV are listed. It should be noted that even for 0.1  $\text{fb}^{-1}$  of integrated luminosity, the ATLAS sensitivity to  $WWZ$  anomalous couplings could be much better than the Tevatron limits based on 1  $\text{fb}^{-1}$  of  $p\bar{p}$  collision data.

To understand the systematic uncertainty effects on the TGC sensitivity, three different systematic uncertainty assumptions are considered: (1) ideal case with no systematic uncertainties:  $\sigma_S = 0$ , and  $\sigma_B = 0$ ; (2) expected uncertainty of 7.2% for signal, and 12% for background, based on estimate from various contributions; and (3) worse than expected systematic uncertainty of 9.2% for signal, and 18.3% for background. Unless otherwise stated, (3) was used to evaluate coupling limits.

The 95% C.L. 1-dimensional limits for the  $WWZ$  anomalous couplings, obtained from the fits to the  $p_T(Z)$  assuming  $\Lambda = 2$  TeV are shown in Table 19, for different scenarios of systematic uncertainties. From this table it is seen that only when reaching 30  $\text{fb}^{-1}$  of integrated luminosity do the systematic uncertainties become significant enough to affect the TGC sensitivities.

The studies on the  $WWZ$  anomalous couplings in two-dimensional space are also based on the  $p_T(Z)$  fits for different integrated luminosities (0.1, 1, 10 and 30  $\text{fb}^{-1}$ ) and for two cutoff values,  $\Lambda = 2$  TeV and 3 TeV. The anomalous coupling limit contours are not very sensitive to these cutoff values. The effects of different systematic uncertainties on the 2-dimensional TGC sensitivity contour are shown in Figure 13. The left plot shows the 95% C.L. anomalous TGC limit contour of  $\lambda_Z$  vs.  $\Delta\kappa_Z = \Delta g_1^Z$  without systematic uncertainties, and the right plot shows the 95% C.L. TGC limit contour with the systematic uncertainties ( $\sigma_S = 9.2\%$ ,  $\sigma_B = 18.3\%$ ) included. Again, the systematic uncertainties become significant when the integrated luminosity reaches 30  $\text{fb}^{-1}$ .

### 5.3 $WW\gamma$ anomalous TGC sensitivity in $W^\pm\gamma$ analysis

The  $W^\pm\gamma$  diboson production involves exclusively the  $WW\gamma$  triple gauge coupling. To extract the 95% C.L. sensitivity intervals of the anomalous parameters,  $\Delta\kappa_\gamma$ , and  $\lambda_\gamma$ , from the  $W^\pm\gamma$  diboson final state, the photon transverse energy  $E_T(\gamma)$  distribution is used to fit the anomalous couplings, with  $\Lambda = 2$  TeV.

Figure 13: The left plot: 95% C.L. WWZ TGC limit contour of  $\lambda_Z$  vs.  $\Delta\kappa_Z = \Delta g_1^Z$ ; without the systematic uncertainties. The right plot: the 95% C.L. WWZ TGC limit contour of  $\lambda_Z$  vs.  $\Delta\kappa_Z = \Delta g_1^Z$ , with systematic uncertainties ( $\sigma_S = 9.2\%$ ,  $\sigma_B = 18.3\%$ ) included. The anomalous coupling limit contours from outer to inner corresponding integrated luminosities of 0.1, 1, 10 and 30  $\text{fb}^{-1}$ , respectively. The systematic uncertainties become significant when the integrated luminosity reaches 30  $\text{fb}^{-1}$ .

Table 19: Comparison of WWZ one-dimensional anomalous coupling parameter 95% C.L. sensitivities for different systematic uncertainties. Results obtained in this table are using the  $p_T(Z)$  fit for  $\Lambda = 2$  TeV for integrated luminosities of 0.1, 1, 10 and 30  $\text{fb}^{-1}$ .

Systematic uncertainties	Int. Lumi ( $\text{fb}^{-1}$ )	$\Delta\kappa_Z$	$\lambda_Z$	$\Delta g_1^Z$
$\sigma_S = 0$ $\sigma_B = 0$	0.1	[-0.942, 1.130]	[-0.203, 0.193]	[-0.227, 0.324]
	1.0	[-0.561, 0.664]	[-0.093, 0.082]	[-0.106, 0.154]
	10.0	[-0.233, 0.231]	[-0.033, 0.024]	[-0.025, 0.061]
	30.0	[-0.128, 0.136]	[-0.024, 0.013]	[-0.009, 0.047]
$\sigma_S = 7.2\%$ $\sigma_B = 12.0\%$	0.1	[-0.950, 1.140]	[-0.204, 0.194]	[-0.228, 0.325]
	1.0	[-0.574, 0.692]	[-0.093, 0.083]	[-0.106, 0.158]
	10.0	[-0.228, 0.302]	[-0.033, 0.027]	[-0.022, 0.070]
	30.0	[-0.164, 0.212]	[-0.026, 0.018]	[-0.009, 0.055]
$\sigma_S = 9.2\%$ $\sigma_B = 18.3\%$	0.1	[-0.956, 1.150]	[-0.204, 0.194]	[-0.229, 0.326]
	1.0	[-0.583, 0.706]	[-0.094, 0.084]	[-0.106, 0.159]
	10.0	[-0.241, 0.316]	[-0.033, 0.028]	[-0.024, 0.071]
	30.0	[-0.184, 0.228]	[-0.028, 0.020]	[-0.011, 0.056]

Table 20: 95% C.L. intervals for the anomalous  $WW\gamma$  coupling parameters obtained from fitting the  $E_T(\gamma)$  distribution to the NLO expectations using the combined sample of  $W(e\nu)\gamma$  and  $W(\mu\nu)\gamma$  events, with  $\Lambda = 2$  TeV.

	$W(\ell\nu)\gamma$		
	$1 \text{ fb}^{-1}$	$10 \text{ fb}^{-1}$	$30 \text{ fb}^{-1}$
$\lambda_\gamma$	[-0.09, 0.04]	[-0.05, 0.02]	[-0.02, 0.01]
$\Delta\kappa_\gamma$	[-0.43, 0.20]	[-0.26, 0.07]	[-0.11, 0.05]

The intervals are calculated for  $W^\pm\gamma$  events by combining the electron and the muon decay channels.

Figure 14 shows an  $E_T(\gamma)$  distribution from  $W^\pm(\ell^\pm\nu)\gamma$  normalized to  $1 \text{ fb}^{-1}$  of data. The signal expectations at LO and NLO are shown by the dashed and dotted lines on the left in Figure 14. On the right in Figure 14 is shown the 95% confidence contour in the  $\lambda_\gamma$ - $\Delta\kappa_\gamma$  parameter space for  $1 \text{ fb}^{-1}$  of data. The 1-dimensional 95% C.L. intervals of  $\lambda_\gamma$  and  $\Delta\kappa_\gamma$  are listed in Table 20.

Figure 14: Left: the  $E_T(\gamma)$  distributions of  $W(\ell\nu)\gamma$  ( $\ell = e, \mu$ ) events for  $1 \text{ fb}^{-1}$  of data. Right: the 95 % confidence contour in the  $\lambda_\gamma$ - $\Delta\kappa_\gamma$  parameter space ( $\Lambda = 2$  TeV) for  $1 \text{ fb}^{-1}$  of  $W^\pm\gamma$  data (with  $W \rightarrow e\nu, \mu\nu$ ).

#### 5.4 $WWZ$ and $WW\gamma$ anomalous TGC sensitivity in $W^+W^-$ analysis

The  $M_T$  spectrum of  $W^+W^-$  pair is fitted to obtain the  $WWZ$  and  $WW\gamma$  anomalous TGC sensitivity intervals at 95% confidence level. A comparison of the  $M_T(WW)$  distribution of the ‘mock data’ to that of models with anomalous coupling is shown in Figure 15. Five anomalous coupling parameters, ( $\Delta\kappa_Z$ ,  $\lambda_Z$ ,  $\Delta g_1^Z$ ,  $\Delta\kappa_\gamma$ ,  $\lambda_\gamma$ ), have been studied with only one parameter varied at the time; the remaining parameters are fixed to Standard Model values. One dimensional anomalous coupling sensitivity intervals at 95% C.L. for different integrated luminosities are given in Table 21. The cutoff  $\Lambda = 2$  TeV is used in these calculations. The two-dimensional anomalous coupling limits from  $W^+W^-$  production with different scenarios relating the anomalous coupling parameters have also been investigated in this study. The two-dimensional contours of the TGC limits at 95% confidence level for 0.1, 1, 10 and  $30 \text{ fb}^{-1}$  integrated luminosities are shown in Figure 16. The left contours are the limits calculated with the HISZ assumption [43]. The right contours are calculated by assuming  $\lambda_Z = \lambda_\gamma$  and  $\Delta\kappa_Z = \Delta\kappa_\gamma$ .

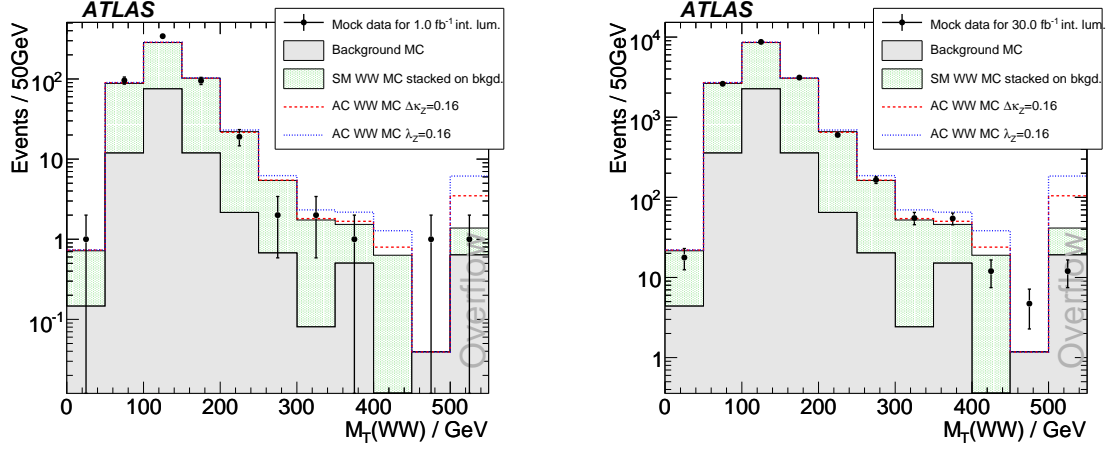

Figure 15:  $W^+W^-$  transverse mass distributions for 1 (left) and 30 (right)  $\text{fb}^{-1}$  of integrated luminosities. The last bins in the plots are 'overflow'-bins.

Table 21: One-dimensional 95% C.L. interval of the  $WWZ$  and  $WW\gamma$  anomalous coupling sensitivities from the  $WW$  final state analysis for 0.1, 1, 10 and 30  $\text{fb}^{-1}$  integrated luminosities, with  $\Lambda = 2$  TeV.

Int. Lumi ( $\text{fb}^{-1}$ )	$\Delta\kappa_Z$	$\lambda_Z$	$\Delta g_1^Z$	$\Delta\kappa_\gamma$	$\lambda_\gamma$
0.1	[-0.242, 0.356]	[-0.206, 0.225]	[-0.741, 1.177]	[-0.476, 0.512]	[-0.564, 0.775]
1.0	[-0.117, 0.187]	[-0.108, 0.111]	[-0.355, 0.616]	[-0.240, 0.251]	[-0.259, 0.421]
10.0	[-0.035, 0.072]	[-0.040, 0.038]	[-0.149, 0.309]	[-0.088, 0.089]	[-0.074, 0.165]
30.0	[-0.026, 0.048]	[-0.028, 0.027]	[-0.149, 0.251]	[-0.056, 0.054]	[-0.052, 0.100]

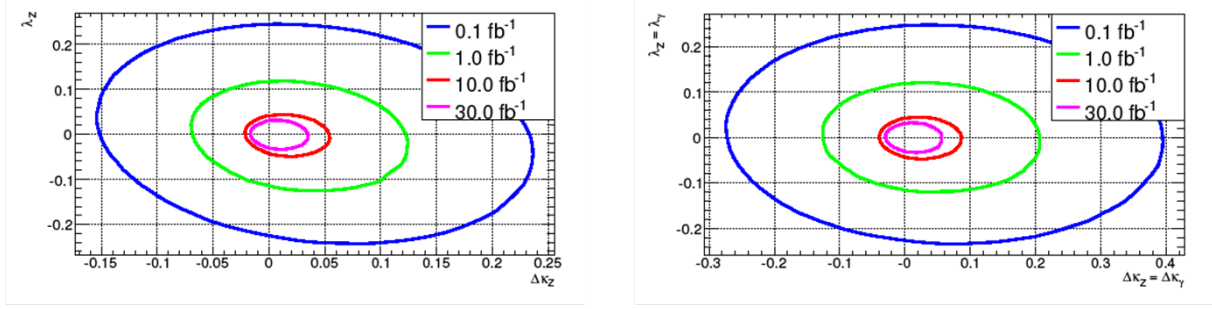

Figure 16: The two-dimensional anomalous TGC limits at 95% C.L. for 0.1, 1, 10 and 30 fb<sup>-1</sup> integrated luminosities.

Figure 17: Example of a fit to one ‘mock data’ sample in each channel. The points show the total number of data events in each bin (not number per unit  $p_T$ ). The histograms show the Standard Model prediction (solid), the best fit (dashed) and the 95% C.L. limit on  $|f_4^Z|$  (dotted).

### 5.5 ZZZ and ZZγ anomalous TGC sensitivity in ZZ analysis

Measurements of the  $pp \rightarrow ZZ$  differential cross-section can be used to measure, or set limits on, ZZZ and ZZγ couplings. These couplings are zero at tree level in the Standard Model. Measurements of the couplings provide a sensitive test of the Standard Model, and non-zero values would indicate the presence of new physics beyond the Standard Model.

In order to estimate limits on anomalous couplings which may be obtained from measurements of ZZ production in early ATLAS data, the  $p_T$  distribution of the Z boson is considered. In the  $ZZ \rightarrow \ell\ell\nu\nu$  channel the visible Z boson reconstructed from the charged leptons is used. In the  $ZZ \rightarrow \ell\ell\ell\ell$  channel one of the two reconstructed Z bosons is chosen in each event at random. Simulated ‘mock data’ distributions are fitted with the sum of expected signal and background distributions, where the signal distribution depends on the anomalous couplings. A binned maximum likelihood fit is employed, with systematic uncertainties included by convolution with the predictions. Fits are performed to each channel separately, and a combined fit is performed by multiplying together the likelihoods from the two channels assuming no correlated uncertainties.

An example fit for each channel is shown in Figure 17. The results presented here use four  $p_T$  bins for the  $\ell\ell\nu\nu$  channel and six  $p_T$  bins for the 4-lepton channel, as shown in Figure 17. Reasonable modifications to the number or position of  $p_T$  bins change the expected limits by up to 15% (12%) in the  $\ell\ell\nu\nu$  ( $\ell\ell\ell\ell$ ) channel. Removing the first two  $p_T$  bins for the  $\ell\ell\ell\ell$  channel, and fitting only the region

Table 22: Expected 95% C.L. intervals on anomalous couplings from fits to the  $ZZ \rightarrow \ell\ell\ell\ell$  channel, the  $ZZ \rightarrow \ell\ell\nu\nu$  channel and both channels together for various values of integrated luminosity, with  $\Lambda = 2$  TeV. In each case, other anomalous couplings are assumed to be zero.

	Int. Lumi / fb <sup>-1</sup>	$f_4^Z$	$f_5^Z$	$f_4^\gamma$	$f_5^\gamma$
$ZZ \rightarrow \ell\ell\ell\ell$	1	[-0.023, 0.023]	[-0.024, 0.024]	[-0.028, 0.028]	[-0.029, 0.028]
	10	[-0.010, 0.010]	[-0.010, 0.010]	[-0.012, 0.012]	[-0.013, 0.012]
	30	[-0.008, 0.008]	[-0.008, 0.008]	[-0.009, 0.009]	[-0.009, 0.009]
$ZZ \rightarrow \ell\ell\nu\nu$	1	[-0.024, 0.024]	[-0.024, 0.025]	[-0.029, 0.029]	[-0.030, 0.029]
	10	[-0.012, 0.012]	[-0.012, 0.012]	[-0.014, 0.014]	[-0.015, 0.014]
	30	[-0.009, 0.009]	[-0.009, 0.009]	[-0.011, 0.011]	[-0.011, 0.011]
Combined	1	[-0.018, 0.018]	[-0.018, 0.019]	[-0.022, 0.022]	[-0.022, 0.022]
	10	[-0.009, 0.009]	[-0.009, 0.009]	[-0.010, 0.010]	[-0.011, 0.010]
	30	[-0.006, 0.006]	[-0.006, 0.007]	[-0.008, 0.008]	[-0.008, 0.008]

$p_T > 100$  GeV has a negligible effect on the limits.

Table 22 shows the mean expected limits from each channel separately, and from combining the channels, for various values of integrated luminosity. With an integrated luminosity of 1 fb<sup>-1</sup> the sensitivities of the two channels are very similar. At higher luminosities, the  $\ell\ell\ell\ell$  channel becomes somewhat more sensitive, because it has lower background and hence a lower associated systematic uncertainty. With as little as 1 fb<sup>-1</sup> of data it should be possible to improve the LEP limits [32] on  $f_4^Z$ ,  $f_5^Z$  and  $f_5^\gamma$  by an order of magnitude using a single channel, while a similar improvement on  $f_4^\gamma$  will require both channels.

At an integrated luminosity of 10 fb<sup>-1</sup>, the expected limits have only a low sensitivity to the background level and to the systematic uncertainties. With the same signal efficiency but no background, the limits from the  $\ell\ell\nu\nu$  channel improve by 10%, while those from the  $\ell\ell\ell\ell$  channel change by only  $\sim 0.2\%$ ; in the latter case, doubling the background has an effect of only  $\sim 0.4\%$ . Reducing all systematic uncertainties to zero improves the limits by 7% (6%) in the  $\ell\ell\nu\nu$  ( $\ell\ell\ell\ell$ ) channel. Thus, the background level and systematic uncertainties are unlikely to be important factors in obtaining limits from early data.

As discussed above, the expected limits are affected by the choice of  $p_T$  bins. The number of bins is currently limited by the statistics of the fully simulated Monte Carlo events. Future studies would benefit from increased signal Monte Carlo statistics, particularly in the high  $p_T$  region. In addition, samples of fully simulated events with anomalous couplings should be used to investigate the dependence of the efficiency at a particular  $p_T$  value on the production diagram.

## 6 Summary

This note presents studies of the production of  $W^+W^-$ ,  $W^\pm Z$ ,  $ZZ$ ,  $W^\pm\gamma$  and  $Z\gamma$  dibosons from pp collisions at the LHC, using leptonic decays of  $W^\pm$  and  $Z$  bosons. The simulated measurements are done using the ATLAS detector with full detector simulation and event reconstruction, and the statistics expected in the initial data taking periods. It focuses on the sensitivities that ATLAS can achieve in the early running of LHC, rather than the ultimate sensitivities that ATLAS might reach after running at the design luminosity. The advanced analysis technique BDT is used in analysis of most of the final states, which improves the sensitivities significantly. Table 16 lists the expected numbers of signal and background events using 1 fb<sup>-1</sup> of data, and the significance of the Standard Model signals after taking into account the known background contributions with 20% systematic uncertainties. It concludes that with

Table 23: 95% C.L. interval of the anomalous coupling sensitivities from  $W^+W^-$ ,  $W^\pm Z$ ,  $W^\pm \gamma$  final states with  $10.0 \text{ fb}^{-1}$  of integrated luminosity and the cutoff  $\Lambda = 2\text{TeV}$ . The table also indicates the variables used in the fit to set the AC sensitivity interval. For reference, some recently published limits from Tevatron and LEP are also listed. These limits calculation assumptions are given in the table as well.

LEP Limit	[-0.30, 0.30]	[-0.34, 0.38]	[-0.17, 0.19]	[-0.32, 0.36]

$0.1 \text{ fb}^{-1}$  of integrated luminosity the Standard Model signals of  $W^+W^-$ ,  $W^\pm Z$ ,  $W^\pm \gamma$  and  $Z\gamma$  can be established with significance better than  $5\sigma$  assuming 20% systematic uncertainties.  $ZZ$  production can be established with  $1 \text{ fb}^{-1}$  of data using the four-lepton decay channels.

Any significant deviation from the Standard Model prediction for these final states can lead to indications of new physics phenomena. In Section 5, the sensitivities to anomalous TGC are presented. The sensitivities are expressed in terms of constraints on the anomalous triple gauge boson couplings in the effective Lagrangian. Table 23 compares the 95% confidence level sensitivity interval for charged anomalous TGC's using observables from different diboson final states with  $10 \text{ fb}^{-1}$  of integrated luminosity.

The neutral anomalous TGC's can be explored with the  $Z\gamma$  and  $ZZ$  final states. In this note, only  $ZZ$  pairs are used for constraining the anomalous coupling, with the study using  $Z\gamma$  still in progress. Both the  $ZZ \rightarrow \ell^+ \ell^- \ell^+ \ell^-$  and  $ZZ \rightarrow \ell^+ \ell^- \nu \bar{\nu}$  final states are used to constrain the neutral anomalous TGC parameters ( $f_4^Z, f_5^Z, f_4^\gamma, f_5^\gamma$ ). The 95% C.L. intervals on the anomalous couplings for  $10 \text{ fb}^{-1}$  of integrated luminosity are listed in Table 24.

The current status of the Monte Carlo generators for diboson is less than satisfactory. MC@NLO is integrated with a parton shower (Herwig), but it does not have matrix elements for the effective Lagrangian beyond the Standard Model with anomalous couplings. The BHO program can generate

parton-level LO and NLO diboson events with anomalous couplings, but can not be correctly integrated with the parton shower programs. In the current analysis, MC@NLO is used to simulate the Standard Model events. The BHO MC with anomalous TGCs is then used to re-weight the events so that the fully simulated events can effectively have the anomalous TGC's, and be used directly to compare with the simulated 'mock data'.

Because of the higher center of mass energy at the LHC, the cross-sections for diboson production are an order of magnitude higher than at the Tevatron. This will allow ATLAS to improve the Tevatron measurements in the early running of the LHC. The large signal statistical significances and signal to background ratios determined from these studies suggest that early observations of these channels will take place at the LHC start up with  $0.1$  to  $1 \text{ fb}^{-1}$  of data. Systematic uncertainties will dominate the cross-section measurement errors starting from  $5\text{-}30 \text{ fb}^{-1}$  of data. With increasing luminosity, the constraints on the anomalous couplings will provide important probes of physics beyond the Standard Model.

# Top Quark

# Top Quark Physics

## Abstract

In the early days of data taking at the LHC, top quark physics will have a role of primary importance for several reasons. At start-up, already with the first few  $\text{fb}^{-1}$  of integrated luminosity, a top quark signal can be clearly separated from the background even with an imperfectly calibrated detector and the top quark pair production cross-section can be extracted at better than 20% accuracy and with negligible statistical error. The first measurement of the top quark mass will provide feedback on the detector performance and top quark events can be used to understand and calibrate the light jet energy scale and the b-tagging. Additionally in scenarios beyond the Standard Model, new particles may decay into top quarks, therefore a detailed study of the top quark properties may provide a hint of new physics. A good understanding of top quark physics is also essential as top quark events are a background for many new physics searches.

## 1 Introduction

The top quark, discovered at Fermilab in 1995 [1], completed the three generation structure of the Standard Model and opened up the new field of top quark physics. Produced predominantly, in hadron-hadron collisions, through strong interactions, the top quark decays rapidly without forming hadrons, and almost exclusively through the single mode  $t \rightarrow Wb$ . The W-boson can then decay leptonically or hadronically. The relevant CKM coupling is already determined by the (three-generation) unitarity of the CKM matrix. Yet the top quark is distinguished by its large mass, about 35 times larger than the mass of the next heavy quark, and close to the electroweak symmetry breaking scale. This unique property raises a number of interesting questions. For example if the top quark mass is generated by the Higgs mechanism as the Standard Model predicts and if its mass is related to the top-Higgs-Yukawa coupling, or if it does play an even more fundamental role in the electroweak symmetry breaking mechanism. Non Standard Model physics could first manifest itself in non-standard couplings of the top quark which show up as anomalies in top quark production and decays. By studying the top quark, some of these questions may be answered. Further insight in top quark properties will come from measurements done with the high statistics sample of  $t\bar{t}$  pairs such as top quark and W polarization studies sensitive to anomalous  $Wtb$  couplings, searches for rare top quark decays indicating the presence of new physics, or for new resonances decaying to  $t\bar{t}$  pairs.

The LHC will be a top quark factory, producing millions of  $t\bar{t}$  pairs in a sample of  $10 \text{ fb}^{-1}$ , which is expected to be collected during the first years of LHC operation.

The understanding of the experimental signatures for top quark events involves most parts of the ATLAS detector and is essential for claiming potential discoveries of new physics.

Since numerous single (anti-)top quark events are produced via electroweak interactions, the top quark properties, such as the  $Wtb$  coupling, can be examined with high precision at the LHC during its first years of running.

## 2 Top quark pair production

In proton-proton collisions top quark pairs are produced through both gluon-gluon and quark-antiquark scattering (Figure 1). The relative importance of both amplitudes depends on the center of mass energy of the collision and nature of the beams: at the LHC the gluon scattering process dominates ( $\sim 90\%$  of

the cases) while at the Tevatron, production of top quark pairs is kinematically restricted to the quark dominated region. This difference appears also in the values of the cross-section: that is about 100 times larger at the LHC than at the Tevatron. The large top quark mass ( $m_t$ ) ensures that top quark production is a short-distance process, and that the perturbative expansion, given by a series in powers of the small parameter  $\alpha_s(m_t)$ , converges rapidly. The cross-section used throughout this note for production at the LHC has been calculated up to NLO order including NLL soft gluon resummation, and results in about  $833 \pm 100$  pb, where the uncertainty reflects the theoretical error obtained from varying the renormalisation scale by a factor of two [2]. The effect of PDF errors accounts for a few percent uncertainty, while varying the top mass by a factor of two, an uncertainty of about 6% on the cross-section is obtained. A calculation that includes NNLL soft-gluon corrections results in a central value for the  $t\bar{t}$  cross-section of 872.8 pb [3]. This translates to about 83,000 top quark pairs in a sample of  $100 \text{ pb}^{-1}$  and of the order of  $10^7$  top quark pairs produced per year before any selection or detection criteria are applied.

Figure 1: Top production processes at lowest order: gluon-gluon scattering diagrams (a) and b)) and quark-quark scattering diagram c).

## 2.1 Observables and phenomenology

In the Standard Model, the decay of top quarks takes place almost exclusively through the  $t \rightarrow Wb$  decay mode. A W-boson decays in about 1/3 of the cases into a charged lepton and a neutrino. All three lepton flavors are produced at approximately equal rate. In the remaining 2/3 of the cases, the W-boson decays into a quark-antiquark pair, and the abundance of a given pair is instead determined by the magnitude of the relevant CKM matrix elements. Specifically, the CKM mechanism suppresses the production of b-quarks as  $|V_{cb}|^2 \simeq 1.7 \times 10^{-3}$ . Thus, the quarks from W-boson decay can be considered as a clean source of light quarks.

From an experimental point of view, one can characterise the top quark decay by the number of W-bosons that decay leptonically. A value of 10.8% and 67.6% has been used for the leptonic and hadronic branching ratio (BR) of the W-boson, respectively [4]. The following signatures can be identified:

- *Fully leptonic*: represents about 1/9 of the  $t\bar{t}$  events. Both W-bosons decay into a lepton-neutrino pair, resulting in an event with two charged leptons, two neutrinos and two b-jets. This mode is identified by requiring two high  $p_T$  leptons and the presence of missing transverse energy ( $\cancel{E}_T$ ), and allows a clean sample of top quark events to be obtained. However, this sample has limited use in probing the top quark reconstruction capability of the ATLAS experiment, due to the two neutrinos escaping detection.
- *Fully hadronic*: represents about 4/9 of the  $t\bar{t}$  decays. Both W-bosons decay hadronically, which gives at least six jets in the event: two b-jets from the top quark decay and four light jets from the W-boson decay. In this case, there is no high  $p_T$  lepton to trigger on, and the signal is not easily

distinguishable from the abundant Standard Model QCD multi-jets production, which is expected to be orders of magnitude bigger than the signal. Another challenging point of this signature is the presence of a high combinatorial background when reconstructing the top quark mass.

- *Semi-leptonic*: represents about 4/9 of the  $t\bar{t}$  decays. The presence of a single high  $p_T$  lepton allows to suppress the Standard Model W+jets and QCD background. The  $p_T$  of the neutrino can be reconstructed as it is the only source of  $\cancel{E}_T$  for signal events.

In this document, top pair production is studied in the semi-leptonic and fully leptonic decay modes.

### 3 Single Top Quark Production

In the Standard Model single-top quark production is due to three different mechanisms: (a) W-boson and gluon fusion mode, which includes the t-channel contribution and is referred to as t-channel or  $Wg$  as a whole (b) associated production of a top quark and a W-boson, denoted  $Wt$ , and (c) s-channel production. The corresponding diagrams are shown in Fig. 2. We note however that these definitions are valid only at leading order (LO): next to leading order (NLO) calculations may introduce diagrams which cannot be categorised so unambiguously. The total NLO cross-section amounts to about 320 pb at the LHC. Among those channels, the dominant contribution comes from the t-channel processes, which account for about 250 pb; the  $Wt$  contribution amounts to about 60 pb while the s-channel mode is expected with a cross-section of about 10 pb [5] [6].

Figure 2: Main graphs corresponding to the three production mechanisms of single-top quark events: (a) t-channel (b)  $Wt$  associated production (c) s-channel.

In the following notes, when discussing the analysis strategy in the s- and t-channels, we will use only the leptonic decay of the W-bosons ( $l\nu b\bar{b}$  and  $l\nu b(\bar{b})q$  final states, respectively)<sup>1</sup>. For the associated  $Wt$  production, we will consider events where one of the W-bosons (either the one produced together with the top quark or the one appearing in the top quark decay) decays leptonically and the other hadronically. The  $\tau$  decay modes were included in all relevant simulated event samples, though signal selection is aimed at electron and muon signatures.

We note that in pp collisions, the cross-section for single-top quark is not charge symmetric. The s-channel  $t\bar{b}$  final state cross-section is predicted to be a factor 1.6 higher than the one corresponding to the  $\bar{t}b$  final state. This ratio is 1.7 if only the t-channel processes are included. This feature is of special interest since it generates a charge asymmetry in the leptonic final state that can be exploited in the analysis to reduce the contamination from the top quark pair production, which constitutes the main

<sup>1</sup>The hadronic decay modes have obvious disadvantages for triggering and the lack of a lepton signature increases the background significantly

background to our signal. On the other hand, the rates for the charge-conjugate processes  $W^- + t$  and  $W^+ + \bar{t}$  are identical.

Significant sources of uncertainties affect the theoretical predictions of the production cross-sections. The s-channel is known with a precision of 9.1% at NLO [5, 7], while the t-channel has an uncertainty of 4.8% [5, 7]. An uncertainty of 3% is quoted for the  $Wt$  channel [6]. Those uncertainties come from three main sources. The uncertainty in the parton luminosity, depending upon the choice of the parton density functions, is particularly important (2 to 4% for the s- and t-channels), since the b parton or the gluons are involved in the hard processes. The choice for the renormalization and factorization scales accounts for about 2 and 3% uncertainty in s- and t-channel calculations respectively. Finally, a few GeV uncertainty on the top quark mass  $m_t$  results in percent level variation of the cross-sections. The uncertainty in  $\alpha_s$  enters marginally in the total error at a value below the 1% level.

## 4 Monte Carlo samples

The Monte Carlo samples which have been used for the top quark analyses reported are described in this section. The calculation of many processes benefit from methods such as resummation of next-to-leading log terms and some are calculated at the full NLO accuracy. All the samples used have been normalized using "K-factors", to the NLO theoretical cross-section calculations whenever available [8]. The value of  $m_t = 175$  GeV has been used for the generation of all samples and all cross-sections correspond to this value. Most samples were processed with the full GEANT4 ATLAS detector simulation and reconstruction code. In some cases, the fast simulation package ATLFAST has been used.

The effect of pile-up in the cavern corresponding to a luminosity of  $10^{33} \text{ cm}^{-2}\text{s}^{-1}$  has been simulated both for  $t\bar{t}$  and single top events.

### 4.1 Simulation of $t\bar{t}$ signal events

Top quark pair production has been simulated using the Monte Carlo generator MC@NLO [9] version 3.1. The hard process of  $t\bar{t}$  production is calculated at NLO, so that diagrams that produce one additional parton in the final state are included at matrix element level. The parton density function CTEQ6M [10] is used. Fragmentation and hadronisation is simulated using HERWIG [11] and the underlying event by Jimmy [12]. The  $t\bar{t}$  main samples for analysis are a sample of single and double leptonic events and one of fully hadronic events. There are no cuts applied at generation level other than the lepton flavor separation according to W-boson decay type that allowed subdividing the generated events into these two samples. A number of other samples mainly aimed at systematic studies have been produced and are listed in Table 1. Among these AcerMC [13] samples interfaced with PYTHIA for the hadronisation and fragmentation and simulation of the underlying event, aimed at initial and final state radiation (ISR and FSR) studies, that will be discussed later in the text. For the  $t\bar{t}$  rare decays samples were produced with TopRex [14] interfaced with PYTHIA for the hadronisation and fragmentation and simulation of the underlying event.

### 4.2 Simulation of single top quark events

For the single top quark signal production, the AcerMC matrix element generator was used in conjunction with PYTHIA, that was used for hadronisation, fragmentation and simulation of the underlying event. The parton density functions CTEQ6M have been used. Compared to TopRex which was previously used in ATLAS, its t-channel generation method is based on a more physically motivated method [15] for combining LO and tree level NLO diagrams. The contribution from NLO diagrams is rather important for the t-channel as the gluon splitting to  $b\bar{b}$  tends to be underestimated with the parton shower method.

Table 1:  $t\bar{t}$  and single top quark simulated samples used throughout the notes. ( $m_t=175$  GeV) is used as default in the generation. Given are a short description of the simulated physics process, the generator used, the production cross-section ( $\sigma$ ), and the K-factor that should be applied to the quoted cross-section.

<b>MC@NLO + HERWIG <math>t\bar{t}</math> – fully simulated events – K-factor = 1.0</b>	$\sigma(\text{pb}) \times BR$
Fully leptonic and semi-leptonic $t\bar{t}$	450
Fully hadronic $t\bar{t}$ ( $m_t=175$ GeV)	380
Fully leptonic and semi-leptonic $t\bar{t}$ ( $m_t=160$ GeV)	450
Fully leptonic and semi-leptonic $t\bar{t}$ ( $m_t=170$ GeV)	450
Fully leptonic and semi-leptonic $t\bar{t}$ ( $m_t=180$ GeV)	450
Fully leptonic and semi-leptonic $t\bar{t}$ ( $m_t=190$ GeV)	450
Fully leptonic and semi-leptonic $t\bar{t}$ no UE	450
Inclusive $t\bar{t}$ ( $p_T(t) \geq 200$ GeV)	100
<b>AcerMC+PYTHIA – <math>t\bar{t}</math> – fully simulated events – K-factor = 1.0</b>	$\sigma(\text{pb})$
Fully leptonic and semi-leptonic $t\bar{t}$	450
Fully leptonic and semi-leptonic $t\bar{t}$ , different ISR/FSR (low top mass)	450
Fully leptonic and semi-leptonic $t\bar{t}$ , different ISR/FSR (high top mass)	450
<b>AcerMC+PYTHIA single top quark Wt-channel – full sim. events K-factor = 1.14</b>	$\sigma(\text{pb})$
Single top quark associated Wt production, semi-leptonic decay	25.5
<b>AcerMC+PYTHIA single top quark s-channel – full sim. events K-factor = 1.5</b>	
Single top quark s-channel leptonic decay	2.3
<b>AcerMC+PYTHIA single top quark t-channel – full sim. events K-factor = 0.98</b>	
Single top quark t-channel leptonic decay	81.3
<b>TopRex+PYTHIA – <math>t\bar{t}</math> rare decays – fully simulated events</b>	
$t\bar{t} \rightarrow bW(\ell\nu)+q\gamma$	
$t\bar{t} \rightarrow bW(\ell\nu)+qZ(\ell\ell); \ell = e, \mu$	
$t\bar{t} \rightarrow bW(\ell\nu)+qg$	

The s-channel and Wt-channel are generated at LO accuracy only. All three channels were generated with W-bosons forced to decay leptonically (e or  $\mu$  or  $\tau$ ). In the case of Wt, either the associated W-bosons or the W-bosons from top quark decay is forced to decay leptonically and no dileptonic events are included. The Monte Carlo samples that have been used in the analyses and the corresponding normalisation cross-sections can be found in Table 1.

### 4.3 Simulation of background W + jet events

For the W + jets production, the ALPGEN [16] generator with HERWIG [11] clustering has been used. HERWIG has been used for the simulation of the fragmentation and the hadronisation and Jimmy for the underlying event. The MLM [17] algorithm has been used to match the parton shower and the matrix element calculations. The matching parameters are the minimum  $p_T$  of the partons and the minimum  $\Delta R$  among two partons, defined as the separation of two objects in the  $\eta$ - $\phi$  space,  $(\Delta R)^2 = (\Delta\eta)^2 + (\Delta\phi)^2$ . Here,  $\eta$  is the pseudorapidity of an object, defined as  $\eta = -\ln(\tan(\theta/2))$  and  $\phi$  and  $\theta$  are the azimuthal and polar angles, respectively. All cones are defined in  $\eta$ - $\phi$  space. The values of the matching parameters that are used in this note are  $p_T = 20$  GeV and  $\Delta R = 0.3$ .

A fraction of this background contains heavy quarks. This background is treated separately in ALPGEN

by producing  $W + b\bar{b}$  and  $W + c\bar{c}$  (plus light jets) samples. The W-boson background samples used throughout the notes are described in Table 2<sup>2</sup>.

#### 4.4 Simulation of background $Z \rightarrow \ell\ell + \text{jets}$ events

The  $Z \rightarrow \ell\ell + n$  jets background events, where the lepton flavor can be any charged lepton, has been generated with ALPGEN, while HERWIG has been used for the simulation of the fragmentation and the hadronisation and Jimmy for the underlying event. The MLM algorithm has been used to match the parton shower and the matrix element calculations. The matching parameters values are  $p_T = 20$  GeV and  $\Delta R = 0.3$ .

The contribution of those backgrounds to our analyses is non-negligible only when there is at least one jet in addition to the Z. The samples have been generated with up to 5 additional jets. Samples generated with PYTHIA have also been used: the complete list of the samples can be found in Table 3<sup>3</sup>.

#### 4.5 Simulation of di-boson background

Di-boson events produced with light jets can be a background for the  $t\bar{t}$  and single top quark signal. WW, WZ and ZZ processes with all decay modes have been generated with HERWIG: a filter was applied to select those events with an electron or a muon with  $p_T > 10$  GeV. WW events with the W-boson decaying leptonically into final states with two electrons, an electron (muon) and a  $\tau$ -lepton and two  $\tau$ -leptons have been generated with MC@NLO interfaced with HERWIG for the hadronisation and fragmentation ( see Table 4).

#### 4.6 QCD background

QCD multi-jet events are a background for  $t\bar{t}$  and single top quark analyses if at least one of the jets in the event is misidentified as an isolated lepton. The level of QCD multi-jet background has large uncertainties with the currently available generation tools, which are based on a leading order description: ALPGEN has been used to generate these events with the same matching parameters as discussed in section 4.3. Given the large cross-section for this process only fast simulated events (ATLFAST) have been produced and used for the present studies. Events with 2 to 5 light jets and  $b\bar{b} + 0, 1, 2, 3$  light jets have been generated requiring at least 3 jets in the final state with  $p_T > 30$  GeV. Di-jet fully simulated PYTHIA events are available and have been used for comparison with the ATLFAST results (see Table 5). In practice, the level of background will be derived directly from the data and will strongly depend on the lepton fake rate, and can depend on the topology of the event. Different cuts can be applied to strongly reduce this background. In fully hadronic  $t\bar{t}$  decays, QCD multi-jet events are the main background and a different strategy has to be developed. These decays are not studied in details in this document.

## 5 Reconstruction of physics objects

We use definitions of high level reconstructed objects (electrons, muons, jets, etc.) that are standard in ATLAS. They are described in the following sections. In the definitions, we often use the distance  $\Delta R$  between objects.

<sup>2</sup>The difference in the cross section for the different leptons in the first set of events in Table 2 (fully simulated W boson events with ALPGEN) is due to the truth jet filter. Electrons and  $\tau$  leptons can also be reconstructed as a jet: it is more probable for electrons than for  $\tau$  leptons that are reconstructed via their visible decay products.

<sup>3</sup>In the truth jet filter applied to the fully simulated Z boson events with ALPGEN in Table 3 jets made from leptons are removed at the filter level.

Table 2: W-boson background samples used throughout the notes. Given are a short description of the simulated physics process, the generator used, the production cross-section ( $\sigma$ ) including filter, matching efficiency for ALPGEN and selection efficiency, and the K-factor that should be applied to the quoted cross-section.

## 5.1 Electron definition

Electron candidates are reconstructed and identified by the calorimeters and inner tracker of ATLAS and are reconstructed in the pseudorapidity range  $|\eta| < 2.5$ . An electron candidate is defined as a medium electron identified by the isEM algorithm [18].

If an electron is found in the calorimeter crack region  $1.37 < |\eta| < 1.52$ , it is vetoed. The electron has to be isolated based on calorimeter energy: the additional transverse energy  $E_T$  in a cone with radius  $\Delta R = 0.2$  around the electron axis is required to be less than 6 GeV. The  $p_T$  and  $|\eta|$  cuts depend on the event signature and are detailed in the various relevant sections.

For electrons above 20 GeV and  $|\eta| < 2.5$  and outside the crack region, the average identification efficiency in  $t\bar{t}$  events is about 67%, with a purity of about 97%.

## 5.2 Muon definition

Muons are reconstructed by the muon spectrometer and the inner detector. The muon reconstruction is performed using the Staco algorithm [19], and muons are defined from the best match combination of the muon chambers and the tracker information. Muons are reconstructed in the pseudorapidity range  $|\eta| < 2.5$  and have to be isolated based on calorimeter energy: the additional transverse energy  $E_T$  in a cone with radius  $\Delta R = 0.2$  around the muon is required to be less than 6 GeV. The  $p_T$  and  $|\eta|$  cuts applied to the muons are given in the selection cuts described in the various sections. For muons above

Table 4: Diboson background samples used throughout the notes. Given are a short description of the simulated physics process, the generator used, the production cross-section ( $\sigma$ ) including filter, matching efficiency and selection efficiency for ALPGEN, and the K-factor that should be applied to the quoted cross-section.

<b>HERWIG + Jimmy – WW – fully simulated events – K-factor = 1.57</b>	$\sigma$ (pb)
1 e or $\mu$ $p_T^\ell \geq 10$ GeV	24.5
<b>HERWIG + Jimmy – ZZ – fully simulated events – K-factor = 1.29</b>	
1 e or $\mu$ $p_T^\ell \geq 10$ GeV	2.1
<b>HERWIG + Jimmy – WZ – fully simulated events – K-factor = 1.89</b>	
1 e or $\mu$ $p_T^\ell \geq 10$ GeV	7.8
<b>MC@NLO + HERWIG – WW – fully simulated events – K-factor = 1.0</b>	$\sigma$ (pb)
$W^+W^- \rightarrow e^+\nu e^-\nu$ ; no filter	1.1
$W^+W^- \rightarrow e^+\nu \tau^-\nu$	1.1
$W^+W^- \rightarrow \tau^+\nu e^-\nu$	1.1
$W^+W^- \rightarrow \mu^+\nu \tau^-\nu$	1.1
$W^+W^- \rightarrow \tau^+\nu \mu^-\nu$	1.1
$W^+W^- \rightarrow \tau^+\nu \tau^-\nu$	1.1

20 GeV, the average reconstruction efficiency in  $t\bar{t}$  events is 88%. The fake rate, defined as the rate at which an object that is not associated with a true muon is mis-identified as a muon, is  $0.1 \pm 0.01$  %.

### 5.3 Jet definition

Jets are reconstructed with the standard ATLAS cone algorithm in  $\eta - \phi$  space, for  $|\eta| < 2.5$  and a cone radius of 0.4, operating on energy depositions in calorimeter towers [20]. In  $t\bar{t}$  events, jets coinciding within  $\Delta R < 0.2$  with electrons (as defined in section 5.1) are removed.

A jet is identified as originating from a b-quark by determining the probability that it contains a secondary vertex. The three-dimensional impact parameter (IP3D) and the secondary vertex (SV1) [21] algorithms are used and we require that the resulting output weight of the event is larger than 7.05. The requirement on the weight is chosen such that an efficiency of about 60% for jets with  $p_T > 30$  GeV in  $t\bar{t}$  semi-leptonic events is reached, with a mistag rate of 100.

### 5.4 Missing transverse energy definition

For the missing transverse energy ( $\cancel{E}_T$ ), we determine the sum of five components.

1. the contribution of cells in identified electron or photon clusters;
2. the contribution of cells inside jets;
3. the contribution of cells in topological clusters outside identified objects;
4. the contribution from muons;
5. the cryostat correction.

For the calculation of  $\cancel{E}_T$  we use the standard ATLAS variable [22]. The sum of the transverse energy in semi-leptonic top events is about 500 GeV, which gives a typical  $\cancel{E}_T$  resolution of the order of 10 GeV.

Table 5: QCD background samples used throughout the notes. Given are a short description of the simulated physics process, the generator used, the production cross-section ( $\sigma$ ) including filter, matching efficiency and selection efficiency for ALPGEN.

<b>PYTHIA – QCD Dijets</b> – fully simulated events –	$\sigma(\text{pb})$
Dijets; $e/\gamma$ filter $p_T \geq 15 \text{ GeV}$	$1.91 \cdot 10^8$
<b>Alpgen + HERWIG – jets</b> – Atlfast –	
2 partons; one jet with $p_T^j \geq 30 \text{ GeV}$	$1.13 \cdot 10^6$
3 partons	$2.03 \cdot 10^6$
4 partons	$1.10 \cdot 10^6$
$\geq 5$ partons	$0.32 \cdot 10^6$
<b>Alpgen + HERWIG – <math>b\bar{b}</math> + jets</b> – Atlfast –	$\sigma(\text{pb})$
$b\bar{b}$ + 0 parton; one jet with $p_T^j \geq 30 \text{ GeV}$	$5.3 \cdot 10^3$
$b\bar{b}$ + 1 parton	$33.6 \cdot 10^3$
$b\bar{b}$ + 2 partons	$29.5 \cdot 10^3$
$b\bar{b}$ + $\geq 3$ partons	$18.9 \cdot 10^3$

## 5.5 Overlap removal

In some cases when there is ambiguity in the definition of an object, the overlaps are removed: if an object is identified as an electron it is not counted in the category of photons or taus or jets.

# 6 Systematics

In this section, we list the sources of systematics common to all analysis and describe how they have been consistently treated.

## 6.1 Estimate of the luminosity and its uncertainty

At the LHC start-up only a rough measurement of the machine parameters will be available. The expected uncertainty on the luminosity during this phase will be of the order of 20-30%. A better determination of the beam profiles using special runs of the machine will lead ultimately to a systematic uncertainty of the order of 5%. The proposed ALFA detector will measure elastic scattering in the Coulomb-nuclear interference region using special runs and beam optics, determining the absolute luminosity with an expected uncertainty of the order of 3%. The optical theorem, in conjunction with a precise external measurement of the total cross-section, can achieve a similar 3% precision [23].

## 6.2 Lepton identification efficiency

For the first  $100 \text{ pb}^{-1}$  of integrated luminosity, the lepton identification efficiency error is expected to be of the order of 1% for electrons and muons, while the error on the fake rate is expected to be 50% and 20%, respectively [18, 19].

## 6.3 Lepton trigger efficiency

The lepton trigger efficiency is measured from data using Z events. We expect the uncertainty to be of the order of 1% for an integrated luminosity of  $100 \text{ pb}^{-1}$  [24].

## 6.4 Jet energy scale

In the difficult hadron-hadron collision environment, the determination of the jet energy scale is rather challenging [25]. While several methods are proposed such as using  $\gamma$ +jet events to propagate the electromagnetic scale to the hadronic scale, the jet energy scale depends on a variety of detector and physics effects. This includes non-linearities in the calorimeter response due, for example, to energy losses in “dead” material, and additional energy due to the underlying event. Energy lost outside the jet cone can also affect the measured jet energy. Effects due to the initial and final state radiation (ISR/FSR) modelling could also affect the jet energy scale but they are evaluated separately. The ultimate goal in ATLAS is to arrive at a 1% uncertainty on jet energy scale though such performance is only reachable after several years of study. The jet energy resolution used throughout the note is  $60\%/\sqrt{E} \oplus 5\%$ .

To estimate the sensitivity of the analyses to the uncertainty on the jet energy scale in early data we have repeated them while artificially rescaling the energies of the jets by  $\pm 5\%$ . The resulting variation in the measurement from the analyses (e.g. cross-section, mass etc.) gives a good measure of the systematic uncertainty due to the jet energy scale.

Since several analyses are using the missing transverse energy in the event to reduce the backgrounds, the effect of the variation of the jet energy scale on the missing energy has been taken into account by calculating the contribution to the transverse missing energy coming from unscaled jets and subtracting it from the overall missing transverse energy in the event. Finally the contribution from the rescaled jets is calculated and added to the missing transverse energy of the event.

## 6.5 b-tagging uncertainties

The use of b-tagging in  $t\bar{t}$  and single top quark events is essential in order to reduce the backgrounds, in particular that from W+jets, and the combinatorial background when reconstructing the top quark. At the beginning of data taking the b-tagging performance will need to be understood and  $t\bar{t}$  events will be used as a calibration tool for the determination of the b-tagging efficiency. To avoid having a large dependence on the b-tagging efficiency in the early days of data taking we have studied methods to extract the  $t\bar{t}$  cross-section and the top quark mass without applying b-tagging. The uncertainty on the b-jet efficiency is currently estimated to be of the order of  $\pm 5\%$  and the uncertainty on the mistag rate is 50% [21].

## 6.6 ISR and FSR systematics

More initial and final state QCD radiation (ISR and FSR) increases the number of jets and affects the transverse momentum of particles in the event. Selection cuts for top quark events include these quantities, therefore ISR and FSR will have some effect on the selection efficiency. In order to evaluate the effect of the ISR and FSR systematics, several studies have been performed using the AcerMC [13] generator interfaced with the PYTHIA parton showering.

Samples of  $t\bar{t}$  and single top quark events with separate variations of the PYTHIA ISR and FSR parameters have been generated. The study was limited to parameters which have been shown to have the biggest impact on the reconstructed top mass at the generator level. The choices of the parameters depend on the analysis and include ISR  $\Lambda_{QCD}$ , the ISR cutoff, FSR  $\Lambda_{QCD}$ , and the FSR cutoff. The effect of the selection efficiency can be as large as 10%, depending on the analysis cuts.

## 6.7 Parton density uncertainties

The systematic error due to the parton density functions (PDF) uncertainties is evaluated on  $t\bar{t}$  signal samples. Both the PDF error sets CTEQ6M and MRST2002 [26] at NLO are used. Both sets have positive and negative error PDFs. In order to evaluate the systematic effect on an observable, the following

formula [27] could be adopted:

$$\Delta X = \frac{1}{2} \sqrt{\Sigma(X_i^+ - X_i^-)^2}$$

where  $i$  varies over the set of PDF errors and  $X^+$  and  $X^-$  is the observable evaluated with the positive and negative error PDFs respectively.

The error PDFs do not guarantee that  $X_i^+ > X_0$  and  $X_i^- < X_0 \forall i$  (here  $X_0$  is the value of the observable as computed with the default PDF set). An alternative approach has thus been proposed in reference [28], which entails the use of the following asymmetric formulas, that are used here:

$$\Delta X_{max}^+ = \sqrt{\Sigma[\max(X_i^+ - X_0, X_i^- - X_0, 0)]^2}$$

$$\Delta X_{max}^- = \sqrt{\Sigma[\max(X_0 - X_i^+, X_0 - X_i^-, 0)]^2}.$$

In order to avoid generating a sample for each set of PDF errors, a re-weighting method has been used. Once an event has been generated with a certain PDF, PDF1, it can be re-weighted as if it would have been generated with a different PDF, PDF2, by using the following re-weight factor:

$$event_{(reweights)} = \frac{f_{PDF2}(x_1, flav_1, Q) f_{PDF2}(x_2, flav_2, Q)}{f_{PDF1}(x_1, flav_1, Q) f_{PDF1}(x_2, flav_2, Q)} \quad (1)$$

The variable  $flav_i$  is the flavor of parton  $i = 1, 2$ , which initiates the hard scattering,  $x_i$  its momentum fraction, and  $Q$  is the mass scale used by the Monte Carlo in the computation of the PDFs.

Eq.1 is an approximation and should be checked by comparing samples obtained with the re-weighting technique and generated ones. Using the re-weighting technique is not the same as generating the samples with the different sets of PDFs, the reason being that in the generator the Sudakov factors of the initial state radiation depend on the PDFs and the dependence does not factorize, i.e. it is not a multiplicative factor. The effect is believed to be generally small, but has been checked for each process by comparing ATLFast subsamples of our signal events generated with the PDFs and re-weighted samples: the selection efficiencies for those samples have been compared for the  $t\bar{t}$  and single top quark analyses and the results agree within the statistical errors.

## 6.8 W+jets normalization

For final states with at least one top decaying leptonically, the ones studied in this document, one of the most important backgrounds is W-boson production in association with jets where the W-boson decays leptonically. The uncertainty on the normalization of this process is particularly relevant in analyses where the background contribution is estimated on the basis of the Monte Carlo expectations rather than fitted from the data.

To evaluate this background we used Monte Carlo samples of W+0,1,2,3,4 jets produced with the ALPGEN Monte Carlo, and we evaluated the selection efficiencies for this background. For the normalisation of the exclusive samples we used the leading order cross-section prediction of the ALPGEN Monte Carlo, with standard settings for the renormalisation and factorisation scales. The inclusive cross-section is then normalised to the NNLO value [8]. However, the normalisation of the exclusive samples has a large theoretical uncertainty due to the matching: we therefore envisage to determine it from data itself.

The exclusive cross-section for W-boson produced in association with jets ( $\sigma(W + nj)$ ) can be extracted from the data by using the following relation:

$$\frac{\sigma(W_{incl})}{\sigma(W + nj)} = \frac{\sigma(Z_{incl})}{\sigma(Z + nj)} \quad (2)$$

where the inclusive W-boson and Z-boson cross-sections ( $\sigma(W_{\text{incl}})$  and  $\sigma(Z_{\text{incl}})$ ) and the exclusive cross-section for Z produced in association with n jets ( $\sigma(Z + n\text{j})$ ,  $n = 0 - 4$ ) are extracted from the data. Equation (2) is demonstrated to be valid to a few percent level in [29], depending on the selection cuts applied (e.g.  $p_T$  cut on jets).

When the data will be available the normalisation of the W+j background will be extracted from relation (2) using Z+nj samples selected in  $Z \rightarrow ee$  events.

Obtaining the normalisation for this background from the data has shown to be essential, since the uncertainty on the exclusive cross-section of the W+nj background obtained from ALPGEN can be as large as 50% [30]. The largest uncertainties affect the topologies with higher number of jets that are typical of  $t\bar{t}$  events. We have verified that such large variations of the exclusive cross-sections are found when selecting events with at least 4 jets with  $p_T > 40$  GeV in ALPGEN W+nj fast simulated samples generated with different sets of matching parameters. While the normalisation has large uncertainties, the shapes of the distributions are found to be basically independent of the choice of the matching parameters. With data driven methods and about  $1 \text{ fb}^{-1}$  of luminosity, a 20% uncertainty on the W+nj normalisation should be reachable.

# Triggering Top Quark Events

## Abstract

Collisions at the LHC occur at a rate of up to 40 MHz, much larger than the 200 Hz storage capacity of the ATLAS experiment. The ATLAS trigger system has the challenging task of rejecting 99.9995 % of the events produced in collisions, while keeping those needed to achieve the physics goals of the experiment. This note evaluates the expected performance of the trigger system in top quark events by investigating the response of the trigger system to single objects such as a muon, an electron or a jet originating from top quark decays. In addition, the methodology needed to efficiently select top quark events in the online trigger system is discussed including methods to determine trigger efficiencies from data.

## 1 Introduction

Triggering at the Large Hadron Collider (LHC) is a challenging task. The selection system is required to reduce the initial bunch-crossing rate of 40 MHz down to a manageable 100-200 Hz while retaining and recording the five in one million most interesting physics events. ATLAS has designed a three-level trigger which aims to select these events, with the highest possible efficiency and lowest possible bias.

The ATLAS trigger is largely based on signatures of high transverse-momentum particles and large missing transverse energy. The first trigger level (L1) is implemented using custom electronics and is based on coarse-resolution data from the calorimeters and dedicated fast muon detectors [1]. The level-2 trigger (L2) and the Event Filter (EF), referred to together as the High Level Trigger (HLT), are implemented in software and run on a commodity computing cluster [2]. The L2 design is based on the concept of Regions of Interest (RoIs). Algorithms request full-resolution data only from the region of the detector corresponding to the L1 candidate object and perform a more refined analysis of its features. The EF works also in a seeded mode although it has access to the full-resolution data of the entire detector. It runs more sophisticated offline reconstruction and selection algorithms.

At the LHC top quarks are mainly produced either in pairs or singly. A large set of different and complex event signatures is expected. For  $t\bar{t}$  events, approximately 44% of the decays will be fully hadronic, resulting in a final state with six jets<sup>1</sup>: four light jets from the W-boson decays and two b-jets. Another 44% of the decays will be semi-leptonic, with a final state containing one lepton, one neutrino, two b-jets and two light jets. Roughly 11% of the  $t\bar{t}$  decays will be purely leptonic, with two leptons, two neutrinos, and two b-jets in the final state. In single-top events, the W-boson decays hadronically two-thirds of the time and leptonically one-third. More details about the properties and decay modes of top events are discussed in the introduction [3].

The trigger efficiencies for top events of the most relevant single object triggers are studied in Section 2 of this note. The rich topologies of top events results in large overlap between trigger signatures. This feature can be exploited to monitor trigger efficiencies as discussed in Section 3. Finally, in Section 4, the electron trigger efficiency is extracted from  $Z \rightarrow ee$  events and is compared to the true efficiency in  $t\bar{t}$  events.

## 2 Single object trigger performance in top quark events

Results are presented for the basic trigger signatures using electron, muon and jet trigger objects, as well as missing transverse energy ( $E_T^{miss}$ ). The main trigger criteria from the ATLAS trigger tables for the

---

<sup>1</sup>Neglecting for now initial or final state radiation.

initial data taking phase are evaluated using simulated top quark signal samples. Two types of  $t\bar{t}$  signal samples are used in this note. The first is the fully hadronic sample with only jets in the final state and the second is a leptonic sample, consisting of a combination of semi-leptonic and di-leptonic events, and will be referred to as *leptonic* sample in the following. For top quarks produced singly, the s, t, and Wt channels are simulated and only those events which result in an electron or a muon from the W-boson decay are considered here. More details about the data samples are given in [3].

Trigger items are described by a combination of letters and numbers. The trigger object is represented by an abbreviation consisting of one or two letters. It is preceded by a number representing the object multiplicity and followed by a number signifying the transverse momentum ( $p_T$ ) of the trigger threshold. If an isolation requirement is applied, it is indicated by the letter ‘i’ after the  $p_T$  threshold. For example, the item name ‘2EM18I’ represents a trigger on two electromagnetic objects, with a threshold of 18 GeV each, including isolation requirements. The L2 and EF item naming conventions are the same as L1 except that lower-case letters are used. A trigger chain consists of the L1, L2, and EF trigger items an object must satisfy and is referred to using the HLT notation. A *trigger menu* is a list of triggers enabled during a data taking run. For a more complete description, see [4].

The dependence of a trigger on the actual  $p_T$  cut will be investigated here by means of *turn-on curves*, which shows the fraction of objects passing a certain trigger as a function of the reconstructed or true simulated  $p_T$  of that object. Trigger candidate objects are matched to reconstructed or Monte Carlo simulated objects by cutting on  $\Delta R = \sqrt{\Delta\eta^2 + \Delta\phi^2}$  between the two objects.

In the following sections, single object triggers are evaluated in detail first in  $t\bar{t}$  events, and then in single-top events.

## 2.1 Electron triggers in $t\bar{t}$ events

### 2.1.1 Introduction

Leptonic  $t\bar{t}$  decays will form a statistically large sample of events early on at the LHC. Figure 1 (a) shows the simulated  $p_T$  spectrum of the electron from a W-boson decay in leptonic  $t\bar{t}$  events. The plot gives an idea of the expected fraction of events the trigger system is confronted with above certain  $p_T$  values. The single-electron trigger threshold is expected to be around 20 GeV, indicating that complex multi-object triggers (with correspondingly lowered thresholds) may be unnecessary.

### 2.1.2 Single electron triggers

The L1 electron triggers operate on reduced granularity ( $0.1 \times 0.1$  in  $\Delta\eta \times \Delta\phi$ ) calorimeter trigger towers which cover the range  $|\eta| < 2.5$ . A central cluster of four towers is formed in the electromagnetic and hadronic calorimeters, along with a ring of 12 towers around this central cluster. The ring is used to select candidates using isolation criteria by cutting on the amount of energy deposited around the central cluster. At L2, electromagnetic clusters are formed, tracking is then performed for the first time, and, finally, the reconstructed cluster is matched to a track. In the final stage, the EF, tracking and cluster determination is performed with more accurate algorithms, further refining the trigger decision. More details can be found in [4].

### 2.1.3 Single electron trigger efficiencies

The lowest unscaled trigger threshold depends on the luminosity. For a luminosity of  $10^{33} \text{ cm}^{-2} \text{ s}^{-1}$ , the e22i trigger is the unscaled trigger with the lowest  $p_T$  threshold. For the start-up luminosity of  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ , an e12i trigger is available. The e12i chain has a lower threshold and hence a higher efficiency in leptonic  $t\bar{t}$  events.

Figure 1: **(a):**  $p_T$  spectrum of electrons from the decay  $W \rightarrow e\nu$  in leptonic  $t\bar{t}$  events. The number of electrons is scaled to an integrated luminosity of  $1 \text{ pb}^{-1}$ , and is shown as a function of the true simulated electron  $p_T$ . **(b):** Turn-on curves for the e22i trigger determined with leptonic  $t\bar{t}$  events. The efficiencies are shown with respect to an offline selection (excluding the cut on  $p_T$ ) as a function of the offline reconstructed  $p_T$  of the electron that fired the trigger.

Table 1: Efficiency of the e22i and e12i trigger for leptonic  $t\bar{t}$  events with a  $W \rightarrow e\nu$  decay. The binomial errors  $\Delta$  on the efficiencies for the different trigger levels are quoted for an integrated luminosity of  $100 \text{ pb}^{-1}$ , and are calculated as  $\Delta^2 = \varepsilon(1 - \varepsilon)/N$ , where  $\varepsilon$  is the efficiency. Note that no matching constraint is imposed between the trigger and the reconstructed or true simulated electrons. Moreover, the efficiencies are determined for  $|\eta| < 2.5$  by cutting on the  $\eta$  of the trigger as well as the reconstructed or simulated electrons.

Trigger	Compared to Monte Carlo	Compared to offline selection
	Eff. [%]	Eff. [%]
<b><u>e22i:</u></b>		
L1 EM18I	$74.7 \pm 0.5$	$96.0 \pm 0.6$
L2 e22i	$59.6 \pm 0.6$	$92.7 \pm 0.9$
EF e22i	$52.9 \pm 0.6$	$89.8 \pm 1.0$
<b><u>e12i:</u></b>		
L1 EM7I	$83.6 \pm 0.4$	$98.6 \pm 0.3$
L2 e12i	$66.7 \pm 0.5$	$92.6 \pm 0.8$
EF e12i	$63.5 \pm 0.5$	$91.8 \pm 0.8$

Table 1 shows the fraction of events passing each trigger level in the e22i chain per  $100 \text{ pb}^{-1}$ . The e22i trigger chain consists of the L1 trigger L1\_EM18I, and the e22i trigger at L2 and EF. The efficiency has been calculated for each trigger level with respect to the total number of leptonic  $t\bar{t}$  events with a  $W \rightarrow e\nu$  decay and with respect to the number of events reconstructed and selected in the *commissioning* analysis [5], requiring  $|\eta| < 2.5$  for the trigger and reconstructed or simulated electrons. The cuts are:

- At least one reconstructed isolated electron with  $p_T > 20 \text{ GeV}$ ;
- $E_T^{\text{miss}} > 20 \text{ GeV}$ ;
- At least 3 reconstructed jets with  $p_T > 40 \text{ GeV}$  and at least 4 reconstructed jets with  $p_T > 20 \text{ GeV}$ .

Also shown in Table 1 are the percentage of events passing each trigger level in the e12i chain.

Compared to e22i, a larger fraction of events passes this looser chain at each level, as expected. Note that the large value of the trigger efficiency with respect to the selection, exceeding 90%, is partly due to jets fulfilling the electron trigger. Eventually this effect has to be accounted for when determining trigger efficiency corrections to be used in an analysis.

Figure 1 (b) shows the turn-on curves for each trigger level in the e22i chain, determined from simulated leptonic  $t\bar{t}$  events. The turn-on behaviour of the trigger is sharp at all levels. From the L1 to the HLT the  $p_T$  dependence is very similar, the curves reveal a flat plateau once beyond the turn-on region. Note that the slight decrease in efficiencies at large  $p_T$  values are due to the isolation requirements of the e22i trigger. This small loss can be recovered using a high-threshold non-isolated trigger, although it has not been considered in this study.

In summary, the single electron trigger efficiency in  $t\bar{t}$  events is high for  $t\bar{t}$  events with a  $W \rightarrow e\nu$  decay in the current physics trigger menus. The electron trigger chain will be, together with the muon chain discussed in the next section, the main trigger for selecting  $t\bar{t}$  events in the *golden* leptonic decay channel. Simple and efficient high- $p_T$  isolated single electron triggers exist to select  $t\bar{t}$  events, avoiding considerable complications in the determination of trigger efficiencies for complex combined trigger signatures.

## 2.2 Muon triggers in $t\bar{t}$ events

### 2.2.1 Introduction

Figure 2: **(a):**  $p_T$  spectrum of muons from  $W \rightarrow \mu\nu$  decays in leptonic  $t\bar{t}$  events. The muon  $p_T$  is the true simulated value. The distribution is scaled to correspond to an integrated luminosity of  $1 \text{ pb}^{-1}$ . **(b):** Trigger efficiencies for the mu20 with respect to an offline selection (excluding the cut on  $p_T$ ), given as a function of reconstructed muon  $p_T$ .

The  $p_T$  spectrum of truth muons from the  $W \rightarrow \mu\nu$  decay in  $t\bar{t}$  events is shown in Fig. 2 (a). As for electrons, rather high- $p_T$  single muon triggers can be used to select  $t\bar{t}$  events with at least one W-boson decaying to a  $\mu$  and  $\nu_\mu$  without much loss of efficiency.

### 2.2.2 Single muon triggers in ATLAS

The L1 muon trigger consists of fast electronics establishing coincidences between hits of different detector layers of the muon system inside programmed geometrical windows. The size of the window defines

the transverse momentum interval corresponding to the deflection of the muon in the toroidal magnetic field. One of six programmable  $p_T$  thresholds is assigned to the candidate. The L2 processing consists of three reconstruction steps applied to full granularity data of the region defined by L1. First, the muon candidate is reconstructed in the muon spectrometer. Then inner detector tracks are reconstructed around the muon candidate. Both are combined to form the L2 muons upon which the trigger decision is based. Currently only the  $p_T$  of the muon candidate is checked. Isolation requirements or constraints on the  $\chi^2$  of the combined inner detector and muon spectrometer track are not imposed here (but might be in future). The muon reconstruction in the Event Filter is done using offline algorithms. The EF muon trigger decision at the moment is also based solely on the  $p_T$  of the reconstructed muon candidate. A more complete description of the muon trigger can be found in [4].

### 2.2.3 Single muon trigger efficiencies

Using the standard L1 muon thresholds, six different trigger items have been defined in the simulated samples under study; L1\_MU06, L1\_MU08, L1\_MU10, L1\_MU11, L1\_MU20 and L1\_MU40. The efficiencies for each trigger item are shown in Fig. 3 (a). Each efficiency is calculated with respect to the number of simulated leptonic  $t\bar{t}$  events with a  $W \rightarrow \mu\nu$  decay. It can be seen that the high- $p_T$  L1 single muon triggers provide a high efficiency for selecting the events. When running at an increased luminosity of  $10^{34} \text{ cm}^{-2} \text{ s}^{-1}$ , the threshold could be raised to 40 GeV without an unacceptable loss in efficiency.

Figure 3: Efficiencies of the single muon triggers for L1 (a), L2 (b), and EF (c), determined using leptonic  $t\bar{t}$  events with a  $W \rightarrow \mu\nu$  decay. For the L1 items, the efficiencies are calculated for the six available thresholds. The HLT efficiencies are plotted as a function of the  $p_T$  cut applied. In Fig. (b) the L2 chain is started by L1 RoIs passing the MU06 threshold and in Fig. (c) the EF chain is started by muon candidates passing the mu06 signature at L2. Note that the efficiencies are calculated with respect to the number of simulated muons within  $|\eta| < 2.4$ .

Figure 3 (b) shows the absolute efficiency of the L2 single muon trigger in the case of the HLT chain being started by a MU06 RoI. The  $p_T$  cut applied by the L2 algorithm is shown on the horizontal axis. Similar efficiencies are shown in Fig. 3 (c) for the EF when the EF chain is started by a L2 muon candidate fulfilling the mu06 signature. The absolute trigger efficiency for the HLT cannot in principle be inferred directly from these plots, as for instance the L2 mu20 processing will only be initiated by L1 RoIs which fulfill the L1\_MU20 requirements. On the other hand, the efficiencies for each trigger level, normalized to the number of events with a true simulated muon from a W-boson decay within  $|\eta| < 2.4$ , have been calculated for a few trigger signatures and are shown in Table 2. Comparing Table 2 with Fig. 3, one can see that the differences are small. Hence these figures can be used to indicate the effects of a change in trigger threshold cuts.

The efficiencies of the single muon trigger signatures have also been evaluated for the events selected by the *commissioning* analysis [5]. The same cuts as described in the electron section 2.1.3 are applied.

Table 2: Efficiencies of the mu06, and mu20 trigger chains for leptonic  $t\bar{t}$  events with at least one  $W \rightarrow \mu\nu$  decay. The numbers are absolute trigger efficiencies, the reference offline selection is given in [5]. The binomial errors  $\Delta$  are calculated as  $\Delta^2 = \varepsilon(1 - \varepsilon)/N$ , where  $\varepsilon$  is the efficiency, for an integrated luminosity of  $946\text{pb}^{-1}$ , which corresponds to the available Monte Carlo statistics. Note that the efficiencies are determined for  $|\eta| < 2.4$  by cutting on the  $\eta$  of the trigger as well as the reconstructed or true simulated muons.

Trigger	Compared to Monte Carlo Eff. [%]	Compared to offline selection Eff. [%]
<b>mu06:</b>		
L1	$83.8 \pm 0.3$	$91.9 \pm 0.4$
L2	$80.2 \pm 0.3$	$88.7 \pm 0.4$
EF	$73.1 \pm 0.2$	$83.1 \pm 0.4$
<b>mu20:</b>		
L1	$74.6 \pm 0.2$	$86.4 \pm 0.4$
L2	$66.3 \pm 0.2$	$82.3 \pm 0.4$
EF	$58.8 \pm 0.2$	$76.6 \pm 0.4$

The results are given in Table 2 for the mu20 trigger chain, which consists of the L1 trigger L1\_MU20, and the mu20 trigger at L2 and EF. The table shows that the mu20 signature is effective in selecting events for the commissioning analysis.

One can also determine the turn-on curve of the trigger efficiency for single muons in  $t\bar{t}$  events. For that purpose a L1 muon is matched to a reconstructed muon by requiring  $\Delta R < 0.15$  while L2 and EF trigger muons are matched by requiring  $\Delta R < 0.1^2$ . Figure 2 (b) shows the mu20 trigger chain efficiencies for reconstructed muons as a function of their reconstructed  $p_T$ . The muons are required to have  $|\eta_\mu| < 2.4$ , as this is the reach of the muon trigger chambers. The L1 turn-on is less steep than those for the higher trigger levels, due to the coarser  $p_T$  threshold assignment at L1 than at the HLT. The thresholds at the different levels are set such as to reach the plateau at the same value of the offline reconstructed  $p_T$ . At all trigger levels, once the plateau is reached, the efficiencies remain flat versus  $p_T$ .

In summary, as for the electrons, the single muon trigger efficiency in  $t\bar{t}$  events is reasonably large. The mu20 is the most relevant muon trigger for selecting  $t\bar{t}$  events with at least one W-boson decaying to a muon.

### 2.3 Jet triggers in $t\bar{t}$ events

Jet triggers are dominated by QCD multi-jet events, which have production cross-sections orders of magnitudes larger than the top signal processes. Therefore it is not obvious that multi-jet triggers giving acceptable rates will correspond to  $p_T$  thresholds efficient for selecting top events. In order to characterize jet distributions in  $t\bar{t}$  events, Fig. 4 (a) shows the  $p_T$  distribution of the six highest- $p_T$  jets (ordered in  $p_T$  and defined using a cone jet algorithm with radius 0.4) for hadronic  $t\bar{t}$  events as obtained after a full event reconstruction. The characteristics of top events are a large number of high- $p_T$  jets. This is expected to provide some discriminatory power against the background, which has a steeply falling  $p_T$  spectrum.

In Fig. 4 (b), turn-on curves are given for different  $p_T$  thresholds at L1, for leptonic  $t\bar{t}$  events. The plot is obtained by matching a jet triggered at L1 with a corresponding fully reconstructed jet within

<sup>2</sup>The  $\Delta R$  cuts were chosen after studying the  $\Delta R$  distributions for the different trigger levels.

Figure 4: **(a):** Reconstructed  $p_T$  distribution of the six leading jets for hadronic  $t\bar{t}$  events. **(b):** Turn-on curves relative to the reconstructed jet  $p_T$  for jets triggered at L1 at various threshold values for leptonic  $t\bar{t}$  events. **(c):** L1 trigger efficiency versus trigger threshold for multi-jet triggers for hadronic  $t\bar{t}$  events. The efficiency is calculated with respect to all events in the sample.

$\Delta R < 0.2$ . The curves reveal, compared to the lepton triggers, a rather slow turn-on of the L1 jet triggers, resulting from coarse resolution at L1 (cf. [6]).

Table 3: Jet trigger efficiencies for  $t\bar{t}$  signal and trigger rates, the latter also for the most important background events (the background samples are described in [3]). The efficiencies are for the whole trigger decision (after the EF), and are calculated with respect to the total number of events. The order of magnitude of the trigger rates are given for a luminosity of  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ .

Process	j20		j160		4j50	
	Eff. [%]	Rate	Eff. [%]	Rate	Eff. [%]	Rate
Leptonic $t\bar{t}$	99.8	$O(10^{-3} \text{ Hz})$	11.2	$O(10^{-4} \text{ Hz})$	9.9	$O(10^{-4} \text{ Hz})$
Hadronic $t\bar{t}$	100.0	$O(10^{-3} \text{ Hz})$	12.9	$O(10^{-4} \text{ Hz})$	21.0	$O(10^{-4} \text{ Hz})$
QCD	-	$O(10^3 \text{ Hz})$	-	$O(\text{Hz})$	-	$O(10^{-1} \text{ Hz})$
W-boson+Jet	-	$O(10^{-3} \text{ Hz})$	-	$O(10^{-4} \text{ Hz})$	-	$O(10^{-4} \text{ Hz})$

Figure 4 (c) shows the L1 trigger efficiency for different jet multiplicities as a function of the trigger  $p_T$  threshold for hadronic  $t\bar{t}$  events. Single jet triggers will be more than 90% efficient for thresholds up to about 60 GeV, and roughly 45% efficient at 100 GeV. Table 3 summarises trigger efficiencies for signal and background rates for a selection of single and multi-jet triggers. Depending on how high the jet trigger thresholds are set, the signal efficiency varies between 10 and 100%. Due to large QCD rates, only high single-jet thresholds or carefully optimised multi-jet triggers are affordable. For example, for the j160, a rate of  $O(\text{Hz})$  is to be expected from QCD multi-jets already for an instantaneous luminosity of  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ .

### 2.3.1 Multi-jet triggers for the fully-hadronic $t\bar{t}$ channel

The multi-jet trigger item 4J50 listed in the previous section is intended to be general purpose, applicable to a wide range of physics channels. In order to optimize the signal efficiency of the jet triggers, especially for the fully-hadronic  $t\bar{t}$  decays not accessible with lepton triggers, other trigger combinations for multi-jet triggers are studied. The aim is to identify optimum trigger combinations that reduce QCD background rates, while keeping a sizable signal acceptance in the fully-hadronic  $t\bar{t}$  decay channel.

Table 4: Set of optimum multi-jet trigger combinations for fully-hadronic  $t\bar{t}$  events. The QCD multi-jet background rates are given relative to the background rate of the 4j50 trigger (cf. Table 3). Efficiencies and rates at the EF are calculated with respect to the total number of events. Note that the names of the triggers are inclusive, “4j60\_2j100\_j170” means 4 jets have to pass the 60 GeV trigger, 2 jets the 100 GeV, and another 1 jet has to pass the 170 GeV trigger.

Trigger	Signal Efficiency [%]	Relative Background Rate	S/B
4j60_2j100_j170	6	0.13	$2.8 \cdot 10^{-3}$
5j45_2j60_j100	16	0.34	$3.0 \cdot 10^{-3}$
6j35_5j45_4j50_3j60	10	0.18	$3.7 \cdot 10^{-3}$

Therefore, trigger combinations requiring at least 4, 5 or 6 jets for a given set of jet thresholds, were tested.

Table 4 summarizes signal efficiencies and increased background suppression for a set of trigger combinations. As figure of merit, the ratio of the trigger efficiency for the signal and QCD events is used. A strong suppression of QCD is observed when tightening the cuts on the jet energies, as expected. The signal-to-background ratio of the 4J50 trigger (cf. Table 3) is improved by a factor of two in the 5J45\_2J60\_J100 trigger (cf. Table 4) for roughly the same signal efficiency. Overall, the three trigger combinations given in Table 4 are optimal in terms of the figure of merit, and the 5 jet trigger combination leads to the best signal efficiency with the lowest background rate for fully-hadronic  $t\bar{t}$  events. It is worth pointing out, that the reliable determination of trigger efficiencies from data is another challenging aspect of multi-jet triggers.

Large uncertainties are inherent in predictions for LHC energies, hence the QCD background trigger rates given here and the jet trigger definitions are preliminary and subject to tuning as soon as data taking starts. This is especially true for the effect of pile-up, which also impacts the signal trigger efficiencies. It is shown nevertheless that it should be possible to trigger on fully-hadronic  $t\bar{t}$  decays with reasonable efficiency by optimising the choice of thresholds and multiplicity. Further HLT studies are underway to fully exploit also advanced methods for background suppression, such as multi-variate analysis techniques.

## 2.4 Missing $E_T$ triggers in $t\bar{t}$ events

The L1  $E_T^{miss}$  trigger performance in  $t\bar{t}$  events is presented in this section. The HLT performance is not discussed due to ongoing development effort at the time of this writing.

The L1 energy triggers calculate missing transverse energy ( $E_T^{miss}$ , trigger item name: XE) based on reduced granularity calorimeter data (the trigger towers) without taking muons into account, across an  $\eta$  range of  $|\eta| < 5.0$  [4].

Figure 5 shows the  $E_T^{miss}$  spectra at L1 for  $t\bar{t}$  signal and background events normalized to an integrated luminosity of  $1 \text{ pb}^{-1}$ . Shown is the QCD background for which  $E_T^{miss}$  is mainly faked by jet response fluctuations and losses in non-instrumented regions of the calorimeters. In the W-boson+jets background, a neutrino from the W-boson decay is present and produces real  $E_T^{miss}$ . Single top quark events are also shown, with a combined rate of about one third of  $t\bar{t}$ . As can be seen from the figure, high QCD rates will not permit inclusive  $E_T^{miss}$  triggers with low thresholds, hence L1 trigger efficiencies for  $t\bar{t}$  events will be small at larger luminosities. While for example L1\_XE30 has an efficiency of 81% for leptonic events (applying no selection cuts in the efficiency calculation), the efficiency decreases to 19% for L1\_XE100. For comparison, the lowest un-prescaled  $E_T^{miss}$  threshold for the early running at a luminosity of  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  is expected to be L1\_XE70 [4].

Figure 5:  $E_T^{miss}$  spectra as measured by the L1 trigger for leptonic and fully-hadronic  $t\bar{t}$  signals and the most significant backgrounds to  $t\bar{t}$ . The samples are normalized to an integrated luminosity of  $1 \text{ pb}^{-1}$ . Note that the  $W + jets$  samples used here include W-boson decays to electrons, muons, and taus, as described in Table 2 of [3].

## 2.5 Single-top trigger

The final state of leptonic single-top events in the s, t, and Wt channels are characterized by one high- $p_T$  muon or electron,  $E_T^{miss}$ , and by one to three jets. Since these leptons are among the high- $p_T$  products of a W-boson decay, a relatively large lepton  $p_T$  threshold can be used to select the single-top events at the trigger level. Therefore, the most important triggers for selecting single-top events are the high- $p_T$  muon and electron triggers. Multi-jet and  $E_T^{miss}$  triggers can be used in combination with lower threshold electron and muon triggers in order to enhance acceptance.

The turn-on curves for the mu20 and e22i trigger are shown in Fig. 6. The trigger efficiencies are shown with respect to the single-top selection (the cut-based one listed in detail in [7]), and are very similar to the ones found in  $t\bar{t}$  events shown in the previous sections. Both triggers exhibit a sharp turn-on behaviour and a flat plateau up to 100 GeV.

The single-top event selection will include the trigger combination e22i OR e55 OR mu20. The efficiency for this combination, as well as the total trigger efficiencies for the individual items in the muon and electron channels, are shown in Table 5. The efficiencies are found to be high, above 80% in the muon channel, and up to 90% in the electron channel.

## 3 Trigger redundancy in top quark events

Due to the rich event topologies, top quark events satisfy many trigger items simultaneously. This redundancy may be exploited to enhance signal over background rates by forming combined trigger items and to monitor the trigger by providing information on trigger efficiencies from data.

Combining suitable trigger items may reduce significantly the background rate. For example, in a combined jet and  $E_T^{miss}$  trigger, the  $E_T^{miss}$  requirement will suppress the QCD background. For the same allocated bandwidth, the jet  $p_T$  threshold of the combined trigger can be lowered compared to the inclusive single jet trigger. Overall this will increase the number of recorded leptonic  $t\bar{t}$  events which

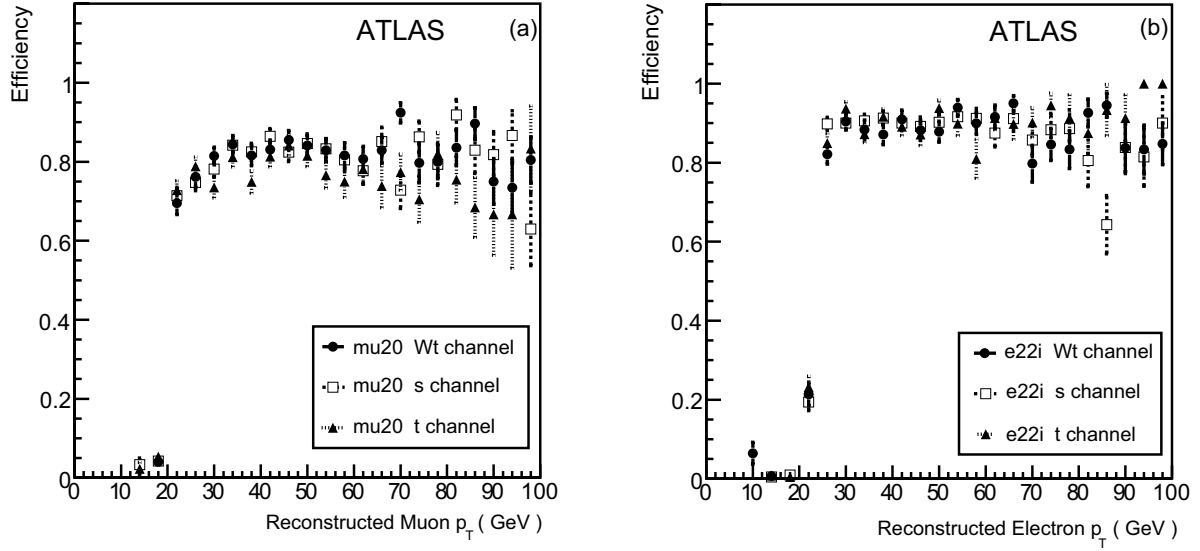

Figure 6: Turn-on curves are shown for the mu20 (a) and the e22i (b) trigger. In both plots, the circles represent Wt-channel single-top, the squares represent s-channel single-top, and the triangles represent t-channel single-top events.

have good acceptance for a moderate threshold on  $E_T^{miss}$ .

On the other hand, if there is sufficient overlap between two triggers, the efficiency for one of the triggers can be measured by selecting offline a clean sample of  $t\bar{t}$  events which satisfied the other trigger. For example, the lepton triggers used to select leptonic  $t\bar{t}$  events could be monitored in events that have been triggered by the combined jet and  $E_T^{miss}$  trigger. Possible biases due to correlation should be checked and eventually corrected for.

### 3.1 Trigger item overlap in $t\bar{t}$ events

The correlation among different trigger items is given in Fig. 7, with plot (a) showing overlaps for fully-hadronic  $t\bar{t}$  events and plot (b) showing overlaps for leptonic  $t\bar{t}$  events. The plots show the percentage of events triggered by the item on the  $x$ -axis that were also triggered by the item on the  $y$ -axis. The trigger items on the axes were representative of the ATLAS trigger menu at the time of this writing.

As expected, there is considerable overlap for the leptonic  $t\bar{t}$  events, and the event topology of these events is clearly illustrated. The leptonic triggers have very low acceptance in the fully-hadronic  $t\bar{t}$  events. Only the very low- $p_T$  muon triggers, which will be prescaled [4], have considerable efficiency due to muons from b-jets. Any combination of trigger items used to enhance the signal-to-background ratio in the fully-hadronic sample will have to rely on the jet triggers (cf. Section 2.3.1) only. For the leptonic channel, trigger combinations involving  $E_T^{miss}$  are potentially useful. Studies done at L1 have shown that  $E_T^{miss}$  trigger items indeed overlap considerably with the leptonic and jet triggers in leptonic  $t\bar{t}$  events.

## 4 Determination of trigger efficiencies from data and application to top quark events

Trigger efficiencies should be determined from data in order to reduce systematic uncertainties, as the shape as a function of  $p_T$  and the absolute value of trigger efficiencies are hard to describe precisely in

Table 5: Total trigger efficiencies for the three single-top channels. Efficiencies for the muon ( $W \rightarrow \mu\nu$ ) and electron ( $W \rightarrow e\nu$ ) channels are shown separately. The errors are calculated using the full available Monte Carlo statistics. Note that the reference event selection [7] selects one and only one isolated lepton for the electron and muon channel. Hence the trigger efficiency in the  $Wt$  channel does not increase when taking the OR of electron and muon triggers as compared to the single electron or muon triggers.

Sample	Muon Channel		Electron Channel	
	Trigger	Efficiency (%)	Trigger	Efficiency (%)
Wt	mu06	$88.4 \pm 0.6$	e22i	$87.1 \pm 0.7$
	mu20	$82.5 \pm 0.7$	e22i OR e55	$90.6 \pm 0.6$
	e22i OR e55 OR mu20	$82.5 \pm 0.7$	e22i OR e55 OR mu20	$90.8 \pm 0.6$
s	mu06	$88.0 \pm 0.6$	e22i	$89.2 \pm 0.7$
	mu20	$82.6 \pm 0.7$	e22i OR e55	$90.7 \pm 0.6$
	e22i OR e55 OR mu20	$82.6 \pm 0.7$	e22i OR e55 OR mu20	$91.0 \pm 0.6$
t	mu06	$86.0 \pm 0.7$	e22i	$89.5 \pm 0.7$
	mu20	$79.6 \pm 0.8$	e22i OR e55	$90.6 \pm 0.7$
	e22i OR e55 OR mu20	$79.6 \pm 0.8$	e22i OR e55 OR mu20	$90.9 \pm 0.7$

ATLAS

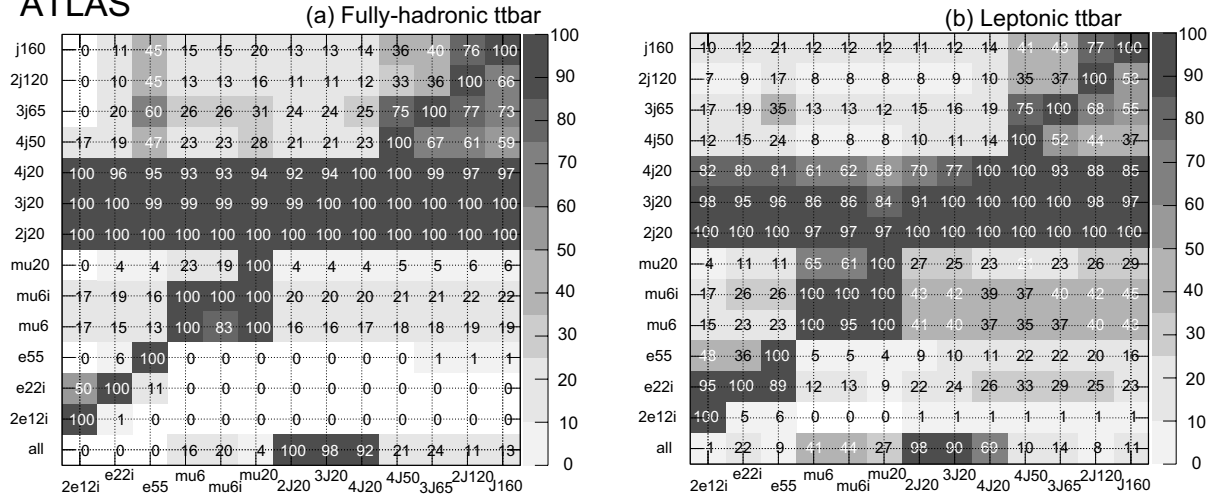

Figure 7: Trigger item overlap at the HLT for fully-hadronic (a) and leptonic (b)  $t\bar{t}$  events. The numbers in the plots indicate the percentage of events triggered by the item on the  $x$ -axis also triggered by the item on the  $y$ -axis. Note that, by definition, the values on the diagonal have full acceptance. The bottom row in each plot gives the total efficiency of the corresponding item on the  $x$ -axis.

simulations.

A methodology is tested to determine the electron trigger efficiency for top events in data. Events with  $Z$ -boson decays are used to parameterize the electron trigger efficiency as a function of  $p_T$  and  $\eta$  by means of the *tag and probe* method [8]. These parametrized efficiencies yield correction factors which can then be applied to top events.

Figure 8: Plots of the reconstructed top mass, reconstructed electron  $p_T$ ,  $\eta$  and  $\phi$ . The darker histogram is the reconstructed value, the black points include the correction from  $Z \rightarrow ee$ . The lighter histogram is from simulation where no trigger selection is applied.

The Standard Model Z-boson decaying to two leptons is relatively free of backgrounds at the LHC, and therefore provides a clean source of events for the *tag and probe* method. This method relies on the ability to obtain a clean sample of Z-boson events using selection cuts after obtaining the initial sample using a single electron trigger. From the di-electron final state one can *tag* the electron that fired the trigger, and *probe* the other in order to measure the trigger efficiency. Once this efficiency is extracted it can be applied to other processes which have been obtained using the same trigger, in this case top events.

Having selected top events using the commissioning selection [5], a correction for the trigger efficiency is applied to recover the number of events that would be measured by an ideal detector. For each event, a weight is applied according to the  $p_T$  and the position in  $\eta$  of the electron in the event. The weight is taken as the inverse efficiency extracted from look-up tables, which have been obtained with the *tag-and-probe* method.

Figure 8 shows the  $p_T$ ,  $\eta$ , and  $\phi$  distributions of the electron in the  $t\bar{t}$  event. The dark histogram represents events that have passed the trigger selection, the black points show the events after the correction is applied. The lighter histogram is from a sample of events run with the trigger disabled. Also shown in the figure is the top quark mass as measured using the above selection, after a correction for the trigger efficiency. It can be seen from the figure that the efficiency correction works well, the effect of the trigger

can be recovered to reproduce the simulated distributions. The effect of additional jet activity in  $t\bar{t}$  events as compared to  $Z \rightarrow ee$  events is thus indicated not to have a big effect at the current level of precision.

The final value of the trigger efficiency, used as a correction to the cross section measurement of the leptonic  $t\bar{t}$  decay channel with one electron in the final state, is a value  $\varepsilon_{trigger}$  of  $92.6 \pm 0.4 \%$  for an e12i trigger chain and  $91.5 \pm 0.4 \%$  for an e22i trigger chain for  $100\text{pb}^{-1}$ . These values are obtained by taking the ratio of the number of events before and after the trigger correction, and the uncertainty is statistical only. Note that to obtain these numbers, a matching between the trigger and the reconstruction electron candidates has to be done ( $\Delta R < 0.2$ ), in contrast to the numbers in Table 1.

In conclusion, it is shown that the *tag-and-probe* efficiency can be successfully applied to leptonic top decays. The method appears robust, however, the issue of background events passing the  $Z \rightarrow ee$  selection and the possible bias introduced thereby needs to be investigated.

## 5 Conclusions and outlook

The first studies of the expected ATLAS trigger performance for top events have been shown. All levels of the electron and muon triggers are found to be highly efficient for the *golden* leptonic  $t\bar{t}$  decays. The jet triggers, especially important for hadronically decaying tops, are much more challenging to use due to the high rate of QCD jets. High jet multiplicities of 5 or 6 jets with optimised  $p_T$  thresholds may provide the best acceptance.

Top quark events at the LHC will have especially rich event topologies and will result in many trigger items being fulfilled simultaneously. The overlap of trigger items was investigated to identify combinations of trigger items with improved signal efficiency and trigger rate, as well as potential monitoring triggers. The use of the  $E_T^{miss}$  trigger should be further investigated.

The trigger efficiency should be determined from data with the least possible bias. This must be validated with Monte-Carlo simulations, comparing the efficiencies derived with the data driven methods to the true efficiencies. Such a study, albeit not yet complete, was shown for the electron trigger efficiency using simulated  $Z \rightarrow ee$  samples. By using the trigger efficiency correction to the reconstructed kinematical distributions, it was shown that the simulated top quark distributions are very well recovered.

# Jets from Light Quarks in $t\bar{t}$ Events

## Abstract

This note describes the properties of jets from light quarks ( $u$ ,  $d$ ,  $s$  and  $c$ ) in  $t\bar{t}$  events, with the goal of obtaining a good reconstruction of the hadronically decaying W-boson, which will be used for an in-situ jet energy scale measurement and will enter, together with jets from  $b$  quarks, into the top quark reconstruction.

## 1 Introduction

The measurement of the top quark mass with a precision of 1 GeV is one of the goals of the LHC experiments. In order to achieve such a precision, several complementary methods can be used [1]. The most straightforward method, namely the measurement of the tri-jet invariant mass from the hadronically decaying top quark in the  $t\bar{t} \rightarrow l\nu b qqb$  channel, can in principle reach such a precision, provided that the three jets are well reconstructed and calibrated.

This note describes some studies of the reconstruction and calibration of jets from light quarks ( $u$ ,  $d$ ,  $s$  and  $c$ ) in  $t\bar{t}$  events, with the goal of obtaining the best possible reconstruction of the hadronically decaying W-boson. After a comparison of various jet algorithms, two methods of in-situ jet calibration using the W-boson mass distribution will be presented. Finally, the stability of the W-boson reconstruction with different gluon radiation settings in the Monte Carlo event generator will be shown.

Unless otherwise specified, the studies presented here have been performed using  $t\bar{t}$  events generated with MC@NLO + Herwig, with the top quark mass equal to 175 GeV, at least one of the W-bosons decaying leptonically, and a full GEANT simulation of the ATLAS detector. The simulation statistics corresponds to a luminosity of about  $0.9 \text{ fb}^{-1}$ . By default, no pile-up is included in the simulation, except in a few dedicated studies. Triggering was not considered, as  $t\bar{t} \rightarrow l\nu b qqb$  events will be triggered mainly by the leptonic decay of the second top quark, without biasing the jets on the hadronic side.

## 2 A comparison of jet reconstruction algorithms

The current default jet algorithm used for  $t\bar{t}$  event reconstruction in ATLAS is the cone algorithm with a size  $\Delta R = 0.4$ . A small cone size was indeed found in previous studies to give the best mass resolution and signal over background ratio. This section presents new studies of the optimal jet algorithm, performed by looking at the jet energy, angular resolutions and at the W-boson mass reconstruction. For these studies, the cone and  $k_T$  algorithms, with various parameters, were tried. Details on jet algorithms can be found in Ref. [2].

Cone algorithms define jets as the combination of input objects from generated stable particles or calorimeter energy deposits within a cone of radius  $R$  around the jet directions  $\eta$  and  $\phi$ . In an iterative procedure, the jets are repeatedly reconstructed until a stable configuration is found. Two different implementations exist: the first one, referred to as seeded cone jet finder, used in this paper, uses high  $E_T$  objects in the event as a starting point, whereas the second, seed-less implementation, is much slower but theoretically more accurate. In both scenarios, the jets obtained undergo a split-merge procedure, to define non-overlapping exclusive jets. The resulting jets then need to be calibrated as explained below.

The second class of jet algorithms consists of the  $k_T$  algorithm, which reconstructs jets via a clustering procedure. Such jets do not necessarily have a cone-shape with a fixed radius. Instead, the algorithm clusters “nearest” protojets together, depending on their relative transverse momentum. Thus, it also ensures a unique association of input clusters to jets, without the need for split/merge procedures as in cone algorithms.

The  $k_T$  algorithm introduces a distance measurement  $\Delta R$  and a recombination scheme [3]. The distance measurement decides which pair of protojets should be merged and when to stop merging a protojet any further. Deciding whether to merge the two closest jets or flagging one of the protojets as a final jet is executed recursively in the algorithm, until there are no more mergeable protojets left. The recombination scheme determines how to combine two protojets into a new protojets. Here we use the E recombination scheme.

There are two modes of operation for the  $k_T$  algorithm, the inclusive and exclusive mode. The inclusive  $k_T$  algorithm is intended for defining inclusive jet cross sections, as they are typically used in hadron-hadron interactions. It has a parameter  $R$ , which controls the decision to merge protojets or declare them as final jets, and plays a role comparable to the cone size in cone jet algorithms.

The  $k_T$  algorithm in its exclusive mode must account for the proton remnants and the underlying event in the p-p interaction for the calculation of exclusive cross sections. Its parameter  $D_{\text{cut}}$  controls the scale which separates “beam jets” from the “hard jets” during the clustering. Moreover, the value of  $D_{\text{cut}}$  can also be determined dynamically if one fixes the desired number  $N$  of final jets.

The basic input objects for both cone and  $k_T$  jet algorithms are either calorimeter towers, defined as a group of cells in a fixed  $(\Delta\eta, \Delta\phi)$  grid, or topological clusters, defined as a group of cells formed around a seed cell [4]. These calorimeter towers or topological clusters are given at the electromagnetic scale. The jets obtained are then calibrated to the hadronic scale using different weighting schemes such as the H1-style [5], whose major drawback is that the set of corrections is specific for each type of jet finder and each value of its parameters.

The comparisons of jet algorithms were performed on  $t\bar{t} \rightarrow l\nu b j j b$  events. In order to consider only jets relevant for the top quark mass measurement, an event selection was performed, requiring:

- a missing transverse energy  $> 20$  GeV to account for the unmeasured neutrino.
- one isolated electron or muon, defined as described in [6], with  $p_T > 20$  GeV and  $|\eta| < 2.5$ .
- at least 3 jets with  $p_T > 40$  GeV, a 4<sup>th</sup> jet with  $p_T > 20$  GeV, with  $|\eta| < 2.5$ .

## 2.1 Jet energy resolution and linearity

This section presents the energy and position measurement performance for various jet algorithms, calibrated with the H1 weighting scheme. Although we investigated, in this section, all the combinations of cone / inclusive  $k_T$  algorithm, 2 jets sizes, made from towers / topological clusters, with / without pile-up, for the sake of clarity not all results are shown in the figures.

In the events passing the event selection cuts, the jets considered for the resolution studies are the two jets closest to the two quarks from the W-boson decaying hadronically, when their distance  $\Delta R$  to the quark is less than 0.3. As the final goal is to improve the two jet invariant mass reconstruction, the jet energies (and directions) are hereafter compared directly to the ones of the associated quarks.

Figure 1 shows, for four jet algorithms, the distributions of the energy difference between the matched quark and jet, divided by the quark energy, for two different jet energy ranges. Larger jets lead, especially at low energies, to a worse resolution and to larger tails because the jet energies are overestimated when they overlap with other particles in the underlying event.

These energy distributions were fitted with a Gaussian distribution <sup>1</sup>. The width of the distribution, as a function of the energy, is shown on figure 2 and in Table 1. The resolutions obtained here are significantly worse than the detector resolution itself, as shown in Ref. [5], mainly because they include the fluctuations of the energy lost outside the jets, as relevant to determine the best algorithm for the

<sup>1</sup>To make the fit stable, a first Gaussian was fitted between the mean of the histogram  $\pm 2$  times the RMS. A second fit was then performed in the same way using the mean and width of the first fit.

Figure 1: Distributions of  $(E_{quark} - E_{jet})/E_{quark}$  for the jets from the W-boson decay, for two different quark energy ranges (left figure: quark energy between 15 and 50 GeV, right figure: quark energy above 350 GeV).

W-boson (and the top quark) mass reconstruction. To quantify this effect, Figure 3 compares these resolutions to the ones obtained by using the jets made from the Monte Carlo hadrons (“Truthjets”). The latter ones are typically 20% better, and comparable to the resolutions shown in [5].

Jet energy resolutions were also studied with events including the pile-up expected at a luminosity of  $10^{33} \text{ cm}^{-2}\text{s}^{-1}$  (figure 4 and Table 1), showing that:

- When jets are made from towers, small sizes are preferable, especially for the cone algorithm. For example, Figure 4 shows that the energy resolutions of cone 0.4 jets made from towers is degraded by 30% to 50% in presence of pile-up.
- The algorithms using topological clusters seem to behave very well, even in the presence of pile-up, as can also be seen on this figure.

For cone 0.4 algorithms, the reconstructed jet energy is on average 4% lower than the quark energy, for quarks with transverse momenta above 40 GeV. This 4% miscalibration can *a priori* come from the detector calibration itself, from the energy lost outside the jet, or from the underlying event. Figure 5 shows that, in the current simulation, the detector is very well calibrated, to a precision better than 3% for all algorithms, and to better than 1% for the cone 0.4 algorithm.

On the other hand, Figure 6 shows that the out-of-cone energy is important, and accounts for the 4% energy shift observed with cone 0.4.

The difference between the quark and the reconstructed jet energies, for quark energies between 15 and 50 GeV, is shown in Figure 7 with and without pileup, for the cone 0.4 from topological clusters algorithm. For such a small jet size and a topological cluster noise suppression, the average energy is shifted by 2.5 %.

## 2.2 Jet angular resolution

Figure 8 shows, for four jet algorithms, the distributions of the distance  $\Delta R$  between the quark and the matched jet, for the lowest and the highest energy bins. It can be seen that smaller jets have a

Table 1: Energy resolution (in %) as a function of the quark energy, for various jet algorithms, with and without pile-up.

algorithm	Energy range [GeV]

$k_T$ $R = 0.6$ , Tower, pile-up	33.3	24.0	19.6	17.0	14.8	11.6
$k_T$ $R = 0.6$ , Topo, pile-up	26.1	18.3	14.4	12.8	11.6	9.3

more precise direction determination. This can also be seen from Figure 9 where the full width at half maximum (FWHM) of these distributions are plotted. It was checked that, as for the energy resolution, the same conclusion remains when pile-up is added, and that jets made from topological clusters are less sensitive to pile-up.

It is observed that, for large cone sizes and large transverse momenta, the distributions of the distance between the quark and the matched jet have larger tails (larger fraction of jets with a distance to the associated quark between 0.1 and 0.3), because of a higher overlap probability.

### 2.3 W-boson mass reconstruction

This section compares the W-boson mass reconstruction performances for the cone algorithms with sizes 0.4 and 0.7 and for the  $k_T$  jet algorithms with different choices of parameters, both using topological clusters.

The choice of the jet algorithm parameters is crucial for the performance of the W-boson reconstruction. Indeed, the probability, averaged over the W-bosons selected in this section, for the two quarks from the W-boson decay to be at a distance  $\Delta R$  smaller than 1.4 is 25%, leading to non-negligible overlap effects for jet sizes of the order of 0.7, as already seen in section 2.1, and eventually to the merging of the two jets coming from the light quarks into a single one. On the contrary, the probability for the 2 quarks from the W-boson decay to be at a distance smaller than 0.8 is only 4%.

The same event selection as the one described in section 2.1 is performed, apart for the requirement that the fourth jet satisfies  $p_T > 40$  GeV, which is needed to improve the W-boson purity. On the selected events, the three jets whose four-momentum sum has the highest  $p_T$  are chosen to belong to the hadronic top quark. Among these three jets, the di-jet combination whose mass is closest to the known value of the W-boson mass (80.4 GeV) is taken to represent the W-boson. The remaining third jet is assumed to be the  $b$  quark; no further b-tagging information is used in this study. The distribution for the reconstructed

Figure 2: Energy resolution for jets from light quarks (integrated over all  $\eta$  values), as a function of the quark energy, for various jet algorithms (events simulated without pileup).

W-boson mass is shown in Figure 10.

To obtain mass values from the invariant mass spectra of Figure 10, the sum of a Gaussian and a 4<sup>th</sup> degree Chebychev polynomial is fitted to the distribution. The polynomial describes the background from wrong jet combinations and from background events, whereas the mean value of the Gaussian and its error are interpreted as the mass ( $m_W$ ) and its statistical error,  $\sigma_{stat}$ . The width of the Gaussian is referred to as  $\sigma_{Gauss}$ . Table 2 shows the obtained W-boson mass with the E recombination scheme for various choices of the  $k_T$  parameters.

The error resulting from 1% variation on the jet energy scale (JES) is obtained by varying the reconstructed jet energies by  $\pm 1\%$  followed by a linear fit across the three W-boson masses (-1%, nominal value, +1%).

With increasing R and  $D_{cut}$  parameter values, the reconstructed W-boson (and also top quark) mass rise monotonically. Higher parameter values lead to fewer but more energetic jets and thus their combination has a higher invariant mass. Part of this effect could in principle be absorbed by the in-situ calibration, but on the other hand, the event is more likely to be misreconstructed due to unwanted jet merging, which makes the choice of the three jets maximizing the  $p_T$ -sum unpredictable.

The efficiencies quoted in Table 2, defined as the number of events in the gaussian part of the mass distribution divided by the initial number of events, which can be as high as 5.8%, drop to less than 4% when the jets become too big.

Table 2 also shows the purity of the W-boson reconstruction, defined as the fraction of events in the gaussian part of the distribution, in the range  $[-1\sigma_{gaus}, 1\sigma_{gaus}]$  from the mean value of the gaussian fit. A purity around 64% can be obtained with some choices of the algorithms / parameters, for example cone 0.4 or  $k_T$  with  $R = 0.4$ , whereas other choices may lead to purities about 15% smaller.

This study indicates that, for the W-boson mass reconstruction in  $t\bar{t}$  events, the cone 0.4 algorithm

$D_{cut} = (10 \text{ GeV})^2$	81.25	7.03	0.17	5.4	54	$\pm 0.21$
$D_{cut} = (20 \text{ GeV})^2$	81.69	7.40	0.18	5.8	55	$\pm 0.27$
$D_{cut} = (30 \text{ GeV})^2$	81.84	7.44	0.20	5.3	57	$\pm 0.33$
$D_{cut} = (40 \text{ GeV})^2$	82.00	7.12	0.22	4.2	57	$\pm 0.39$
N = 5	82.02	7.35	0.21	4.5	54	$\pm 0.34$
* Cone R = 0.4	81.00	6.38	0.14	5.6	64	$\pm 0.36$
* Cone R = 0.7	85.15	8.03	0.26	3.9	53	$\pm 0.55$

leads to the best performance both in terms of resolution and in terms of efficiency / purity.

Finally, in addition to this study which uses jets calibrated with H1-style weights, a study of the W-boson reconstruction using local hadron calibration, described in detail in [5] and in [7], has been started. Although the local hadron calibration algorithm is still being improved, the W-boson mass reconstruction

Figure 10: Invariant di-jet mass as an estimate of the hadronically decaying W-boson mass in the selected events. The luminosity used corresponds to  $1 \text{ fb}^{-1}$  of signal and background events. The inclusive  $k_T$  algorithm in the E scheme with  $R=0.4$  is used for jet reconstruction. The data points for signal and background events are shown in black. The hatched histogram shows the distribution for background events (fully hadronic  $t\bar{t}$  events, single top events and W + jets events).

capabilities are similar to the ones obtained with H1-weighted jets, both in terms of mass resolution and purity.

## 2.4 Conclusion

The studies shown here indicate that a small jet size should be preferred for a proper reconstruction of the jets in  $t\bar{t}$  events, to avoid overlap effects spoiling the energy and angular resolutions and, eventually, leading to the merging of jets. Thus, the cone 0.4 jet algorithm from towers used in the following sections and in most top physics studies is a good choice for looking for top events in the first LHC data, although it could be complemented by an algorithm using topological clusters, which seem to be robust against pileup. The effect of the pile-up on the W-boson mass reconstruction needs however to be assessed.

# 3 Measuring the light jet energy scale

## 3.1 Introduction

The miscalibration of jet energies is one of the main sources of systematic error in the measurement of the top quark mass in the three-jet invariant mass method [1]. Indeed, a 1% error on the jet energy translates into a 0.9 GeV error on the top quark mass, 0.2 GeV coming from the light jet energy scale and 0.7 GeV from the b-jet energy scale. The goal of measuring the top quark mass with a precision of 1 GeV thus puts the limit on the miscalibration at 1% or better.

Several physics processes will be used in ATLAS to achieve such a precision [8]: di-jet events will help check the uniformity of the response as a function of rapidity;  $Z$ +jet and  $\gamma$ +jet events will be used to measure the energy scale as a function of energy. However, these processes cannot be applied directly to the jets in  $t\bar{t}$  events, for several reasons:

1. These processes contain a mixture of jets from light quarks, jets from  $b$  quarks and jets from gluons, with calibration factors probably different by a few % due to their different fragmentation and neutrino content
2. The underlying event may be different in  $t\bar{t}$  events
3. Jet selection performed to purify the  $t\bar{t}$  sample could lead to a different average jet energy scale in this sample

The use of  $W \rightarrow jj$  from the  $t\bar{t}$  events themselves (in-situ calibration) will thus be very important. After having shown how to select a clean  $W \rightarrow jj$  signal from  $t\bar{t}$  events, two possible methods for extracting the light jet energy scale will be presented. All the studies presented in this section (apart from the check of the stability with different top quark masses shown in section 3.6.3) use the default MC@NLO + HERWIG simulated events (with a top quark mass of 175 GeV), without pileup. The cone 0.4 jet algorithm from towers with the H1-style calibration is used for all studies in this section.

### 3.2 Event and $jj$ pair selection

In order to measure the jet energy scale with a precision of about 1%, a clean  $W \rightarrow jj$  sample must be selected. In this section the following selection cuts, which are stricter than the ones used previously, are thus used:

- One and only one isolated lepton (electron or muon) with  $P_T > 20$  GeV
- Missing  $E_T > 20$  GeV
- At least 4 jets with  $p_T > p_T^{cut}$
- Among them, 2 and only 2 jets must be tagged as  $b$ -jets. The other jets are called “light jets” in the following.

In order to increase the purity, the W-boson candidate  $jj$  pairs are selected among all light jet pairs which lead to a reconstructed top quark mass between 150 and 200 GeV. In addition, one may want to consider only events with only two light jets.

The estimated number of  $jj$  pairs selected for  $1 \text{ fb}^{-1}$  and the purity of the selection, defined as the fraction of  $jj$  pairs with both jets within  $\Delta R = 0.25$  of the two W-boson quarks, are shown in table 3 as a function of  $p_T^{cut}$ , and whether or not one uses only events with two light jets.

Requiring two light jets only reduces the number of  $jj$  pairs by about a factor of almost two, but is necessary if one aims to measure the jet energy scale down to 20 GeV, in order to minimize the bias due to the combinatorial background.

Figure 11 shows the  $jj$  mass distribution for  $p_T^{cut} = 40$  GeV and exactly two light jets. The combinatorial background (shown in grey) is almost flat. The systematic error due to the knowledge of the combinatorial background will be discussed later. Because of the requirement for 2  $b$ -tagged jets, the background from other processes is of the order of a few percent and is neglected here.

Table 3: Number of selected  $W \rightarrow jj$  pairs (for  $1 \text{ fb}^{-1}$ ) and purity of the selected pairs (the statistical uncertainty on the purity is about 1%)

$p_T^{cut} [\text{GeV}]$	2 jets only		2 jets or more	
	$jj$ pairs	purity [%]	$jj$ pairs	purity [%]
20	3100	76.9	7100	64.3
30	2300	77.7	4100	71.5
40	1200	81.0	1900	79.1

Figure 11: Invariant mass  $m_{jj}$  of the selected jet-jet pairs when the two jets are at  $\Delta R < 0.25$  from the two quarks from the W-boson decay (white histogram) and when at least one of the jets is not from the W-boson decay (grey histogram).

### 3.3 The $P_T$ cut effect in the Jet Energy Scale measurement

When measuring the jet energy scale, one must be aware of a shift introduced by any cut on the transverse momentum of the jets needed for the event selection. Indeed, when one selects jets with a reconstructed  $p_T$  greater than  $p_T^{cut}$ , jets with a true  $p_T$  lower than the cut but a reconstructed one above are selected, whereas jets with a true  $p_T$  above the cut but a reconstructed one below are lost. These two effects lead to a ratio (reconstructed energy) / (true energy) higher than one near the cut, even if the calibration is perfect.

This can easily be seen, and the size of the effect measured, with a simple Monte Carlo simulation where the momenta of the quarks from the  $W$  boson decays in  $t\bar{t}$  are smeared according to the expected jet resolution<sup>2</sup>, and a  $p_T$  cut on the smeared quark momenta is applied.

Figure 12 shows the apparent calibration as a function of the jet  $p_T$  cut, using this simple simulation.

<sup>2</sup>The value  $\sigma(E) = 3.8 \text{ GeV} + 0.063 \times E_q$  was used.

This apparent calibration is greater for jets whose energy is closer to the value of the  $p_T$  cut. The size of the effect is fully determined once the  $p$ ,  $p_T$  spectra and the detector resolution are known. With the expected resolution of the ATLAS calorimeter, the global apparent calibration is 2% for a  $p_T$  cut = 40 GeV.

Figure 12: The apparent jet energy scale due to a cut on the transverse momenta of the reconstructed jets. The error bars indicate how the shift varies when changing the jet resolution by  $\pm 20\%$ . This figure was obtained using the simple simulation described in the text.

The shift in the energy scale also leads to a shift on the reconstructed  $W$  boson and top quark masses, which are shown in Figures 13 and 14. With a  $p_T^{\text{cut}}$  at 40 GeV, the bias on the  $W$  boson mass is about  $1.5 \pm 0.6$  GeV, whereas the bias on the top quark mass is about  $2.0 \pm 0.4$  GeV.

The two jet energy scale determination methods described below handle this effect in a different way:

- The iterative method measures the effective jet energy scale above the  $p_T^{\text{cut}}$ , which will not reflect the bare jet energy scale, but will lead to  $W$  boson and top quark masses with the correct values.
- The template method aims at finding the bare jet energy scale (which was by definition 1 in the simple Monte Carlo simulation). The reconstructed  $W$  boson and top quark masses will then be shifted, and must be corrected.

### 3.4 Expected Jet Energy Scale

The energy scales fitted by the two methods described below will be compared with the true jet energy scale, obtained by comparing the reconstructed jet energy and the quark energy.

In the simulation version used for this note, the mean value of the ratio of jet to quark energies, when the two jets chosen to form the hadronic  $W$ -boson are at  $\Delta R < 0.25$  from the two quarks from the  $W$ -boson, for quarks with  $p_T > 40$  GeV is  $0.961 \pm 0.003$ , as can be seen in figure 15.

As shown in section 2.1, this 4% miscalibration is mainly due to the out-of-cone energy.

Figure 13: Shift of the reconstructed  $W$  boson mass,  $\langle m_{jj} \rangle$ , due to the  $p_T^{\text{cut}}$  on the jet energies. The error bars indicate how the bias varies when changing the jet resolution by  $\pm 20\%$ . This figure was obtained using the simple simulation described in the text.

Figure 14: Shift of the reconstructed top mass,  $\langle m_{t\bar{t}} \rangle$ , due to the  $p_T^{\text{cut}}$  on the jet energies. The error bars indicate how the bias varies when changing the jet resolution by  $\pm 20\%$ . This figure was obtained using the simple simulation described in the text.

Figure 15:  $E_{jet}/E_{quark}$  for jets originating from a W-boson and with  $p_T(quark) > 40$  GeV.

### 3.5 The iterative rescaling method

#### 3.5.1 Method

This method uses the precisely known W-boson mass as a reference to extract the light jet energy scale. The invariant mass of the two jets with energies  $E_1$  and  $E_2$  and an opening angle  $\theta_{jj}$ , originating from the W-boson can be written as :

$$M_{jj} = \sqrt{2E_1E_2(1 - \cos(\theta_{jj}))}$$

Figure 16 shows that the angle between the two jets is measured without any significant bias for most jet-jet pairs. Any deviation of  $M_{jj}$  therefore comes mainly from the energy miscalibration.

The peak value of this invariant mass matches the PDG W-boson mass value if the appropriate jet energy scale factors  $K(E_1)$  and  $K(E_2)$  are used:

$$M_W^{PDG} = \sqrt{2(K(E_1)E_1)(K(E_2)E_2) \times (1 - \cos(\theta_{jj}))} = \sqrt{K(E_1)K(E_2)}M_{jj}$$

If the jet calibration is independent of the energy ( $K = K(E_1) = K(E_2)$ ), the jet energy scale factor  $K$  is simply  $K = M_W^{PDG}/M_{jj}$ . The simple rescaling gives the effective jet energy scale, taking into account the  $p_T$  cut effect from the jet selection.

With  $1 \text{ fb}^{-1}$  of luminosity, around 4000 jets originating from the W in the  $t\bar{t}$  sample are available for calibration. Normalizing the sample to  $1 \text{ fb}^{-1}$ , the truth calibration, for jets with  $P_T > 40$  GeV, is  $K_{truth} = (E_{jet}/E_{parton})^{-1} = 1.014 \pm 0.002$ . The value obtained by the simple rescaling of jet pairs originating from a W boson (no background contribution) is  $K = M_W^{PDG}/M_{jj} = 1.014 \pm 0.003$ . The 1% goal on the precision on the global jet energy scale is therefore obtainable with  $1 \text{ fb}^{-1}$ , provided the luminosity dependence is small or can be corrected for.

Figure 16:  $(1 - \cos(\theta_{jj}^{MC})) / (1 - \cos(\theta_{jj}))$  as function of the reconstructed  $\cos(\theta_{jj})$ , where  $\theta_{jj}$  is the reconstructed angle between the two jets and  $\theta_{jj}^{MC}$  the angle between the two associated quarks.

Since the calibration is not constant over the energy and pseudorapidity, and since the two jets from the W-boson decay have in general different energies, the rescaling method has to be adapted to get the calibration  $K(\text{var})$  (var=jet energy, jet pseudorapidity or any other jet variable). Instead of building one jj mass distribution, the first step is to split the studied jet variable in N bins, and to build all associated jj invariant mass distributions. In such a way, the distributions become correlated to the studied variable.

It can be shown that, if the rescaling method is iterated M times, extracting at each iteration j the correction factor for the bin i ( $K_i^j$ ) and recomputing the invariant mass by adding the new  $K_i^j$  for the next iteration, the exact correction  $K_i$  per bin i can be obtained (thus the function  $K(\text{var})$ ):

$$K_i = \prod_{j=1,M} K_i^j \quad (1)$$

This method converges in 3-4 iterations, and is stopped when the maximum difference between  $K^j$  and  $K^{j-1}$  is less than 1%. The number of bins N depends on the available jet statistics.

### 3.5.2 Results

The simple rescaling method allows to determine a global jet energy scale factor. A W-boson mass value  $M_W = 79.12 \pm 0.25$  GeV is obtained from a fit with a polynomial+gaussian function to the jet-jet invariant mass spectrum. The resulting jet energy scale factor is thus  $K = M_W^{PDG}/M_{jj} = 1.016 \pm 0.003$ <sup>3</sup>. This value is very close to the one obtained previously by a fit on the same sample without combinatorial background included.

Figures 17 and 18 show the effective calibration to be applied on the selected jets after the  $t\bar{t}$  selection for  $10 \text{ fb}^{-1}$  of integrated luminosity<sup>4</sup>. The observed discrepancy between the fit result and the truth  $K$  factors is due to the  $(\eta, E)$  correlations existing on the jet energy scale factors. This is particularly true for high jet  $\eta$  and high jet energy. The discrepancy at low energy is a threshold effect which could be removed by lowering the  $p_T \text{ cut}$  on the jets to 30 GeV when measuring the jet energy scale above 40 GeV. Nevertheless the jet energy scale as a function of  $\eta$  and E can be extracted with a precision of the order of 1%, without any a priori knowledge of the function shape before the fit. The treatment of the correlation could be resolved by a fit on W mass distributions defined as a function of both jet  $\eta$  and E.

For  $1 \text{ fb}^{-1}$  of integrated luminosity, the number of available jets ( $\approx 4000$ ) limits the number of bins and therefore the accuracy of the extracted jet energy scale functions ( $K(\eta)$  and  $K(E)$ ). The resulting plots for  $1 \text{ fb}^{-1}$  are shown in Figures 19 and 20. A precision better than 2% is obtained in each energy or  $\eta$  bin.

### 3.5.3 Systematic uncertainties

The systematic uncertainties associated to each point are of three types:

- the first is related to the method itself. Performing the fit on a large sample shows up to 1% deviation, due to the  $(\eta, E)$  correlations on the jet energy scale which are not taken into account yet.
- the second is related to the impact of the background on the mass peak measurements. It is rather low since the W-boson sample has a purity above 80%. Further purification cuts can be applied to increase the purity. The associated error depends on the available statistics and is higher for

<sup>3</sup>The W boson mass is set to  $M_W = 80.4$  GeV in the simulation.

<sup>4</sup>The calibration factors are large in the barrel-endcap transition region. In principle this dependence is corrected at the level of jet reconstruction algorithm using a  $p_T$  balance method in di-jet events. This correction has not been applied on the used sample.

Figure 17: Result of the iterative rescaling fit as a function of  $E_{jet}$ , with  $10 \text{ fb}^{-1}$ : the expected effective calibration factors are shown as square points, in addition to the fitted calibration factors with circles. The calibration factor obtained from Monte Carlo truth information  $K_{truth}(E) = (E_{parton}/E_{jet})$  are shown as square points while the calibration factor  $K(E_i)$  obtained in the iterative rescaling procedure as described in section 3.5.1 are described with circles.

low jet energy where the background contribution is higher. It should be noticed that the jet pairs contributing to the background are mainly composed of one jet originating from the  $W$ -boson, the others being jets coming from the remaining part of the event or gluon radiation. An event mixing technique, described in [1] paragraph 4.2, will be useful to assess the shape of the background contribution on real data. To evaluate the systematics induced by the background contribution, the background contribution was changed by +20%, separately for the FSR and non-FSR contributions<sup>5</sup>. The fitted  $M_W$  values are all within 0.2 GeV, compatible with the statistical uncertainty leading to an uncertainty of  $0.003 \pm 0.003$  for the global jet energy scale factor.

- the last comes from the correction factor to be applied on the fitted value to take into account the  $p_T$  bias discussed in section 3.3. This correction of the effect is fully determined once the jet  $p$ ,  $p_T$  spectra and energy resolution are known. The size of this correction is  $-1\%$  above 100 GeV and up to 2% at 40 GeV. In order to assess the error on these values, the resolution has been rescaled by  $\pm 10\%$ , leading to variation less than one percent of the correction factors.

<sup>5</sup>The shapes of the background when a jet coming from the  $W$ -boson decay is associated with a FSR or a non FSR jet are different. They are taken from a fast simulation Monte Carlo.

Figure 18: Result of the iterative rescaling fit as a function of  $\eta_{jet}$ , with  $10 \text{ fb}^{-1}$ : the expected effective calibration factors are shown as square points, in addition to the fitted calibration factors with circles.

### 3.6 The template method

#### 3.6.1 Method

The template method for the light jet energy scale determination is similar to the method described in [9] for the electromagnetic energy scale determination using  $Z^0 \rightarrow e^+e^-$  events. It uses template histograms with various energy scales  $\alpha$  and relative (to the default jet energy resolution) energy resolutions  $\beta$ . The  $\chi^2$  between each template histogram and the “data” is then computed. The minimum of the  $\chi^2$  is found in the  $(\alpha, \beta)$  plane. With  $1 \text{ fb}^{-1}$ , this method fits both the average jet energy scale and a relative jet resolution. With enough data, it can be extended to measure these quantities as a function of the jet energy or rapidity.

The template histograms were generated from  $W \rightarrow qq$  decays in 1.2 million PYTHIA  $t\bar{t}$  events by smearing the quark energies by a gaussian number with width equal to  $3.8 \text{ GeV} + 0.063 \times E_q$ , determined on reconstructed jets in an older simulation of  $t\bar{t}$  events. As will be shown later, the exact choice of the default energy resolution in the templates is not very important, as it will lead at the end only to a change in the fitted  $\beta$  and not in the fitted  $\alpha$ . However, in order to obtain a  $\beta$  value close to 1, the jet angles are also smeared, according to the expected resolution, in the templates and the observed correlation between the two jet energies is added by using correlated gaussian numbers for the energy smearing.

After smearing the quark energies, the same  $p_T^{cut}$  as used in the data is applied. This ensures that the fitted energy scale is not affected by the bias described in section 3.3. Figure 21 shows the reconstructed jet-jet mass (for events with two jets or more, with the combinatorial background included), the template histogram for  $\alpha = 1$ ,  $\beta = 1$  and the best fit histogram.

Figure 19: Result of the iterative rescaling fit as a function of  $E_{jet}$ , with  $1 \text{ fb}^{-1}$ : the expected effective calibration factors are shown as square points, in addition to the fitted calibration factors with circles.

### 3.6.2 Results

Table 4 summarizes the results obtained for jets with  $P_T > 40 \text{ GeV}$ . The combinatorial background, which is flat as shown in Figure 11, doesn't affect the fitted jet energy scale (less than 0.6%), but degrades the fitted relative resolution by 30 to 40%. The choice to use or not events with more than two jets is also not changing the fitted jet energy scale.

Finally, these fitted energy scales are in good agreement with the expected value from the Monte-Carlo ( $0.961 \pm 0.003$ ), as obtained in section 3.4.

Table 4: Fitted jet energy scale and relative jet energy resolution using the template method, for jets with transverse momentum greater than 40 GeV. *Good combinations* refers to the cases where the two jets come from the W-boson decay, while the results with *all combinations* include the effect of the combinatorial background.

	$\alpha$	$\beta$
2 jets, good combinations	$0.9693 \pm 0.0045$	$1.145 \pm 0.054$
2 jets, all combinations	$0.9638 \pm 0.0049$	$1.434 \pm 0.064$
$\geq 2$ jets, good combinations	$0.9696 \pm 0.0033$	$1.089 \pm 0.035$
$\geq 2$ jets, all combinations	$0.9660 \pm 0.0036$	$1.308 \pm 0.041$

Figure 20: Result of the iterative rescaling fit as a function of  $\eta_{jet}$ , with  $1 \text{ fb}^{-1}$ : the expected effective calibration factors are shown as square points, in addition to the fitted calibration factors with circles.

### 3.6.3 Systematic uncertainties

Several checks of the stability of the method have been performed:

- The influence of the combinatorial background, and the choice of using or not events with more than two jets was already described in the previous section. All fitted energy scales are compatible within  $\pm 0.3 \%$ .
- The stability with respect to the ingredients used in the templates was checked by generating template histograms without the smearing of the angles, or without the correlation between the jet energies, or with a default jet resolution degraded by 20%. The fitted jet energy scales were found to be compatible within  $\pm 0.3\%$ , and only the fitted relative resolutions were changing. This shows that the method is not very sensitive to the simulation used for the templates.
- The jet energy scales were fitted on  $t\bar{t}$  events simulated with various top masses but the same version of the simulation and reconstruction codes. The results are shown in Figure 22. All results are compatible within  $\pm 0.5\%$ , even when including top masses in a very wide range.

### 3.6.4 Stability of the template method with smaller integrated luminosities

In order to check the stability of the template method at lower luminosities, the  $770 \text{ pb}^{-1}$  full dataset was split into sixteen parts, each part thus corresponding to  $48 \text{ pb}^{-1}$ . The fitted jet energy scales in the sixteen pseudo-experiments are shown in Figure 23. The average of the sixteen measurements is 0.9534, in good

Figure 21: Jet-jet invariant mass in fully simulated events (dots) superimposed on the template histogram with  $\alpha = 1$ ,  $\beta = 1$  and the best fit histogram.

Figure 22: Fitted jet energy scale as a function of the top mass.

agreement with the fit on the full sample ( $0.9562 \pm 0.0039$ ). The RMS of the sixteen measurements is 1.9%, only slightly worse than the value expected by a scaling with the square root of the luminosity (1.6%). In addition, the average of the errors given by the fit is 1.5%, showing that this error is correctly estimated by the fit even at low luminosities.

Figure 23: Fitted jet energy scale for sixteen  $48 \text{ pb}^{-1}$  pseudo-experiments. The horizontal lines show the result of the fit on the full sample with its error bar.

### 3.7 Conclusion on light jet energy scale

Two complementary methods for measuring the light jet energy scale from the  $W \rightarrow jj$  mass distribution in  $t\bar{t}$  events have been studied. The template method is well suited to measure the bare jet energy scale (integrated over some transverse momenta), with a precision which could be around 2% with  $50 \text{ pb}^{-1}$ . Within the statistical precision of the available datasets, no systematic error larger than 0.5% has been identified. The required precision of 1% on the light jet energy scale should thus be achievable. The iterative method, on the other hand, is well suited to measure the jet energy scale of the selected jet sample, possibly as a function of the energy or as a function of rapidity.

In this study, the invariant mass of selected jet pairs present a clear W-boson signal on top of a flat background dominated by combinatorial from top events (Figure 11). This is possible because b jets are tagged with a high efficiency and purity. In the early data-taking phase, b-tagging may be less performant and the level of background will be much higher with contribution from QCD or W+jet events. The performance of the methods for calibration of the light jet energy scale in these conditions need to be evaluated.

The dependence of the jet energy scale with the level of pile-up has to still to be investigated, in order to decide whether a specific correction is needed.

## 4 W-boson mass reconstruction and gluon radiation

The stability of the W-boson reconstruction with different QCD-related jet activity, commonly referred to as initial- and final-state radiation (ISR and FSR) has been evaluated by using the standard HERWIG + MC@NLO simulation and the “low mass” and “high mass” ACERMC + PYTHIA event samples described in [6].

### 4.1 Reconstructed W-boson masses

The same event selection (described in the previous section) and mass reconstructions is applied on the 3 samples, with jets being reconstructed with the  $\Delta R = 0.4$  cone algorithm from towers.

Figure 24 shows that the W-boson mass distributions for the 3 samples, normalized to the same number of events after selection, are clearly not compatible before calibration. The results of the mass peak fits are shown in Table 5. The difference between the high mass dataset and the low mass dataset is  $1.7 \pm 0.2$  GeV.

Figure 24: Reconstructed W-boson mass distribution (before calibration) in datasets with different gluon radiation settings. The distributions are normalized to the number of events after selection in the standard simulation and fitted with a gaussian function.

Table 5: Fitted top and W masses for the three datasets with different gluon radiation settings.

	maximum mass	minimum mass	MC@NLO + Herwig
W mass (GeV)	$81.29 \pm 0.12$	$79.59 \pm 0.15$	$80.44 \pm 0.14$
fitted energy scale	$0.9779 \pm 0.0024$	$0.9489 \pm 0.0026$	$0.9636 \pm 0.0025$
W mass after calibration (GeV)	$82.46 \pm 0.12$	$82.38 \pm 0.14$	$82.63 \pm 0.14$

The jet energy scales obtained with the template method described in section 3.6 are also shown in the table, together with the W-boson masses obtained after recalibrating the jet four-momenta. One observes that the calibrated W-boson masses are above the true W-boson mass because of the bias explained in section 3.3, but are all compatible within errors, showing that the calibration method is indeed working well.

## 4.2 Light jet properties

Although the in-situ calibration leads to W-boson mass distributions which are independent of the gluon radiation level, we looked for additional measurable quantities which could help to understand these effects and tune the Monte Carlo simulations.

Figure 25 show the  $p_T$  distributions for the light jets coming from the W-boson decay<sup>6</sup>. Only a very small difference, at low energies, is visible, which would probably be very difficult to measure in the data.

Figure 25:  $p_T$  distribution of the jets from the hadronic W-boson decay for datasets with different gluon radiation settings. The distributions are normalized to the number of events after selection in the standard simulation. In order to look for a possible difference at low values, the cut on the  $p_T$  value of the jets has been reduced to 20 GeV for this figure.

On the contrary, a very large difference is visible in the number of jets, as can be seen for example in the total number of jets with  $p_T > 10$  GeV reconstructed in the events, shown in Figure 26. If the jet reconstruction efficiency is well understood, this distribution in the data could help to tune the simulations, although the number of jets may also depend on the underlying event and may need to be corrected for luminosity.

Finally, no large difference has been seen in the  $p_T$  distributions for the jets not assigned to top quark decays, as shown in Figure 27.

<sup>6</sup>A cut  $p_T > 20$  GeV is applied in these figures

Figure 26: Total number of reconstructed jets with  $p_T > 10$  GeV for datasets with different gluon radiation settings. The distributions are normalized to the number of events after selection in the standard simulation.

Figure 27:  $p_T$  of the additional jets for datasets with different gluon radiation settings. The distributions are normalized to the number of events after selection in the standard simulation.

## 5 Conclusions

This note has presented several aspects of the W-boson reconstruction in  $t\bar{t}$  events.

First, it was shown in section 2 that small jet sizes should be preferred to avoid overlap effects. The current default (cone algorithm with  $\Delta R = 0.4$ ) is well suited for the study of the first data, but could be complemented by a reconstruction using topological clusters, which seems robust in the presence of pileup.

Two methods for the in-situ calibration of the light jet energy scale have been studied (section 3). The two methods should be able to provide a light jet energy scale to the 1% level with  $1 \text{ fb}^{-1}$ , and could perhaps be used to follow the jet energy scale with time and/or luminosity. The two methods use complementary approaches and should be both applied in real data, up to the level of a top quark mass measurement, to allow for cross-checks.

A study of simulations performed with different gluon radiation settings (section 4) has demonstrated that, although the reconstructed W-boson mass can change by a large amount with different settings, the in-situ calibration method is able to correct for it.

More generally, the clean and large W-boson sample which should be available in  $t\bar{t}$  events will be a good laboratory to study the performance of jet reconstruction and calibration in real data, and compare them with the performance in Monte Carlo simulated events.

Most studies presented in this note were performed without including pile-up effects. The dependence of the results with luminosity should thus be checked. In addition, a scenario of not yet optimal detector performance, which would lead to higher backgrounds, should also be studied in order to understand the potential of the method for the early phase of data-taking.

Finally, in order to reconstruct properly the top quarks, the knowledge of the  $b$  jets will be of particular importance. For instance, the  $b$  jet energy scale is, in our simulation, about 5% lower than the light jet energy scale. This difference should be checked in the data to reach the ultimate precision for the top quark mass measurement.

# Determination of Top Quark Pair Production Cross-Section

## Abstract

An accurate determination of the top quark pair production cross-section at the LHC provides a valuable check of the Standard Model. Given the high statistics which will be available, corresponding to about one top-quark pair per second, at a luminosity of  $10^{33} \text{ cm}^{-2}\text{s}^{-1}$ , the cross-section measurement can be performed relatively fast after the turnon of the LHC. Prospects for measuring the total top quark pair production cross-section with the ATLAS detector during the initial period of LHC are presented in this note. The cross-section is determined in the semi-leptonic channel, and in the dilepton channel. For the semi-leptonic channel we perform the measurement both with and without relying on the tagging of b-quark initiated jets.

## 1 Introduction

The determination of the top quark pair production cross section is one of the measurements that will be carried out once the first data samples are available at the ATLAS experiment. It casts light on the intrinsic properties of the top quark and its electroweak interactions. Cross section measurements are also an important test of possible new production mechanism, as non Standard Model top quark production can lead to a significant increase of the cross section. New physics may also modify the cross section times branching ratio differently in various decay channels, as for example predicted by Supersymmetric models [1] with charged Higgs particles,  $t \rightarrow H^- \bar{b}$ , or with super-partners of the top quark,  $t \rightarrow \tilde{t} \chi_0$ . The selection of top quark events is based on the identification of a jet from a b-quark, assuming a branching ratio  $BR(t \rightarrow Wb) = 1$ . The consistency of this assumption, performed with kinematic methods, is another important check of the Standard Model prediction but falls outside the scope of this paper.

Last but not least, the top pair production process will be valuable for the in-situ calibration of the ATLAS detector during the commissioning phase. The large cross section and the large signal to background ratio for the semileptonic channel, allows to identify high purity samples with large statistics in a short period of time. Understanding the experimental signatures of top events involves most parts of the ATLAS detector and is essential for claiming discoveries of new physics.

The cross-section values and the Monte Carlo samples which have been used throughout this note, are described in [9].

### 1.0.1 Cross section measurements at Tevatron

During Tevatron Run I (1992-1996) an integrated luminosity of about  $100 \text{ pb}^{-1}$  at a centre of mass energy of  $\sqrt{s} = 1.8 \text{ TeV}$  allowed to measure top pair production cross sections of  $6.5^{+1.7}_{-1.4} \text{ pb}$  and  $5.7 \pm 1.6 \text{ pb}$  by the CDF and DØ collaborations respectively [2]. The Tevatron Run II started in 2001 and until spring 2006 about  $1 \text{ fb}^{-1}$  of  $p\bar{p}$  collisions at  $\sqrt{s} = 1.96 \text{ TeV}$  have been collected and analysed. At this higher centre of mass energy an increase of about 30% in the cross section is expected. The most recent calculations predict a cross section of  $6.7^{+0.7}_{-0.9} \text{ pb}$  [3] at NLO+NLL or  $6.8 \pm 0.6 \text{ pb}$  [4] at NLO+ threshold resummation for a top mass,  $m_t = 175 \text{ GeV}$ . CDF and DØ measured a combined channels cross-section equal to  $7.3 \pm 0.5(\text{stat}) \pm 0.6(\text{sys}) \pm 0.4(\text{lum})$  [5] and  $7.4 \pm 0.5(\text{stat}) \pm 0.6(\text{sys}) \pm 0.4(\text{lum})$  [6] respectively. All the measurements are in good agreement with the predictions. From a combination of all results, an experimental error of the order of the theoretical error is expected.

## 2 Single lepton channel

In this section the strategy for the determination of the  $t\bar{t}$  cross-section in the semi-leptonic decay mode is described. This channel, which has a branching fraction of approximately 45%, has a clear signature, is experimentally easily accessible and is expected not to suffer from large backgrounds.

A robust analysis is presented of the first  $100 \text{ pb}^{-1}$  ATLAS data, which are expected to be collected during the first few months of the LHC data taking period. In particular it is studied whether a pure  $t\bar{t}$  sample can be identified without utilizing the full ATLAS b-tagging capabilities. This is brought about by the fact that efficient tagging of jets originated from the hadronization of b-quarks, called b-tagging from now on, is non trivial and implies a precise alignment of the inner detector, which will probably require several months of data taking. This analysis solely relies on the measurement of jets, leptons and  $E_T^{\text{miss}}$  (transverse missing energy), and requires a functioning lepton triggering system. Thanks to the over-constrained kinematics of the  $t\bar{t}$  system, with the selected events it will be possible to measure the b-tagging performance and the  $E_T^{\text{miss}}$ , as well as to calibrate the light jet energy scale.

### 2.1 Event selection

The identification of semi-leptonic  $t\bar{t}$  events starts by requiring a highest level (event filter) lepton trigger to have fired. In this study we assume that either the single isolated electron trigger e22 or the muon trigger mu20 (for the definition see [7]) has fired. A correct description of the trigger efficiencies is vital for the cross-section determination. The strategy for determining the trigger efficiencies from the Monte Carlo, as well as from the data without relying on Monte Carlo, is not pursued in this note, but included in [7].

Further, we define a candidate  $t\bar{t}$  event as having one reconstructed high- $p_T$  isolated lepton (electron or muon), a minimal amount of missing energy and at least four reconstructed jets. The definition of electrons, muons and jets in our analysis has been discussed before.

For our default off-line selection the events are required to fulfil the following:

- One lepton (electron or muon) with  $p_T > 20 \text{ GeV}$ .
- $E_T^{\text{miss}} > 20 \text{ GeV}$ .
- At least four jets with  $p_T > 20 \text{ GeV}$ .
- Of which at least three jets with  $p_T > 40 \text{ GeV}$ .

The fraction of events passing the individual selection requirements and the overall selection efficiency are shown in Table 1 for semi-leptonic events. In this table we split the efficiencies for semi-leptonic  $t\bar{t}$  events according to the  $W$  decay in the Monte Carlo generator:  $t\bar{t}$  (electron) where it decayed to an electron and a neutrino and  $t\bar{t}$  (muon) where it decayed to a muon and a neutrino.

We observe a combined efficiency for these requirements which is somewhat larger for the  $t\bar{t}$  (muon) events compared to the  $t\bar{t}$  (electron) events.

#### 2.1.1 Reconstructing $t\bar{t}$ events

Before discussing additional requirements to improve the purity of the  $t\bar{t}$  event selection, we present the second step in the event reconstruction. In this step we test the events for compatibility with a  $t\bar{t}$  hypothesis. In the  $t\bar{t}$  candidates, three of the reconstructed jets are expected to form the hadronic top-quark. In the absence of b-tagging there is an additional ambiguity in choosing the correct three-jet

Table 1: Fraction of events passing the various selection criteria and the combined ‘default’ selection efficiency for semi-leptonic (electron and muon) analyses respectively. The statistical uncertainties on these numbers are negligible.

	Trigger eff (%)	Lepton eff (%)	$E_T^{\text{miss}}$ eff (%)	Jet req. (I) eff (%)	Jet req. (II) eff (%)	Combined eff (%)
$t\bar{t}$ (electron)	52.9	52.0	91.0	70.7	61.9	18.2
$t\bar{t}$ (muon)	59.9	68.7	91.6	65.5	57.3	23.6

Figure 1: (a): Three-jet invariant mass distribution for the electron analysis default selection, normalised to  $100 \text{ pb}^{-1}$ . The statistical errors in each bin are indicated. (b): The same distribution after the additional  $W$ -boson mass constraint..

combination among the reconstructed jets. We define our top-quark decay candidate as the three-jet combination of all jets that has the highest transverse momentum sum.

Fig. 1 (a) shows the reconstructed top mass for this selection (from now on referred as default selection) for the  $t\bar{t}$  sample. The top mass peak is clearly visible, and the tails of the distributions correspond to the combinatorial background.

### 2.1.2 Selection variations: I

Apart from the default event selection as described above, a number of additional criteria are defined to further increase the purity of the top sample. Here we improve on the simple  $t\bar{t}$  analysis by exploiting additional information: every three-jet combination that originates from a top decay also contains a two-jet combination that originates from a  $W$ -boson decay. To illustrate the presence of the  $W$ -boson we take the three jets that constitute the top quark, and select from the three combinations of di-jets the one that results in the highest value of the sum of the  $p_T$  of the two jets. The  $W$ -boson mass is then the invariant mass of the two jet system. In Fig. 2 (a) this mass distribution is shown for the electron analysis, and the  $W$ -boson mass peak around 80 GeV is clearly visible.

However we prefer an unbiased  $W$ -boson mass distribution in the analysis, for which we choose not to pick/define one particular  $W$ -boson di-jet pair out of the three combinations, but rather require that at least one of the three di-jet invariant masses is within 10 GeV of the reconstructed mass of the  $W$ -boson (taken as the peak value of the mass distribution of the  $W$ -boson candidates). This selection will be referred to as the  $W$ -boson mass constraint selection. The distribution of all three di-jet combinations in

Figure 2: (a): The di-jet combination with highest  $p_T$  (left) for the electron analysis. (b): The three di-jet combinations invariant masses among the top-quark candidates in a  $100 \text{ pb}^{-1}$  event sample for the muon analysis.

the top candidate is shown in Fig. 2 (b). Note that each event enters three times in this distribution. In this figure the background, as discussed in the next section, is already included.

The distribution of the three-jet invariant mass after the additional requirement that at least two jets are compatible with the mass of the  $W$ -boson is shown in Fig. 1 (b). This requirement shows a substantial reduction in the  $t\bar{t}$  combinatorial background compared to Fig. 1 (a). Notice that, compared to the default selection, the top mass peak becomes narrower and the tail of the distribution is reduced. However, the  $W$ -boson mass constraint also introduces a visible shoulder in the distribution which makes fitting to the data more subtle.

In Table 2 we show the fraction of  $t\bar{t}$  events that pass these various selection requirements.

Table 2: Efficiencies at different stages of the electron and muon analyses for several event types: after trigger and event selection (left column), after a cut on the di-jet masses (see text for details) in the top candidate (middle column) and events with, in addition to the di-jet mass cut, a hadronic top mass  $141 < m_t < 189 \text{ GeV}$  (right column). The first three rows correspond to the single-lepton final states, the fourth row to the di-lepton final state and the last row to the hadronic final state.

Event type	Electron analysis			Muon analysis		
	Trigger+Selection (%)			Trigger+Selection (%)		
	$W$ const.	$m_t$ win		+ $W$ const.	$m_t$ win	
$t\bar{t}$ (elec)	18.2	9.2	4.5	0.1	0.0	0.0
$t\bar{t}$ (muon)	0.0	0.0	0.0	23.6	12.0	5.8
$t\bar{t}$ (tau)	1.4	0.7	0.3	2.0	1.0	0.5

$t\bar{t}$ (hadron)	0.0	0.0	0.0	0.1	0.1	0.0

### 2.1.3 Background evaluation

We consider a number of background processes. The dominant expected background is  $W$ -boson+jets, but also single top production,  $Z$ -boson+jets and  $Wb\bar{b}$  are sizeable. Tables 3 and 4 summarise the ex-

Table 3: Number of events which pass the various electron selection criteria for the  $t\bar{t}$  signal and for the most relevant backgrounds normalised to  $100 \text{ pb}^{-1}$ .

pected numbers of signal and background events for the electron and muon analysis respectively. The first column of the two tables shows the event numbers obtained by applying the default selection, whilst the second column gives the corresponding numbers with the  $W$ -boson mass constraint. All numbers are normalised to  $100 \text{ pb}^{-1}$ . The evaluation of the QCD fake rate deserves a separate discussion. The QCD production of  $pp \rightarrow b\bar{b}$  is characterised by a cross-section of about  $100 \mu\text{b}$ , and can therefore be an important background for our signal. Requiring the presence of a high  $p_T$  lepton and missing energy can reduce its contribution, but since the cross-section enhancement relative to the signal is so large, there might be QCD events with a fake lepton and/or poor missing energy reconstruction that pass these requirements as well.

The rate for extra (medium [8]) electrons is studied and found to be roughly  $1.0 \times 10^{-3}$  per jet. This number is divided between semi-leptonic  $B(D)$  decays and true fakes, i.e. hadronic objects identified as electrons. The origin of extra isolated muons is dominated by semi-leptonic  $B$  decays, i.e. by the presence of hard b-quarks. The isolated muon rate per b-parton reaches a few times  $10^{-3}$  for b-parton momenta around 40 GeV, while the fake rate is only a few times  $10^{-5}$ . By studying their origin and dependence on jet/parton kinematics like the  $p_T$ ,  $\eta$ , jet multiplicity and quark content of the jet, we can get an estimate of the fraction of multi-jet events that will pass the lepton requirement in the event selection. The validity of this approach has been checked using a large sample of di-jet events at various transverse momenta. As a result, the QCD background has been evaluated to be smaller than the  $W$ -boson+jets background and will not be discussed further.

The distribution of the invariant mass of the three-jet combination that forms the hadronic top-quark candidate with the default selection and with the backgrounds added together, is shown in Fig. 3 (a). The events where the correct jets were selected to reconstruct the hadronically decaying top quark candidate are clearly visible as the mass peak (open histogram) on top of a smooth background distribution. This background is partially composed of events from non-top processes (light shaded histogram), but is dominated by the (combinatorial) background from semi-leptonic  $t\bar{t}$  events (dark shaded histogram). The combinatorial background was determined using the matching of the top candidate with the generated

top-quark in a cone of size  $\Delta R < 0.2$ .

In Fig. 3 (b) the reconstructed three-jet mass after the  $W$ -boson mass constraint is presented. The background is also shown.

Table 3 and 4 show the number of signal and background events in a  $100 \text{ pb}^{-1}$  data sample. To give an indication of the signal purity in the top mass peak region, in the third column of Tables 3 and 4 we give the number of events in a hadronic top mass region:  $141 < m_t < 189 \text{ GeV}$ . Although not all signal events are correctly reconstructed, in both the electron and muon analyses the purity of the signal in the top mass window is close to 80%.

Figure 3: (a): Expected distribution of the three-jet invariant mass after the standard selection. The white area represents the  $t\bar{t}$  signal in the muon channel. The dark shaded area is the combinatorial background and the light shaded area represents the background contribution. (b): The same after the  $W$ -boson mass constraint in a  $100 \text{ pb}^{-1}$  event sample. Both plots are for the muon analysis.

### 2.1.4 Selection variations: II

Additional ways to kinematically select top events other than the  $W$ -boson mass constraint, or to improve the signal purity after having applied the  $W$ -boson mass cut itself, were explored. In the commissioning phase, it can happen that the barrel calorimetry will be better calibrated than the forward one. Therefore, it can be useful to apply the additional request that the three highest  $p_T$  jets are all at  $|\eta| < 1$ . The reconstructed top mass in this case is shown in Fig. 4.

Figure 4: (a): Reconstructed top mass after  $W$ -boson mass constraint for the electron analysis. The white area represents the  $t\bar{t}$  signal in the electron channel, while the three shaded areas corresponds, going from the lighter to the darker, to the background from  $W$ -boson+jets, single top and all the other background sources considered in the analysis. The distribution is normalised to  $100 \text{ pb}^{-1}$ . (b): The same distribution, but in addition requiring that the three highest  $p_T$  jets are at  $|\eta| < 1$ .

The centrality requirement applied after the default selection allows to reach the same signal-over-background that one obtains after applying the  $W$ -boson constraint. Tables 3 and 4 show the signal-over-background and signal efficiencies for the electron and muon analyses if the centrality requirement is applied in addition to the  $W$ -boson constraint (fifth column).

Other variables were exploited as well, like the  $\cos\theta^*$ <sup>1</sup> and the total invariant mass of the event. In the following no cuts on these variables are used in the analysis.

## 2.2 Determination of the cross-section

In this section two complementary methods to determine the  $t\bar{t}$  cross-section of the commissioning analysis are presented. The first method estimates the  $t\bar{t}$  signal by performing a maximum likelihood fit on the three-jet invariant mass distribution. The second is based solely on counting the number of top candidate events that pass the selection, and subtracting all backgrounds in order to get the yield of  $t\bar{t}$  events in the sample. The two methods are affected by different systematics. Whereas this counting method needs all backgrounds to be properly addressed and normalised, it does not rely on a correct reconstruction of the top quark. The peak-fit method is rather insensitive to background normalisation and efficiencies, but requires a fairly well understood top mass peak.

<sup>1</sup>It is the angle that one jet forms with the direction of the incoming proton in the centre of mass of the event (it is expected that the top decay products are emitted more centrally than the  $W$ -boson+jets and jets from QCD)

### 2.2.1 Likelihood fit method

To extract the number of completely reconstructed  $t\bar{t}$  events (after having applied the default +  $W$ -boson mass constraint selection) a maximum likelihood fit is performed to the three-jet mass distribution with a Gaussian signal on top of the background described by a Chebychev polynomial, see Fig. 5. It has been verified that the background model correctly describes the combined  $t\bar{t}$  combinatorial and background distribution in the signal region by comparing the fitted background to the subset of events that are not fully reconstructed signal as determined from truth matching information.

Using 10000 pseudo-experiments, based on the input from the full simulation Monte Carlo events, one can extract the average fraction of signal events that pass all selection requirements and enter in the peak (i.e., the fraction correctly reconstructed). The average number of events in the peak in the muon analysis, i.e. correctly reconstructed semi-leptonic  $t\bar{t}$  (muon) events, in  $100 \text{ pb}^{-1}$  is 508 events as shown in Fig. 5 (a). This corresponds to an efficiency of  $(4.23 \pm 0.57)\%$ . For the electron analysis this efficiency is  $(2.73 \pm 0.47)\%$ .

The signal significance is defined using the likelihood ratio from two hypotheses: the presence of a signal (a peak) and its absence (only the Chebychev polynomial). The amount of data needed to make a statistically significant observation of the  $t\bar{t}$  signal depends on the amount of background. For low luminosities, for example for  $25 \text{ pb}^{-1}$ , the sampling fluctuations are too large and there is no typical plot like the one of Fig. 3. To quantify the relation between signal significance, luminosity and the amount of background, 10000 pseudo-experiments based on the full simulation distribution of the three-jet mass as a function of the integrated luminosity, have been modelled and fitted. The expected statistical significance is shown in Fig. 5 (b), where the yellow band is obtained by assuming the nominal level of QCD  $W$ -boson+jets background, while the red one refers to the case when this background is multiplied by two. .

Figure 5: (a): Fit to the top signal. The Chebychev polynomial fit to the background is indicated by the dotted line and the Gaussian fit of the signal events is indicated by the full line. (b): Distribution of the expected statistical significance of the top signal in the peak as a function of the integrated luminosity for two background scenarios. The yellow band is obtained by assuming the nominal level of QCD  $W$ -boson+jets background, while the red one by assuming that this background is doubled.

To go from a fitted number of properly reconstructed hadronic top quarks to a cross-section, one needs to correct for the event selection efficiency and the hadronic top reconstruction efficiency. The statistical error is estimated from having simulated 100000 pseudo-experiments, applying the fluctuations which are expected in  $100 \text{ pb}^{-1}$  to both signal and background and fitting the peak in both the electron and muon channels.

One of the biggest uncertainties is the correct modelling of the jet multiplicity distribution as it affects

the fraction of  $t\bar{t}$  signal events that are correctly reconstructed using the algorithm described earlier. An overview of the systematic uncertainties is given in [9].

### 2.2.2 Counting method

The  $t\bar{t}$  cross-section can be obtained by performing a counting experiment:

$$\sigma = \frac{N_{\text{sig}}}{\mathcal{L} \times \varepsilon} = \frac{N_{\text{obs}} - N_{\text{bkg}}}{\mathcal{L} \times \varepsilon}$$

$N_{\text{bkg}}$ , the number of background events estimated from Monte Carlo simulations and/or data samples, is subtracted from  $N_{\text{obs}}$ , the number of observed events meeting the selection criteria of a top-event signature. This difference is divided by the integrated luminosity  $\mathcal{L}$  and the total efficiency  $\varepsilon$ . The latter includes the geometrical acceptance, the trigger efficiency and the event selection efficiency, and is slightly dependent on  $m_t$ . The advantage of using event counts in the commissioning phase is that, early on, the Monte Carlo simulations may not predict the shapes of distributions very well.

In order to perform the counting experiment the Monte Carlo samples were divided into two, statistically independent: one which represents real data, used to obtain  $N_{\text{obs}}$  and the other one used as a Monte Carlo to obtain both  $\varepsilon$  and  $N_{\text{bkg}}$ .

### 2.2.3 Systematic uncertainties

The main sources of systematic uncertainties are described in [9]. Some relevant points for the analyses presented here are discussed for the case of the default selection plus the  $W$ -boson mass constraint. The systematic uncertainty on the cross-section due to the luminosity determination, is factorised and mentioned as a separate uncertainty on the overall results. The event selection efficiencies have a nearly linear dependency for jet energy scale variations, which affects the counting method directly. The hadronic top reconstruction efficiency has an inverse dependence on the jet energy scale, caused by the algorithm that picks the three-jet combination that are considered to be the hadronic top. If the jet energy scale is lowered, the jet multiplicity (and therefore the number of three-jet combinations) increases. The probability that the algorithm picks the right combination generally decreases with the number of combinations to choose from.

The effect of ISR and FSR parameter variations (chosen in such a way to maximise the effect on the cross-section measurement) has been evaluated. For the uncertainties related to the PDFs, both the uncertainty coming from CTEQ and MRST, have been considered and the largest one (coming from CTEQ) has been used for the final systematics evaluation.

The main systematics uncertainties for the two analysis are listed in Table 5. For the likelihood method a 5% change in jet energy scale causes a 2.3% (0.9%) change in the combined reconstruction efficiency for the electron (muon) channel. The different jet multiplicity distributions affect not only the event selection efficiencies (jet requirements), but also the overall efficiency of the hadronic top reconstruction algorithm. A comparison between the two generators MC@NLO and ALPGEN has been made to study these systematic effects. ALPGEN predicts 7% and 4% larger selection efficiencies in the electron and muon channels respectively. For the overall efficiencies the values are 10.5% and 4.7% larger in the electron and muon channel. However, these numbers were not added in the final result since there is overlap with the ISR/FSR systematics. Systematics effects on the shape of the fit as well as the normalisation of the peak fit w.r.t. background is estimated with toy Monte Carlo's. Deviations of 14.0 (10.4)% for the electron (muon) channel are found, while the effect of changing the fit-ranges is negligible. For the counting analysis the uncertainty arising from the Monte Carlo used to generate the signal process has been taken into account as well. This has been done by comparing the cross-section obtained applying the same analysis to  $t\bar{t}$  events generated with MC@NLO and with the ACERMC Monte Carlo.

Table 5: Systematic uncertainties on the commissioning likelihood and counting method cross-section measurement, in percent.

Source	Likelihood fit		Counting method (elec)	
	Electron (%)	Muon (%)	Default (%)	W const. (%)
Statistical	10.5	8.0	2.7	3.5
Lepton ID efficiency	1.0	1.0	1.0	1.0
Lepton trigger efficiency	1.0	1.0	1.0	1.0
50% more $W$ +jets	1.0	0.6	14.7	9.5
20% more $W$ +jets	0.3	0.3	5.9	3.8
Jet Energy Scale (5%)	2.3	0.9	13.3	9.7
PDFs	2.5	2.2	2.3	2.5
ISR/FSR	8.9	8.9	10.6	8.9
Shape of fit function	14.0	10.4	-	-

The  $W$ -boson+jets normalization uncertainty has been evaluated using the  $Z$ -boson+jets sample as discussed in the general introduction of systematic uncertainties, but also varying the level of the expected  $W$ -boson+jets level by 20%, 50% and even by a factor of two. For the final selection (including the  $W$ -boson mass constraint) this corresponds to an uncertainty of 4%, 10% and 19% respectively. As reference value to calculate the overall systematic error, the 50% case will be used.

#### 2.2.4 Contributions of new physics

Many models of physics beyond the Standard Model contain new particles which couple to top-quarks. For example, in a supersymmetric extension of the Standard Model (SUSY) these new particles are top squarks [10] and in warped extra dimensions they are Kaluza-Klein resonances [11]. Since the new particles are expected around the TeV scale, the typical cross-sections are of order a few pico barns and hence one can expect a few hundreds new physics events in the first  $100 \text{ pb}^{-1}$  of data. In principle, these new physics events could represent a significant background to the cross-section measurement. For new physics models with much lower masses, e.g. low mass supersymmetry models, there will be many more events: this case will be considered later on. Here the existence of a new particle  $V$  which decays only into  $t\bar{t}$  pairs,  $V \rightarrow t\bar{t}$  it is assumed. It is further assumed that this particle has a production cross-section of  $5 \text{ pb}$ , so that  $25/9 \text{ pb}$  is the cross-section for the non-fully hadronic decays of  $V$ . As a model for  $V$  a  $1 \text{ TeV } Z'$  is used. The efficiency for these events with respect to the default selection + the  $W$ -boson mass constraint is roughly twice the one obtained for Standard Model  $t\bar{t}$  events, and the number of events passing the selection will be of the order of 1% or less of the  $t\bar{t}$  events. Hence the new particle  $V$  will not affect the cross-section determination significantly.

The predictions at several mSUGRA benchmark points [12] have been studied as well. The results are shown in Table 6 and demonstrate that the expected signals are small. At specific parameter points however, like SU4 [12], the cross-section is sizeable and the event topology is similar to that from top quark pairs which results in additional backgrounds as large as the total Standard Model background. In Fig. 6 one can see that the shape of the SU4 supersymmetry signal in the top quark candidate three-jet invariant mass distribution is very similar to that from the Standard Model background.

The separation of  $t\bar{t}$  events and these new physics signals is addressed in more detail in [12], dedicated to searches for supersymmetry.

Table 6: Expected number of events in a  $100 \text{ pb}^{-1}$  data sample at different stages of the analysis for several event types: after trigger and event selection (left column), after a cut on the di-jet masses in the top-quark candidate (middle column) and events with in addition to the di-jet mass cut a hadronic top mass cut  $141 < m_t < 189 \text{ GeV}$ (right column).

Event type	Electron analysis			Muon analysis		
	Trigger+Selection			Trigger+Selection		
	$W$ const.	$m_t$ win		$W$ const.	$m_t$ win	
SU1	53	9	1	64	12	2
SU2	10	2	0.5	13	3	0.7
SU3	108	22	4	124	26	4
SU4	1677	541	155	2141	700	199
SU6	29	5	0.6	35	6	0.6
SU8	27	5	0.6	33	6	0.8

Figure 6: (a): Expected distribution of the three-jet invariant masses among the top-quark candidates after the requirement on the mass of the di-jet system in the electron channel in a  $100 \text{ pb}^{-1}$  event sample. (b): Same distribution for the muon channel. The light histogram represents the Standard Model background. i.e. the background from mSUGRA point SU4 is shown separately.

### 2.3 Implementation of b-tagging

The possibility to identify b-flavoured jets (b-tagging) will improve the signal to background ratio of the selection. The b-tagging requirements are described in [9]. The number of “tagged” b-jets in the  $t\bar{t}$ , single top and  $W$ -boson+jet events which pass the default selection is shown in Fig. 7.

Tables 3 and 4 list the number of  $t\bar{t}$  and background events in the electron and muon channel which survive the default selection plus the  $W$ -boson mass constraint, and the request of having one and only one, or two and only two b-jets (column six and seven). For all these cases, the corresponding signal to background ratios are given. Requiring one or two b-tagged jets improves the purity of the sample by more than a factor of four, while the signal efficiency is only reduced by a factor of two.

In Fig. 8 the reconstructed three-jet mass is shown when one or two b-tagged jets are required for the default selection (a) and for the default selection + the  $W$ -boson mass constraint (b). To reconstruct the top mass, we find the three-jet combination with the highest possible  $p_T$ , obtained by requiring that one and only one of the three jets is a b-jet. The  $W$ -boson mass constraint can then be applied to the two jets which are not b-tagged (among the three). If the three-jet combination chosen above is such that the two

Figure 7: Number of jets tagged as coming from a b-quark in  $t\bar{t}$ , single top and  $W$ -boson+jet events after the default electron selection.

non-b-jets don't combine to give a  $W$ -boson candidate, that event is rejected.

Figure 8: (a): Reconstructed three-jet mass for  $t\bar{t}$ , single top and  $W$ -boson + jet events for the default electron selection, requiring one or two jets tagged as coming from a b-quark. (b): Same distribution for the default selection + the  $W$ -boson mass constraint and requiring one or two jets tagged as coming from a b-quark.

The statistical error on the cross-section which is obtained by requiring one or two b-tagged jets is 4.5%. The systematic error due to the jet energy scale is in this case of 4.9%, while a wrong normalization of the  $W$ -boson+jets background by a factor of 20%, 50% or even a factor two, brings a systematic error on the cross-section of 3.4%, 4.7% and 6.9% respectively. A 5% relative error on the b-tagging efficiency is expected from present studies for an efficiency of 50-60% and for a luminosity of  $100 \text{ pb}^{-1}$ . The resulting uncertainty on the cross-section turns out to be negligible. The uncertainty on the mistag rate is assumed to be of the order of 50%.

## 2.4 Results

With the first  $100 \text{ pb}^{-1}$  of data, we can observe a  $t\bar{t}$  signal and determine its production cross-section. This will be determined with a number of methods and we expect to reach the following accuracies (for

the default selection with the  $W$ -boson mass constraint, using electron and muons):

$$\text{Likelihood method: } \Delta\sigma/\sigma = (7(\text{stat}) \pm 15(\text{syst}) \pm 3(\text{pdf}) \pm 5(\text{lumi}))\% \quad (1)$$

$$\text{Counting method: } \Delta\sigma/\sigma = (3(\text{stat}) \pm 16(\text{syst}) \pm 3(\text{pdf}) \pm 5(\text{lumi}))\% \quad (2)$$

## 2.5 Differential cross-sections

We studied several differential distributions for  $t\bar{t}$  production. First, we present the momentum and rapidity distribution of the hadronically decaying top quarks, after having applied the default selection and the  $W$ -boson mass constraint. The results are shown in Fig. 9 (a) and (b).

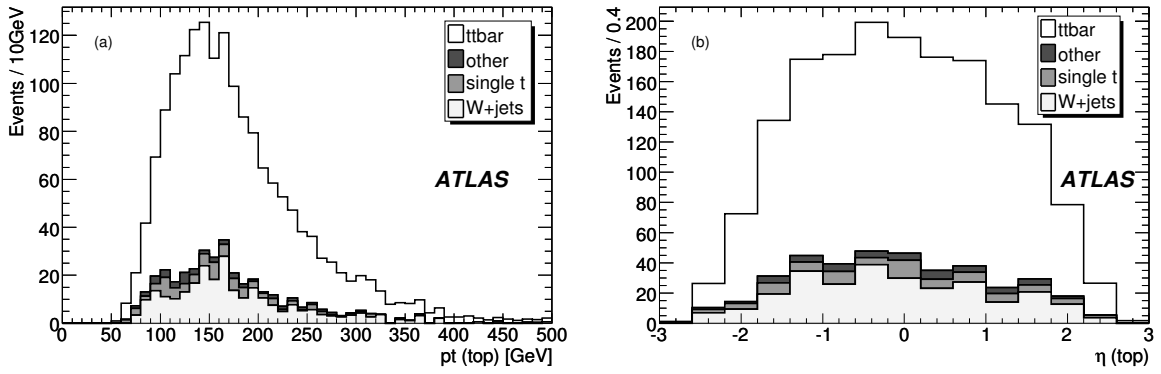

Figure 9: (a): Momentum distribution of the reconstructed three-jet mass for  $t\bar{t}$ , single top and  $W$ -boson+jet events for the electron analysis. Right plot: Rapidity distribution of the hadronically decaying top quark.

A more detailed study has been performed for the differential cross-section as a function of the  $t\bar{t}$  system mass, and for several double differential distributions as shown in the following sections.

The differential cross-section for  $t\bar{t}$  production can be measured as a function of the invariant mass of the  $t\bar{t}$  system in the semi-leptonic channel (with no tau leptons in the final state). Such a measurement provides an important check of the Standard Model and, at the same time, deviations from the  $t\bar{t}$  continuum could indicate the presence of new physics, for example new heavy resonances decaying into a  $t\bar{t}$  pair [14].

The standard commissioning selection is applied and the momenta of the four jets with highest  $p_T$ , the lepton and the best estimate of the  $E_T^{\text{miss}}$  vector are used as inputs to a least squares fit with the constraints that, in each event, the masses of both the  $W$ -boson and top-quark are consistent with 80.4 GeV and 175 GeV respectively. The fit procedure is documented in [15]. The goal is to improve the measurement of the reconstructed final state particles' four vectors by incorporating the precise knowledge of the masses of the  $W$ -boson and the top-quark. No b-tagging is used in this analysis and hence there are 12 possible combinations to assign jets to the (anti-) top. All combinations were investigated and one was chosen: the assignment which returned the smallest weighted sum of squared residuals obtained from the kinematic fit. A simpler reconstruction scheme obtains the  $t\bar{t}$  mass by deriving the leptonic  $W$ -boson momentum from the lepton and missing energy momenta with the  $W$ -boson mass constraint and then combining it with the momenta of the four highest  $p_T$  jets.

The reconstructed mass distributions for the two methods are compared to the true di-top mass distributions in Fig. 10 (a) for the non-hadronic signal. The true di-top mass distribution is in better agreement with the result obtained by making use of the full event fitting technique.

In this case, the expected mass resolution ranges from 5% to 9% between 200 and 850 GeV. A variable bin size of about twice the expected resolution is used to take such variation into account and reduce bin-to-bin migrations. The di-top mass spectrum ( $dN/dm_{t\bar{t}}$ ), reconstructed with the full event fit, is shown in Fig. 10 (b) for the signal and the backgrounds studied. Backgrounds include: full hadronic top, single top,  $W$ -boson+jets,  $Wb\bar{b}$ ,  $Wc\bar{c}$ , inclusive  $Z$ -boson to leptons. The contribution from the di-boson ( $WW, WZ$  and  $ZZ$ ) backgrounds is negligible.

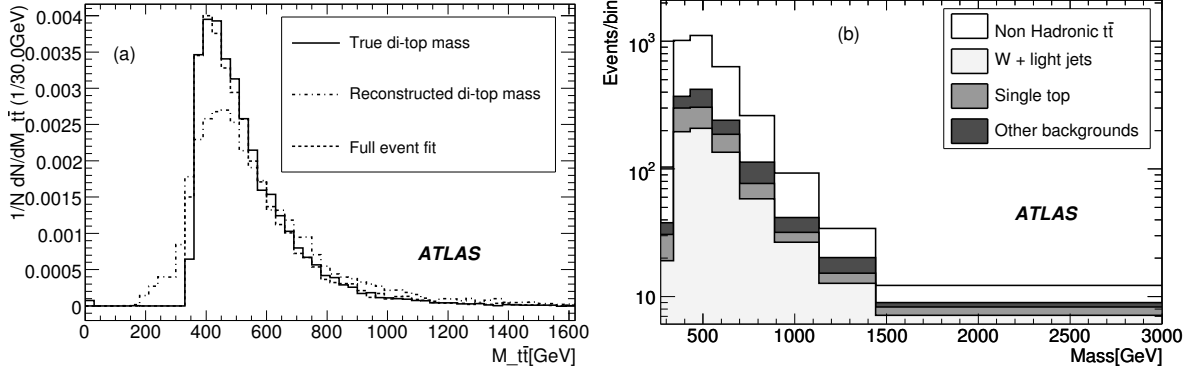

Figure 10: (a): Normalised di-top mass distribution for the more complex (dashed line) and the simple reconstruction (dotted line). The normalised true di-top mass is also shown for reference (solid line). (b): Expected reconstructed di-top mass distribution after all cuts for signal and studied backgrounds, normalised to  $100 \text{ pb}^{-1}$ .

### 2.5.1 Double differential cross-section as function of $p_T$ and $y$

The double differential cross-section for  $t\bar{t}$  production is sensitive to possible new physics beyond the Standard Model, e.g. extra dimensions based on studies of the top quark spin correlation [13], which depends on the knowledge of the top quark's momentum. A measurement investigates the decay products of the top quark in its rest frame and therefore good knowledge of its  $p_T$  and  $y$  as defined in (3), for a top quark of energy  $E$  and longitudinal momentum  $p_z$ , is needed.

$$y = \frac{1}{2} \ln \left( \frac{E + p_z}{E - p_z} \right) \quad (3)$$

Theoretical predictions can be found in [4]. Here we present a feasibility study which, since the neutrino momentum cannot be directly measured, concentrates on the reconstruction of the hadronically decaying top quark in semileptonic  $t\bar{t}$  events. Since in this case a high purity is needed, the default event selection is tightened by requiring exactly two b-tagged jets. The reconstruction of the hadronic top quark proceeds as follows: all possible combinations of two non-b-tagged jets with  $60 \text{ GeV} < m_{jj} < 100 \text{ GeV}$  are selected as  $W$ -boson candidates. The nearest b-tagged jet for every  $W$ -boson candidate is found. The combination with the highest transverse vector sum momentum is then taken as the reconstructed hadronic top quark. This results in a purity of well reconstructed top quarks of 45%. The main background is due to combinatorics.

Figure 11 shows the reconstructed double-differential distribution of the hadronic top scaled to an integrated luminosity of  $1 \text{ fb}^{-1}$ . In (a) the truth distribution of the  $t\bar{t}$  signal is presented, while in (b) the distribution of reconstructed hadronic top-quarks is shown. In this distribution the contribution of background (from single top,  $W$ -boson + jet,  $Wb\bar{b}$  and  $Wc\bar{c}$ ), which is very small after the requirement

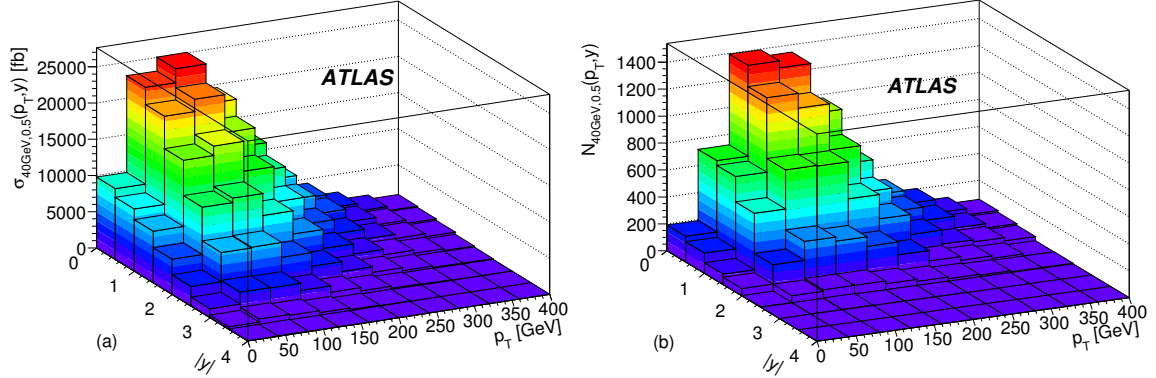

Figure 11: (a): Distribution of  $p_T$  and  $y$  of hadronically decaying top quarks calculated by MC@NLO. (b): Reconstructed distribution of  $p_T$  and  $y$  of hadronically decaying top quarks from fully simulated samples scaled to an integrated luminosity of  $1 \text{ fb}^{-1}$ .

of two b-tagged jets, has been added. After such a selection, the number of expected events limits the region of interest to  $|y| < 2$  and  $50 \text{ GeV} < p_T < 280 \text{ GeV}$ .  $1 \text{ fb}^{-1}$  is a reasonable statistic which allows to fill a significant number of bins with an appropriate statistical error. A lower integrated luminosity of  $100 \text{ pb}^{-1}$  would increase the statistical error of the bin contents at the edge of the interesting area from 10% to approximately 30%, which would limit the measurement to a smaller phase-space. The systematic uncertainties of this feasibility study are expected to be small and under control.

The potential to determine the double differential cross-section of  $t\bar{t}$  events decaying semileptonically has been estimated. The phase space can be determined with an average efficiency of  $3.98 \pm 0.04\%$  and a peak efficiency of 8% near the central rapidity region and for  $p_T \leq 140 \text{ GeV}$ .

The main systematic uncertainties for this study will come from the jet energy scale and from the initial and final state radiation: each source contributing with an uncertainty of the order of  $\pm 15\%$  in the central region.

### 3 Di-Lepton channel

In this section the determination of the  $t\bar{t}$  cross-section where both  $W$ -bosons decay leptonically is presented. This measurement depends crucially on the correct identification of leptons. We proceed by investigating the channel with two electrons, one electron and a muon, and two muons in the final state. Final states with tau leptons are not studied here. The determination of the cross-sections is performed with a simple ‘cut and count’ method, a template method and a likelihood fit.

#### 3.1 Event selection

The di-lepton sample is expected to be triggered with high efficiency using a combination of single-lepton and di-lepton triggers [7]. The overall trigger efficiency for the electron-muon channel is  $(97 \pm 1)\%$ , for the two electron channel it is  $(98 \pm 1)\%$  and for the two muon channel it is  $(96 \pm 1)\%$ . Due to the trigger OR condition between the channels and the high statistics available for efficiency measurements, the uncertainty is small.

The offline selection of di-lepton events is based on the identification of leptons as described in the introductory section. Two high- $p_T$  opposite signed leptons, i.e. two electrons, two muons, or one electron and one muon, are required. These requirements define the preselection sample and additional selection criteria are imposed depending upon the  $t\bar{t}$  cross-section extraction method. The expected number of

events produced after the preselection cuts of two isolated opposite charged leptons is shown in Table 7. None of the selections makes use of b-tagging.

Table 7: Simulated Monte Carlo samples and expected events produced for  $100 \text{ pb}^{-1}$  of integrated luminosity. Cross-sections  $\sigma$  are at least Next-to-Leading Order total cross-sections, and  $\sigma_{\text{eff}}$  are the effective Monte Carlo cross-sections including generator level filter efficiencies (reported in the "Filter(%)” column). The last three columns show the number of preselected events after requiring two opposite signed leptons.

Sample	$\sigma(\text{pb})$	Filter(%)	$\sigma_{\text{eff}}(\text{pb})$	$e\mu$	$ee$	$\mu\mu$
$t\bar{t}$ (di-lepton)	833	7(2l)	55	699	312	381
$t\bar{t}$ (semi-leptonic)		48(1l)	397	31	20	8
$Z \rightarrow e^+e^-$	2015	86	1733	5	37418	0
$Z \rightarrow \mu^+\mu^-$	2015	89	1793	153	0	51139
$Z \rightarrow \tau^+\tau^-$	2015	5	101	249	101	159
$W \rightarrow e\nu$	20510	63	12920	42	69	0
$W \rightarrow \mu\nu$	20510	69	14150	152	0	40
$WW$	117	35	41	76	32	44
$WZ$	48	29	14	6	41	52
$ZZ$	15	19	3	1	25	31
single top	324	31	99	5	3	2

### 3.1.1 Lepton identification and isolation

The inclusive di-lepton selection requires at least one of the electrons to be identified with the ‘tight-electron’ algorithm<sup>2</sup> to improve the fake lepton rejection.

One of the major backgrounds in this channel is given by semi-leptonic  $t\bar{t}$  events where the second lepton candidate is faked by a jet. A requirement on the isolation of the electrons lowers this background substantially. Fig. 12 (a) shows the distribution of the variable  $\Sigma_{\Delta R < 0.2} E_T$ , defined to be the energy deposited in a hollow cone with radius  $\Delta R$  of 0.2 around the electron candidate. The figure shows this variable for reconstructed electrons in the semi-leptonic  $t\bar{t}$  background sample which are close to a monte carlo truth electron ( $\Delta R < 0.1$  to a truth electron from the  $W$ -boson decay) and for reconstructed electrons with  $\Delta R > 0.1$ . With the requirement  $\Sigma_{\Delta R < 0.2} E_T < 6 \text{ GeV}$ , the signal is reduced by only  $\sim 4\%$  whereas the semi-leptonic  $t\bar{t}$  background is reduced by a factor of two.

Two cuts are used to select muons from  $W$ -boson decays while simultaneously rejecting muons from b-jets. The first cut selects the muon candidate with tracks in the muon spectrometer that match best with tracks in the inner detector. Additionally it is required that the muon is not closer than  $\Delta R < 0.2$  to a jet, otherwise the muon is removed.

Fig. 12 (b) shows the distance of muons to the closest jet in the event. Muons that are close ( $\Delta R < 0.2$ ) to a monte carlo truth b-quark are separated from muons that are close to a monte carlo truth muon ( $\Delta R < 0.1$ ). A  $\Delta R$  cut of 0.2 removes the muons that do not originate from the  $W$ -boson decay. This requirement reduces the semi-leptonic  $t\bar{t}$  background by  $\sim 25\%$ , whereas the signal is reduced by only  $0.8\%$ .

<sup>2</sup>The tight-electron algorithm makes full use of the TRT information as described in Ref. [16].

Figure 12: (a) The  $\Sigma_{\Delta R < 0.2} E_T$  variable for reconstructed electrons of the semi-leptonic  $t\bar{t}$  background, in black are electrons matched to truth electrons, in white otherwise. (b)  $\Delta R$  from a muon to the closest jet in the semi-leptonic  $t\bar{t}$  sample. In white are muons matched to truth muons, in black are muons that are close to a b-quark.

### 3.2 Backgrounds

The backgrounds to the  $t\bar{t}$  di-lepton signal can be classified into two main categories: prompt leptons originating from an electroweak decay, or non-isolated non-prompt leptons and jets that are falsely identified as leptons mainly originating from QCD jets.

For the estimation of the electroweak backgrounds we use Monte Carlo samples, as shown in Table 7. For the same-flavour Drell-Yan processes we made an exception, as the size of this contamination depends on the determination of the  $E_T^{\text{miss}}$  which is difficult to model. As a default we use the shape of the  $E_T^{\text{miss}}$  distribution for events with a di-lepton mass inside a window around the Z-boson mass, to correct the shape of the  $E_T^{\text{miss}}$  distribution in the Monte Carlo. The same correction factor is used for Drell-Yan processes with di-lepton invariant masses outside the Z-boson mass window.

The backgrounds from fake leptons are estimated from the QCD dijet samples. These estimations of fake leptons are subsequently applied to all objects that can lead to fake leptons (e.g. jets) in the inclusive single electron or muon samples.

### 3.3 Cross-section measurement

As mentioned, three methods to determine the cross-section for the di-lepton channel are presented. The di-lepton channel profits from having smaller backgrounds and systematics and the methods are complementary to each other. The robust 'cut and count' method can be replaced with the more sophisticated template and likelihood method with increased accumulated data.

#### 3.3.1 'Cut and count' method

A 'cut and count' analysis is the most straightforward method to determine the cross-section. It can be used as the basis and reference for the more elaborate likelihood methods and act as a cross check between the different approaches.

The selection criteria are defined to maximise the efficiency  $\varepsilon$  and the purity  $p$  at the same time. The figure of merit is the product

$$\varepsilon \times p \propto \frac{S}{\sqrt{S+B}} = s$$

which is referred to as significance.

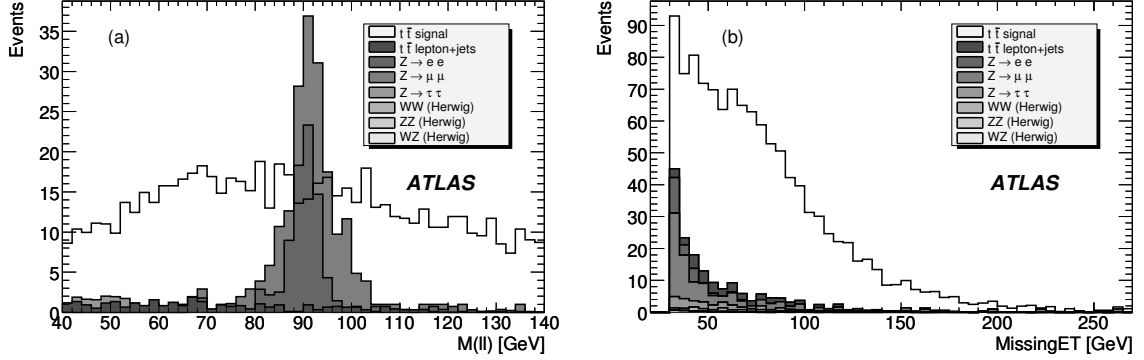

Figure 13: (a) Di-lepton mass in signal, semi-leptonic  $t\bar{t}$  and  $Z \rightarrow \ell^+\ell^-$  events. (b) Distribution of the  $E_T^{\text{miss}}$  for signal and various backgrounds, normalised to  $100 \text{ pb}^{-1}$

The variables that best characterise the signal events are the transverse momenta of the two leptons and the two jets, as well as the missing transverse energy. The jet momenta are high since they originate from the b-quarks, not present in the prominent background processes  $Z \rightarrow \ell^+\ell^-$  or dibosons  $\rightarrow \ell^+\ell^-$  ( $WW$ ,  $WZ$  and  $ZZ$ ). A large amount of missing transverse energy is expected in signal events due to the two escaping neutrinos. In addition a veto on events with a di-lepton invariant mass around the Z-boson mass is applied. Fig. 13 (a) shows the di-lepton mass distribution in  $Z \rightarrow \ell^+\ell^-$  events. Most of the events are found to have an invariant mass between 85 and 95 GeV. In the case of the  $Z \rightarrow \tau^+\tau^-$  events the peak is shifted and broadened, since the visible leptons do not come directly from the Z-boson. Also the neutrinos from the  $\tau$  decay add to the missing transverse energy. It is therefore expected that this background will be dominant, although the branching ratio for both  $\tau$ 's decaying leptonically is only  $\sim 9\%$ . The optimal selection was found from a multidimensional scan of the significance  $s$ . Exactly two leptons are required and at least two jets. The requirements on the lepton and jet transverse momenta and on the  $E_T^{\text{miss}}$  is then varied from 20 to 60 GeV. Finally, the cuts with the maximum significance are used to evaluate the cut and count performance.

As a result, the multidimensional scan indicates that the values of the preselection requirement of 20 GeV for the two leptons and for the two jets with the highest transverse momentum already maximise the significance. One additional cut is imposed: the  $E_T^{\text{miss}}$  is required to be at least 30 GeV for a selection of two leptons (all sub-channels together), at least 20 GeV for the  $e\mu$  decay channel and at least 35 GeV for the same flavour lepton channels. The distribution of the missing transverse momentum for the signal and the background samples is presented in Fig. 13 (b). The efficiencies, signal over background ratios and the significance for an integrated luminosity of  $100 \text{ pb}^{-1}$  are shown in Table 8.

The cross-section is derived from:

$$\sigma = \frac{N_{\text{sig}}}{\mathcal{L} \times \varepsilon} = \frac{N_{\text{obs}} - N_{\text{bkg}}}{\mathcal{L} \times \varepsilon}$$

To evaluate the statistical uncertainty on  $\sigma$ , the error on  $N_{\text{obs}}$  is taken to be Gaussian assuming it will be measured in the data. The error on  $N_{\text{bkg}}$  is calculated here from Monte Carlo and scaled to the desired luminosity. The relative error on the efficiency  $\varepsilon$  (the product of geometrical acceptance and selection efficiency) here is also calculated from the Monte Carlo. The expected statistical error on the cross-section measurements for different integrated luminosities is given in Table 9. In data the efficiencies regarding leptons will be estimated from  $Z$  data events using tag and probe. Also the rates of backgrounds containing misidentified leptons can only be measured in data reliably.

Table 8: Number of events which survive the optimised selection criteria for signal and background samples, scaled to a luminosity of  $100 \text{ pb}^{-1}$ .

### 3.3.2 Inclusive template method

The inclusive template method is based on the observation that the three dominant sources of isolated leptons which can be selected in the  $e\mu$  channel are  $t\bar{t}$ ,  $WW$  and  $Z \rightarrow \tau\tau$ . However, these three processes can be separated looking at the two-dimensional plane spanned by  $E_T^{\text{miss}}$  and number of jets, as shown in Fig. 14. Table 7 shows that there might be instrumental effects that introduce non-prompt non-isolated or falsely identified leptons, primarily in single  $W$ -boson and Drell-Yan decays to muons. These non-prompt non-isolated or falsely identified leptons can weaken the separation of the templates if their contribution is too large. To reduce this effect we add a ‘tight-electron’ requirement on one of the electrons. Signal sensitivity and robustness against systematic uncertainties are improved by adding also the  $ee$  and  $\mu\mu$  channels. In the  $\mu\mu$  channel we reject events where the  $E_T^{\text{miss}}$  is aligned along any of the reconstructed muons. To further reduce the Drell-Yan background in the  $ee$  and  $\mu\mu$  channels a  $E_T^{\text{miss}} > 35 \text{ GeV}$  cut and a  $Z$ -veto are added in those channels. The estimated number of events remaining after these additional background rejection cuts are shown in Table 10.

By constructing normalised 2D templates for each channel we determine the relative size of the  $t\bar{t}$ ,

Figure 14: Monte Carlo  $e\mu$  templates spanning the plane  $E_T^{\text{miss}}$  and number of jets for  $t\bar{t}$  (a),  $WW$  (b) and  $Z \rightarrow \tau\tau$  (c).

Table 10: Estimated number of events remaining after the background rejection cuts used in the inclusive template analysis.

Sample	$e\mu$	$ee$	$\mu\mu$
$t\bar{t}$ (di-lepton)	516	213	178
$t\bar{t}$ (semi-leptonic)	12	11	2
$Z \rightarrow e^+e^-$	3	9	0
$Z \rightarrow \mu^+\mu^-$	9	0	18
$Z \rightarrow \tau^+\tau^-$	151	10	2
$W \rightarrow e\nu$	35	28	0
$W \rightarrow \mu\nu$	11	0	11
$WW$	57	17	19
$WZ$	5	3	2
$ZZ$	1	1	1
single top	3	1	1

$WW$  and  $Z \rightarrow \tau\tau$  contribution by performing a binned log likelihood fit to pseudo-experiments. To ensure a fit with a pull distribution compatible with a Gaussian with zero mean and unit sigma we relax the template likelihood using nuisance parameters constrained to their expected errors. The nuisance parameters are: common acceptance and common background normalization for each final state. Bias from potential new physics is avoided by adding one free parameter with an associated orthogonal background template. Orthogonal in this context means that an additional background template does not introduce a bias when only SM events are present in the pseudo-experiments. The fit has in total ten free parameters including the  $t\bar{t}$ ,  $WW$  and  $Z \rightarrow \tau\tau$  cross-sections.

Many different configurations of background templates are scanned and the template with the highest probability is selected. For robustness, the fit is first performed in the  $e\mu$  channel, and then the fitted parameters are fed as start values into the full fit which includes all channels:  $e\mu$ ,  $ee$  and  $\mu\mu$ . The result from the full fit applied to pseudo-experiments including all systematics is shown in Fig. 15.

Systematic uncertainties enter in two ways: in the acceptance of the two leptons, and in the shapes of the 2D templates exemplified in Fig. 14. The impact of the systematic uncertainties is estimated using pseudo-experiments where all uncertainties and correlations, as discussed in section 3.4, are included, except the luminosity. Note that the acceptance is by definition not affected by the jet energy scale, but has a 2% uncertainty from QCD showering. The shape has a 2% uncertainty from QCD initial

state showering, and 2% from the jet energy scale. QCD final state showering only comes from  $t\bar{t}$  and is found not to have any measurable effects on the fit when all channels are included. The projected significance versus integrated luminosity including all systematic uncertainties, except luminosity, is shown in Fig. 15.

Figure 15: (a) Total composition of the inclusive di-lepton selection versus number of jets. (b) Projected significance from pseudo-experiments for the inclusive template fit versus integrated luminosity including all channels and all systematic uncertainties.

### 3.3.3 Likelihood method

The likelihood method uses the following log-likelihood function to extract the parameters  $N_{\text{sig}}$  and  $N_{\text{bkg}}$  given the fixed total number of events  $N_{\text{tot}}$  and the measurements ( $x_i$ ):

$$L = - \sum_{i=1}^{N_{\text{tot}}} \ln(G[x_i | N_{\text{sig}}, N_{\text{bkg}}]) + N_{\text{tot}}$$

with

$$G(x) = N_{\text{sig}} \times S(x) + N_{\text{bkg}} \times B(x)$$

The multidimensional function  $G(x)$  is the sum of the functions  $S(x)$  which describes the signal distribution and of  $B(x)$  that describes the background distribution. The functions are determined by fitting Chebychev polynomials to the signal and background Monte Carlo distributions after the cut and count cuts were applied in the variables  $|\Delta\phi(\text{lepton}_0, E_T^{\text{miss}})|$  ( $\Delta\phi$  between the highest  $p_T$  lepton and the missing transverse energy vector) and  $|\Delta\phi(\text{jet}_0, E_T^{\text{miss}})|$  ( $\Delta\phi$  between the highest  $p_T$  jet and the  $E_T^{\text{miss}}$  vector). Fig. 16 shows one of the distributions and the solid line shows the fits to the distribution that are used as  $S(x)$  and  $B(x)$ .

The sum of the semi-leptonic  $t\bar{t}$ ,  $Z \rightarrow \ell^+ \ell^-$  and  $WW$  events are considered as background and added up according to their cross-section to produce one single background distribution.

To estimate the error on the cross-section, ensemble tests were performed for different integrated luminosities ranging from 10 pb<sup>-1</sup> to 1 fb<sup>-1</sup>. The relative statistical errors are presented in Table 11.

## 3.4 Systematic uncertainties

The systematic uncertainties have been evaluated according to the standard prescription [9]. In particular, the lepton ID efficiency will be measured from data using Z-boson events and the uncertainty is expected to be of the order 1%. The lepton trigger efficiency will be measured from data using Z events with an

Figure 16: Distribution of  $\Delta\phi$  between the highest  $p_T$  lepton and the  $E_T^{\text{miss}}$  momentum vector for (a) signal, (b) background and (c) signal/background composition according to the ratio obtained from the cut analysis.

Table 11: Expected statistical error evaluated from ensemble tests on the cross-section measurement for the likelihood method for different luminosities. For  $10 \text{ pb}^{-1}$  the fits in the subchannels do not converge well enough to give results.

Luminosity [ $\text{pb}^{-1}$ ]		10	100	1000
$\Delta\sigma/\sigma$	$e\mu$	-	9.1 %	2.7 %
	$ee$	-	16.0 %	4.6 %
	$\mu\mu$	-	7.8 %	2.5 %
	All channels	18.2 %	5.2 %	1.7 %

Table 12: Uncertainties on the cross-section measurement for the cut and count and the likelihood methods.

$\Delta\sigma/\sigma$ [%]	cut and count method				likelihood method			
	$e\mu$	$ee$	$\mu\mu$	all	$e\mu$	$ee$	$\mu\mu$	all
CTEQ6.1 set	2.4	2.9	2.0	2.4	0.3	0.4	0.2	0.2

ISR	1.1	1.1	1.2	1.1	2.5	1.8	0.0	1.7
parameters- $1\sigma$					-3.0	-0.2	-2.1	-1.8
parameters+ $1\sigma$					3.2	0.8	2.0	2.0

uncertainty which should also be of the order 1%. The lepton fake rate uncertainty is estimated from dijet events, and during the initial phase of data taking we expect this uncertainty to be of the order of 50%. The systematic effect due to the uncertainty of the jet energy scale is investigated by scaling the reconstructed jet energies by  $\pm 5\%$ . The value of the  $E_T^{\text{miss}}$  is rescaled accordingly. The initial and final state radiation was investigated and the results are summarised in Table 12 as well.

For the likelihood, the fit parameters of the Chebychev polynomials were varied by  $1\sigma$  at the same time in the same direction. The results can be seen in Table 12.

The reweighting technique, to assess the systematic uncertainties from parton densities is also described in Section [9]. To cross-check the technique ATLAST samples with different PDFs were used. For the cut and count method the efficiency using MRST PDFs is larger than the efficiency using CTEQ PDFs. Table 12 summarises the changes in the selection efficiency. For the cut and count analysis this directly translates into an uncertainty on the cross-section determination. For the likelihood method the reweighted events were used to fit the  $N_{\text{sig}}$  and  $N_{\text{bkg}}$  to the templates which were generated with the unmodified fully simulated events.

### 3.5 Contribution of new physics

Many models of physics beyond the Standard Model can have a significant branching ratio to the di-lepton final state. In particular the 'cut and count' method is sensitive to these potential contributions. In some SUSY scenarios the contribution can be as large as one-third of the total  $t\bar{t}$  signal. This indicates how crucial it is to include all final states in order to verify the global consistency of the  $t\bar{t}$  cross-section. The template/likelihood methods are able to consider more distinctive  $t\bar{t}$  event properties and can be made much more robust against non-Standard Model sources.

Data-driven methods which consider the full kinematics of the di-lepton  $t\bar{t}$  system can further help to disentangle new physics, as described in other notes [12] of this volume.

### 3.6 Results

The final results in percent for the combined di-lepton channels for an integrated luminosity of  $100 \text{ pb}^{-1}$  are summarised here

$$\text{Cut and Count method: } \Delta\sigma/\sigma = (4(\text{stat})_{-2}^{+5}(\text{syst}) \pm 2(\text{pdf}) \pm 5(\text{lumi}))\% \quad (4)$$

$$\text{Template method: } \Delta\sigma/\sigma = (4(\text{stat}) \pm 4(\text{syst}) \pm 2.(\text{pdf}) \pm 5(\text{lumi}))\% \quad (5)$$

$$\text{Likelihood method method: } \Delta\sigma/\sigma = (5(\text{stat})_{-5}^{+8}(\text{syst}) \pm 0.2(\text{pdf}) \pm 5(\text{lumi}))\% \quad (6)$$

## 4 Discussion and outlook

In this note we have demonstrated that ATLAS will be able to reliably determine the  $t\bar{t}$  production cross-section already from the startup period of LHC. We have determined this cross-section for the  $t\bar{t}$  system decaying both into a single electron or muon with associated jets, or two electrons or muons with jets. For the single-lepton mode, we have investigated robust selection criteria that do not depend on the  $b$ -quark tagging. For the di-lepton channel various complementary channels have been investigated.

With only  $100 \text{ pb}^{-1}$  of accumulated data, we have shown that we can observe the top-quark signal and measure its production cross-section. Various methods have been presented and the corresponding uncertainties studied. Apart from the luminosity uncertainty, the overall uncertainties are of the order of (5-10)% and are dominated by systematics. Consistency between the methods constrain contributions of new physics as they affect the various methods differently.

# Prospect for Single Top Quark Cross-Section Measurements

## Abstract

At the LHC, the single top quarks will be produced at a third of the rate of top quark pairs. With more than two million single top quark events produced every year during the low luminosity run, a precise determination of all contributions to the total single top quark cross section seems achievable. Comparison between the measured cross section and the theoretical prediction will provide a crucial test of the Standard Model. These measurements will lead to direct measurement of  $V_{tb}$  at the few percent level of precision, and constitute a powerful probe for new physics, via the search for evidence of anomalous couplings to the top quark or the measurements of additional boson contributions to single top quark production.

The single top quark production mechanism proceeds through three different sub-processes resulting in distinct final states, topologies and backgrounds. Given the level of backgrounds affecting the individual selections and the importance of the systematic uncertainties, the use of sophisticated methods appears mandatory to unambiguously observe each process and determine precisely the corresponding cross sections. This report presents the methods developed to optimize the selection of single top quark events in the three channels and establishes the ATLAS potential for the cross section measurements for the early data period and for a  $30 \text{ fb}^{-1}$  low luminosity run.

## 1 Introduction

The top quark is one of the key particles in the quest for the origin of particle mass. In particular the electroweak interaction of the top quark is sensitive to many types of new physics. The electroweak production of top quark leads to a final state of a single top quark plus other particles. The production cross section is sensitive to contributions from new particles such as new heavy bosons  $W'$  or charged Higgs bosons  $H^\pm$ . Other processes such as flavor-changing neutral currents also result in a single top quark final state [1]. Furthermore, single top quark production is an important background to many searches for new physics.

The D0 [2] and CDF [3] collaborations at the Fermilab Tevatron reported evidence for single top quark production and a first direct measurement of the CKM matrix element  $V_{tb}$ . This involved advanced analysis methods to extract the small single top quark signal out of the large backgrounds. The Tevatron experiments will collect several  $\text{fb}^{-1}$  of data, and expect to not only observe single top quark production at the 5 sigma level but also separate two different production modes: the s-channel and the t-channel. However, the single top quark production cross section is small at Tevatron energies and single top quark measurements will be limited by statistics.

At the LHC, the number of signal events is not a problem anymore. The LHC will not only be a strong interaction top quark factory but will also produce several million single top quark events. The cross section for all three modes of single top quark production as well as the CKM matrix element  $V_{tb}$  can be measured with high precision [4]. Once the single top quark signal has been established, detailed measurements of the process will follow, for example of the top quark polarization, ratios of cross sections, and charge asymmetries. Searches in each of the single top quark channels are sensitive to new physics even before the Standard Model single top quark signal is found. The D0 collaboration has published limits on  $W'$  boson production and flavor changing neutral currents [5, 6].

This paper describes the cross section measurements for the three single top quark production modes and is organized as follows: the single top quark phenomenology is introduced in Section 2. All studies are based on a common event preselection, presented in Section 3. The prospects for the cross section measurements for the t-channel, s-channel and Wt-channel are then presented in Sections 4, 5, and 6. Finally, we summarize our conclusions in Section 7.

## 2 Phenomenology and strategy for single top quark analyses in ATLAS

In the Standard Model single-top quark production is due to three different mechanisms: (a) W-boson and gluon fusion mode, which includes the t-channel contribution and is referred to as t-channel as a whole (b) associated production of a top quark and a W-boson, indicated as Wt-channel, and (c) s-channel production coming from the quark anti-quark annihilation. Among those channels, the dominant contribution comes from the t-channel processes which account for  $246^{+12}_{-12}$  pb [7, 8]. The Wt-channel contribution amounts to  $66 \pm 2$  pb [9] while the s-channel mode is expected to have a cross section of  $11 \pm 1$  pb [7, 8]. The cross sections are calculated at the next-to-leading Order (NLO) with an input top quark mass of 175 GeV. A 4.3 GeV uncertainty on the top quark mass is included in t-channel and s-channel cross section uncertainties, while the Wt-channel uncertainty includes strong energy scale variations only.

In the Standard Model, the top quark is assumed to decay almost exclusively into a W-boson and a b quark. The W-boson can then decay leptonically or hadronically. In the following, when discussing the analysis strategy in the s- and t-channels, only the leptonic decays of the W-boson are considered ( $lvb\bar{b}$  and  $lvb\bar{b}q$  final states, respectively)<sup>1</sup>. For the associated production (Wt-channel), only the modes where a lepton originating either directly from the W-boson produced together with the top quark or from the top quark decay are used. The  $\tau$  decay modes are included in all relevant samples and treated as a signal for leptonic  $\tau$  decays, since the signal selection is aimed at electron and muon signatures.

Top quark pair production constitutes a dominant background to single-top quark events. The LHC total production cross section computed at NLO with next-to-leading logarithmic resummations is  $\sigma(t\bar{t}) = 833 \pm 100$  pb [10] [11], about 3 times larger than the single top quark cross section, and more than 80 times that of the s-channel. Given the fact that single top quark final state topology is characterized by one high  $p_T$  lepton, missing energy and jets,  $t\bar{t}$  production represents a significant background in its lepton+jets decay mode, i.e. when one of the W's decays leptonically and the other hadronically ( $t\bar{t} \rightarrow lvbjb$ ), with a final state containing two jets from the hadronization of b quarks and two jets from light quarks, a high  $p_T$  lepton and missing energy. The “dilepton” channel ( $t\bar{t} \rightarrow lvblvb$ ) where a lepton is lost in acceptance also constitutes a major background. Finally, top quark pairs with one or both W-boson(s) decaying into a  $\tau$  lepton where the  $\tau$  decays into an electron or a muon, may also survive the selection.

W+jets events constitute another major source of background because of a cross section several orders of magnitude above the one of the single top quark production. The Leading Order (LO) Alpgen [12] generator with the HERWIG [13] parton shower algorithm was used for the generation of W+jets and  $Wb\bar{b}$ +jets events in this analysis. The corresponding LO cross-sections have also been used. A 20% uncertainty on the W+jets and  $Wb\bar{b}$ +jets cross-sections is considered in the following. WW and WZ diboson processes were also studied using samples generated with the HERWIG generator. The corresponding cross-sections are reported in [10].

While QCD dijet and multijet processes do not have features of the signal, they contribute to the background due to their overwhelming cross section and small but finite rate of object misidentification.

<sup>1</sup>The hadronic decay modes have obvious disadvantages for triggering and the lack of lepton signature increases the background significantly.

The estimation of this background needs to be done using data-driven methods and has been studied using full simulated dijet events generated with PYTHIA [14].

### 3 Single top quark event preselection

The three production modes of single top quark events are characterized by similar features that motivate a common set of preselection criteria. This preselection, which classifies the events according to exclusive electron and muon selections, is also aimed at reducing the level of three types of processes which constitute the main backgrounds to single top quark analyses: the top quark pair production, the W+jets and the QCD events.

#### 3.1 Triggering and event preselection

The triggers for single top quark events rest upon the use of the inclusive isolated electron and muon triggers. Their design and performance for the three levels of trigger are presented extensively elsewhere [15]. Triggering efficiency is  $84 \pm 1\%$  overall for top pair quark events. Only marginal differences are seen in single top events. Note that for fast simulation samples like W+jets datasets, where no trigger information is available, a trigger weight derived from turn on curves established on  $t\bar{t}$  events is applied to every event.

Selected events must have at least one offline high  $p_T$  isolated lepton in the central region with  $|\eta| \leq 2.5$ . The isolation criterion requires that the energy in a cone of  $\Delta R = 0.2$  around the lepton direction be less than 6 GeV and is important for the rejection of QCD background in which a jet can fake an electron or a muon [10]. Muons and electrons are required to have a transverse momentum greater than 30 GeV ensuring that the trigger efficiency is on the plateau and hence less sensitive to trigger uncertainties. Finally, the sign of the highest  $p_T$  lepton gives the flavor of the decaying top quark.

The event must then pass a second isolated lepton veto cut, applied to any lepton with a  $p_T$  above 10 GeV and in the pseudo-rapidity region  $|\eta| \leq 2.5$  in order to reduce contamination from dilepton backgrounds. The rejection of  $t\bar{t}$  events in the dilepton channel is increased by a factor 2.5 as this requirement is applied. The impact on the signal efficiency is limited, with a loss of 3.6% in both the s- and t-channel and 2.7% in the Wt-channel.

Events are preselected if at least two jets are reconstructed with a  $p_T$  above 30 GeV in the pseudo-rapidity region  $|\eta| \leq 5.0$ . The  $t\bar{t}$  production being the dominant background to single top quark analyses, the use of a jet veto appears mandatory. The event jet multiplicity is thus further required to be lower or equal to four, where the extra jets must be reconstructed with  $p_T$  above 15 GeV. It is important to keep this threshold as low as possible, since lowering the veto  $p_T$  threshold from 30 to 15 GeV results in a rejection of  $t\bar{t}$  events increased from 5 to almost 10. Among those events, the l+jets decay modes are the most sensitive to such a requirement with a rejection rate that is doubled compared to the 30 GeV threshold. Dilepton events are less affected with a rejection rate going from 5 to 6.6. This requirement results in a relative loss of 20 to 25% of the single top quark in the t- and Wt-channel channels and of 7% in the s-channel.

Among the highest  $p_T$  jets, one at least must be b-tagged, have a  $p_T$  above 30 GeV and be in the central pseudo-rapidity region  $|\eta| \leq 2.5$ . The b-tagging algorithms are described elsewhere [10]. A cut on the b-tag weight corresponding to a 60% efficiency and a mistag rate of light jets of 100 [16] is used. The mistag rates being small, we use an additional method to estimate backgrounds which do not contain b partons in the final states but are present in the selected sample because of a cross section several orders of magnitude above that of the signal. This is the case for the W+jets production. In those events, each jet is assigned a tag weight based on the parametrization of the mistag rate as function of the jet pseudo-rapidity and transverse momentum. The combination of all jets results in a weight assigned to the event

to be considered as a “1 b-tag inclusive”, “2 b-tags” etc... event. Known as the “tagging rate function”, this method, which applies on Monte Carlo events, improves the statistics in the distributions of such events, while keeping a global normalization corresponding to the actual mistag rates [17].

Finally the transverse missing energy is required to be larger than 20 GeV. This criterion is consistent with the leptonic decays of a W-boson while reducing the contamination from QCD events.

### 3.2 Preselection efficiency

Preselection efficiencies as well as event yield for an integrated luminosity of  $1 \text{ fb}^{-1}$  are reported in Table 1. The single top quark efficiency ranges between 5 and 6% in the electron channel and between 5.5 and 7.5% in the muon channel respectively. These numbers translate into a total of approximately 5,000 and 4,200 single top quark events in the muon and electron channel respectively including  $\tau$  decays.

The production of  $t\bar{t}$  events constitutes the dominant source of background to single top quark analyses. The  $t\bar{t}$  events in the  $l + \text{jets}$  ( $l = e, \mu$ ) modes are selected with an efficiency lower than 5%, resulting in a total of 22,580 events. The  $\tau + l$  (and  $\tau\tau$ ) modes also contribute significantly with about 6,000 expected events. Despite the use of a second lepton veto dilepton events, where a lepton escapes detection, also contribute to the preselected sample significantly with about 4,000 events surviving the selection. The production of W+jets events is also an important source of background, with about 13,000 events in the preselected sample. However these events populate mostly the lower jet multiplicity bin and their selection depends crucially on the mistag rates. The selection of  $Wb\bar{b} + \text{jets}$  events results in about 1,000 events.

QCD events may also contribute to the selected sample of events. However, the requirements of the presence of at least one isolated identified lepton and one jet tagged as a b-jet reduce very significantly their level as discussed in [11]. Typically QCD background is expected to be smaller than the W+jets background. Further rejection may be achieved by applying more restrictive requirements on the lepton identification, or on the missing transverse energy and its correlation in  $\phi$  with reconstructed objects like leptons and jets [18]. The uncertainty on the remaining level of QCD background may be large. The QCD background contamination in selected samples should preferably be monitored, for example by the reconstruction of the transverse W-boson or top quark reconstructed masses [19].

### 3.3 Cross-section determination and systematic uncertainties

Specific selections have been defined for the t-, s- and Wt- channels analyses. A general procedure to determine the cross-section on the selected samples and assess the errors associated to the measurement has been defined and is common to all three single top quark analyses. The following expression is used to calculate the cross section,  $\sigma$ :

$$\sigma = \frac{N_{sig}}{a \times \mathcal{L}} = \frac{N_{tot} - B}{a \times \mathcal{L}}, \quad (1)$$

where  $N_{sig}$  and  $N_{tot}$  are the number of signal and all selected events respectively,  $B$  is the number of background events,  $a$  is the signal acceptance and  $\mathcal{L}$  is the luminosity of the data sample. In the following studies, these numbers are estimated using Monte Carlo samples only. Data driven methods are expected to be used to estimate specific backgrounds in the forthcoming data analyses.

The propagation of the errors into the cross-section has been done in a consistent way among the three channels. They are combined and propagated to the measured cross section using a Monte Carlo method, which randomly generates  $N_{tot}$  according to a Poisson distribution, and varies randomly  $B$  and  $a$  for every systematic source by an amount chosen around its central value, according to a gaussian distribution. This procedure is performed a few thousand times and the RMS of the resulting distribution is interpreted as the total uncertainty.

Table 1: Preselection efficiency, including trigger, for signal and background events. The uncertainties come from Monte Carlo statistics only. The convention  $l = e, \mu$  is used.

Process	Muon channel		Electron channel	
	$\varepsilon(\%)$	$N(1\text{fb}^{-1})$	$\varepsilon(\%)$	$N(1\text{fb}^{-1})$

The total uncertainty is calculated using a common procedure as described in Section 4.2.3 in the three individual analyses. The main sources of experimental systematic errors taken into account are the b-tagging efficiency, jet energy scale, luminosity, for which central values are provided in the corresponding sections. Theoretical uncertainties that have been considered are the errors on the background cross-sections, as well as the impact of the uncertainties in the parton distribution functions and the b-quark fragmentation in the selection efficiency. Note that we consider the errors as fully correlated between signal and background for jet energy scale, b-tagging, and luminosity.

## 4 Measurement of the t-channel cross section

The t-channel is the most promising channel for single top quark observation at the LHC. It has the largest theoretical cross section of the three channels and its event features give us reasonable visibility of the signal according to the studies done so far [20]. In addition to the cross section measurement, the t-channel single top quark is one of very few candidate channels for the  $V_{tb}$  and the top quark polarization measurements. It is hoped that these measurements will shed light on our understanding of the electroweak symmetry breaking since these quantities have not been studied with high precision in past experiments. Compared to  $t\bar{t}$ , the t-channel single top quark analysis suffers from a higher level of background due to its lower jet multiplicity, which makes the selection sensitive to QCD and W+jets backgrounds whose cross sections are several orders of magnitude higher than that of the signal. Thus, while the signal production rate is not statistically limited at the LHC, a good strategy for signal extraction is required and a careful estimation of the background rate is necessary.

Figure 1: Signal and background distributions of the b-tagged jet  $p_T$  and multiplicity of jets with  $p_T > 30$  GeV after the t-channel selection.

### 4.1 Cut based event selection

After the common preselection, the contribution from the background is still high mainly due to W+jets at the lower end of the kinematic distributions (such as in the jet  $p_T$  spectrum) and  $t\bar{t}$  at the higher end. The b-tagged jets coming from  $t\bar{t}$  and the t-channel single top quark tend to have high  $p_T$  and to be located more centrally since they mainly originate from top quark decays. On the other hand, b-tagged jets from W-boson events are much softer as they primarily come from mistagged jets originating from extra gluon radiation. Furthermore, the recoiling forward quark in the t-channel single top quark produces a high  $p_T$  light jet in the forward direction. This was found to be one of few features useful to reject  $t\bar{t}$  background

events because light jets from the  $t\bar{t}$  events are typically initiated from hadronic W-boson decays and are therefore more central. A cut on b-tagged jet  $p_T > 50$  GeV reduces the W+jets significantly, while a cut on the hardest light jet  $|\eta| > 2.5$  can reject  $t\bar{t}$ . Figure 1 shows the  $p_T$  distribution of the hardest b-tagged jet and the composition of the sample in terms of the jet multiplicity after the additional event selection.

Table 2 lists the number of preselected events, the number of events selected after the cut on b-tagged jet  $p_T$  and the number after the light jet  $\eta$  cut for the signal and the background processes. The signal efficiency is 1.81% and the signal to background ratio after all selection is 37%. Note that the single top quark  $\tau$  decays are included in the signal count. By far the largest background contribution comes from the  $t\bar{t}$  process; the l+jets top quark pair events contribute the most, although dilepton events have a higher survival probability of 1.36% compared to 0.64% of the l+jets. W+jets is the second largest background while the  $Wb\bar{b}$  contribution is relatively small. The s-channel single top quark contribution is almost negligible and the diboson background is even smaller and therefore is not included in the table.

Table 2: Number of events selected after each cut in the t-channel analysis. The last column shows the number of remaining events in the cut-based analysis at the integrated luminosity of  $1 \text{ fb}^{-1}$ . Note that the convention  $1 = e, \mu$  is used.

Process	Preselected		b Jet $p_T$		light jet $\eta$	
	$\epsilon(\%)$	$N(1\text{fb}^{-1})$	$\epsilon(\%)$	$N(1\text{fb}^{-1})$	$\epsilon(\%)$	$N(1\text{fb}^{-1})$
t-channel	7.7%	$6191 \pm 112$	5.5%	$4412 \pm 95$	1.8%	$1460 \pm 56$
$\mu$ channel	4.1%	$3312 \pm 83$	2.9%	$2352 \pm 71$	0.9%	$728 \pm 40$
$e$ channel	3.6%	$2879 \pm 78$	2.6%	$2060 \pm 66$	0.9%	$732 \pm 40$
s-channel	9.0%	$316 \pm 5$	7.0%	$245 \pm 4$	0.8%	$26 \pm 1$
Wt-channel	8.9%	$2575 \pm 37$	6.4%	$1854 \pm 32$	0.4%	$122 \pm 9$
$t\bar{t}$ l+jets	9.3%	$22580 \pm 176$	7.3%	$17775 \pm 158$	0.6%	$1556 \pm 48$
$t\bar{t} \rightarrow l + \tau/\tau + \tau/\tau$ jets	4.3%	$7342 \pm 104$	3.4%	$5776 \pm 93$	0.4%	$740 \pm 34$
$t\bar{t} \rightarrow ll$	10.4%	$4018 \pm 75$	8.1%	$3143 \pm 67$	1.3%	$520 \pm 28$
W+jets	0.025%	$12886 \pm 138$	0.012%	$6082 \pm 95$	0.0017%	$873 \pm 36$
$Wb\bar{b}$	4.7%	$939 \pm 27$	3.0%	$597 \pm 22$	0.4%	$69 \pm 8$
$S/B$		0.12		0.12		0.37
$S/\sqrt{B} (\sigma)$		27.5		23.4		23.4
$\sqrt{S+B}/S$		3.9%		4.5%		5.0%

As seen in Table 2, a precision ( $\sqrt{S+B}/S$ ) of 5% can be obtained after the final selection. Note, however, that the selection cut does not optimize the precision nor the significance of the signal observation. From purely statistical arguments, the t-channel cross section can be measured to a few percent accuracy with a few  $\text{fb}^{-1}$  of data.

In comparison to the previous study in the ATLAS physics TDR [20], which reported S/B a ratio of 3, there is a significant apparent reduction in the event selection performance. The cut-based selection used here is similar to that used in the TDR and we would have expected a similar result. Further investigation revealed several issues with the TDR analysis. Firstly, Monte Carlo (MC) generators changed drastically in recent years. PYTHIA introduced a new parton shower algorithm, which is much more radiative. The matrix-element generator for the signal has also changed to AcerMC, which combines the NLO diagram contribution to the LO ones as opposed to PYTHIA, which only uses LO. For the W+jets background production, Alpgen is used because it is shown that it reproduces better the high  $p_T$  tails of jet distributions at the TeVatron [21], while Herwig was used in the TDR. In addition, the TDR analysis did not include some of the crucial background processes, like dilepton  $t\bar{t}$  channels and  $\tau$  decay modes which are shown to contribute significantly in the present analysis. Therefore, the result of the TDR can

now be seen as too optimistic.

Note that the presence of pile-up affects the reconstruction of the objects selected in the event. In particular, the selection efficiency is directly affected by the presence of extra jets in the events. Specific Monte Carlo samples of single top quark and  $t\bar{t}$  events have been produced with or without pile-up events superimposed. The use of events with pile-up results in a decrease of about 25% for signal events, and 34% for  $t\bar{t}$  events. No systematic uncertainties will be associated with this value. The use of data will be mandatory for the tuning of the pile-up modeling and the corresponding uncertainty is expected to be brought down to a negligible value with respect to the other sources of error.

## 4.2 Systematic uncertainties

The systematic uncertainties have been evaluated following a procedure common to all three analyses. This procedure is defined here and the results specific to all analyses are reported in the corresponding sections.

### 4.2.1 Experimental systematic uncertainties

Various criteria need to be considered to assess the systematic effects as it depends on a number of detector sub-components and theoretical assumptions. A general procedure has been defined to assess all systematic errors in a consistent way for the three single top quark analyses. The estimate is shown here for the t-channel analysis only.

The effect of the uncertainties on the measured cross section is summarized in Table 4. While the statistical uncertainty is not a constraint for the t-channel cross section analysis even with the early data, systematic uncertainties can only be reduced with detailed understanding of the detector performance and theoretical uncertainties. The measurement in the t-channel is largely limited by such effects.

Table 3: Effect of b-tag and jet energy scale systematics. Numbers are quoted from relative variation of selected event.

Process	b-tag -5%	b-tag +5%	JES -5%	JES +5%
t-channel	-4.0%	+4.8%	-4.8%	+5.0%
s-channel	-5.2%	+3.6%	-6.6%	+12.7%
Wt-channel	-8.9%	+8.9%	-2.0%	+6.9%
$t\bar{t}$	-6.4%	+6.8%	-3.1%	+5.9%
$Wb\bar{b}$	-4.0%	+8.9%	-12.6%	+12.7%
W+jets	-1.6%	+2.5%	-9.9%	+14.6%
Total bkgd.	-4.6%	+6.1%	-4.8%	+8.1%

The uncertainty in the b-tagging performance and jet energy scale can have crucial effects on the measured cross section since we rely on jet kinematics to reduce the background. In particular, the large background contribution from  $t\bar{t}$  can cause a large fluctuation on the total event rate with these uncertainties, which leads to a large error on the cross section measured. The jet energy scale uncertainty affects the  $p_T$  distribution of jets strongly at the low end of the distribution. Cutting on  $p_T$  in this region can lead to a larger uncertainty on the signal acceptance. The effect of 5% variation of the b-tagging performance has been considered together with the corresponding change in the mistag rate of non b-tagged jets. The effect of a 5% change of the jet energy scale determination (JES) has also been evaluated

on the efficiency. The impact of both effects on the selection is summarized in Table 3. It should be noted that the  $Wb\bar{b}$  and  $W$ +jets backgrounds are more affected by the jet energy scale due to the fact that most of the jets in these sample are in the low- $p_T$  region, which means that they are more likely to enter or leave the acceptance as the scale is changed.

The uncertainty due to the trigger requirements has been estimated by computing the variation in the signal and background rates resulting from a bias of 1% in the inclusive lepton trigger efficiency. This corresponds to the expected level of precision derived from turn on curves determination with the early data. Similarly, a 1% uncertainty in the lepton identification was considered and the corresponding impact on the cross section measurement assessed. These two effects are expected to contribute to less than 2% of the total uncertainty with  $1\text{fb}^{-1}$ .

Note that for all those results, the limited statistics of the Monte Carlo samples may result in fluctuations in the variable distributions used to discriminate signal from background events. The uncertainty associated to the low statistics is found to be 6-8% with  $W$ +jets being the largest cotrigger requirements.

#### 4.2.2 Theoretical and Monte Carlo systematic uncertainties

Since the event selection relies heavily on the jet multiplicity, the number of additional jets from the parton shower can affect the selection efficiency. To evaluate the effect of ISR/FSR uncertainty, two sets of PYTHIA parameter variations were considered for comparison, which control the free parameters in the underlying event, initial- and final-state radiation, showering, and multiple interactions. The variations were combined to maximize the variation in the number of selected events to give a conservative estimate. The effect on the jet multiplicity is shown in Figure 2. It can be seen that the loose jet ( $p_T > 15\text{ GeV}$ ) distribution is affected more severely, which affects the selection efficiency due to the jet veto cut. The parameter variation set that gave the largest uncertainty leads to an overall uncertainty in the t-channel selection efficiency of  $-11\% + 7\%$ , and is quoted as a systematic uncertainty.

Figure 2: Variation in t-channel multiplicity for the loose ( $p_T > 15\text{ GeV}$ , left) and the tight ( $p_T > 30\text{ GeV}$ , right) jets due to ISR/FSR parameter variation. The distributions are shown without applying the t-channel selection cuts. The jet veto cut ( $\leq 4$  loose jets) and the requirement of b-tagged jet were also removed for these plots to show the uncertainty over all multiplicities<sup>2</sup>. Black points are the nominal entries while the mesh band shows variation from “3/4 jet parameter set” and the filled band shows that of “2/3”, which are the two sets of parameter variations compared to study different jet multiplicity events.

The uncertainty due to PDF was calculated using a re-weighting method together with error PDF

sets provided by the PDF packages. While the event generation was done only for the central value PDF, weights were calculated in each event according to:

$$w_i^{\pm} = \frac{f_1(x_1, Q; S_i^{\pm}) \cdot f_2(x_2, Q; S_i^{\pm})}{f_1(x_1, Q; S_0) \cdot f_2(x_2, Q; S_0)}, \quad (2)$$

where,  $f_1$  and  $f_2$  are the PDF values for a given hard scattering process (characterized by flavors  $f$  and momentum fractions  $x$  of the initial partons, and by  $Q$ , the event energy scale) evaluated for the  $i^{th}$  error PDF pair  $S_i^{\pm}$ . The variation in efficiency was calculated by applying an event selection similar to the preselection cuts at the generator level. The variations in efficiency were added using the Hessian formalism and the results from CTEQ and MRST PDF error sets [22] [23] were consistent. The effect of the PDF uncertainty on the signal was evaluated to be +1.4% -1.1% and it is a minor contribution to the final systematics. A larger effect of +6.2% -5.5% was seen on the  $t\bar{t}$  background. The PDF uncertainty was estimated for the leading contribution from the  $t\bar{t}$  process only.

In addition to the above, the t-channel process has a fairly large uncertainty from MC generator predictions. Comparing various combinations of ME and PS generators, it was observed that the Pythia and Herwig parton shower algorithms give significantly different jet multiplicities. While we assume that this difference can be eliminated by tuning the parameters to the observed data<sup>3</sup>, the instability of theoretical prediction from matrix element generators is an outstanding issue and a 4.2% variation in signal acceptance was seen by comparing AcerMC+Herwig and MC@NLO+Herwig. We quote this as an estimate for systematic uncertainty from the theoretical prediction. In our present analysis, the background is es-

Table 4: Summary of all uncertainties that affect the measured cross section, shown for the cut-based analysis and the BDT analysis. “Data statistics” represents the Poisson error one would expect from real data

Source	Analysis of 1 fb <sup>-1</sup>			Analysis of 10 fb <sup>-1</sup>

timated from Monte Carlo and its normalization is currently estimated based on theoretical uncertainties. When data will be available, the  $t\bar{t}$  and the W+jets backgrounds will be measured from data as well. It

<sup>3</sup>The current tunings of Pythia and Herwig parton shower weres obtained independently based on extrapolation from the Tevatron data. [24]

is beyond the scope of this paper to discuss methods for the data-driven background estimation and the uncertainty from the background is currently estimated based on theoretical uncertainties.

#### 4.2.3 Summary of uncertainties

A large part of the final uncertainty is due to the overwhelming amount of  $t\bar{t}$  background. For this reason, the event selection optimized for statistical significance or statistical precision does not give the smallest total uncertainty when systematics are included. Table 4 reports the uncertainties associated the cross section determination. The total uncertainty is dominated by systematic effects related to the background normalization. Reducing the background contamination to increase signal to background ratio would help to minimize the systematic uncertainty. It is therefore desirable to further optimize the selection beyond what can be achieved with simple cuts on the existing variables.

Note that for an analysis based on  $10 \text{ fb}^{-1}$ , the table reports the expected performance assuming a better understanding of the experimental aspects of the detection. Assuming a b-tagging efficiency known with a precision of 3%, the jet energy scale determined at 1%, a luminosity known at 3% and a better understanding of the background to the 3% level and the radiation modeling at 3%, a total systematic uncertainty of 10% seems achievable for the BDT analysis.

### 4.3 Multivariate event selection

In the cut-based analysis no variable was found that was effective to reject the  $t\bar{t}$  background. One commonly employed separation technique is a Multivariate Analysis (MVA), which effectively factorizes the process of cut optimization using a set of rules for separating the signal from the background events. In the present analysis, an attempt to eliminate the remaining background contribution from  $t\bar{t}$  makes use of the Boosted Decision Tree (BDT) method [25] within the TMVA [26] framework. The sample used is selected with the b-tagged jet  $p_T$  cut selection, without applying the forward jet  $\eta$  cut. This cut is indeed effective to reduce the  $t\bar{t}$  contribution but not very efficient. About 40 object/event level variables were studied using a genetic algorithm, which scanned a large number of variable sets. Extensive studies of this variable sets revealed that a small subset of the variables can achieve signal to background discrimination close to what was achieved using all variables. This set was further refined so that the chosen variables are not too sensitive to JES systematics:

- $p_T$  of the leading b-tagged jet and non-b-tagged jet;
- $\eta$  of the leading non-b-tagged jet and  $\cos \theta$  of the leading jet;
- Centrality ( $\frac{p_T^{jet0} + p_T^{jet1}}{|p|^{jet0} + |p|^{jet1}}$ );
- Scalar sum of the  $p_T$  of the two highest energy jets, the transverse missing energy  $\cancel{E}_T$ , and the lepton  $p_T$ ;
- $\Delta R$  between the two jets with the highest transverse momentum
- $\Delta R$  between the leading jet and the lepton;
- $\Delta R$  between the leading non-b-tagged jet and the lepton;
- the lepton, and the W-boson transverse mass;
- $\eta$  of the jet with largest  $|\eta|$ ;
- the number of jets with  $p_T > 30 \text{ GeV}$ .

Figure 3 (left) shows the BDT output discriminator constructed from the variables discussed above. By cutting on a high value of the discriminator, the  $t\bar{t}$  background can be removed more effectively than by cutting on individual input variables. Since the BDT was optimized for the  $t\bar{t}$  separation, as expected the output is not effective against W+jets. It can be seen in the right figure that a high level of signal purification is achieved using the BDT discriminator. We optimized the cut on the BDT output by min-

Figure 3: Boosted decision tree output for signal and background after the b-tagged jet  $p_T$  cut (left) and leptonic top quark mass distribution using cut on BDT output at 0.6 (right).

imizing the final uncertainty on the measured cross section, including the systematic effects. For each cut, the systematic uncertainties were calculated assuming that the relative systematic uncertainty stays constant for each channel for each source of uncertainty. This is a fairly reasonable assumption considering that the relative uncertainty changes slowly with the cuts and the variables were chosen to avoid larger systematics. For most cut values, the systematic effects are dominant and the total uncertainty is reduced with increasing signal to background ratio. On the other hand, with very tight cuts the statistical error becomes larger than systematics. The overall minimum was found to be at 0.6 where the signal to background ratio is 1.3 and 542 signal events are left as shown in Table 5. The reconstructed top mass distribution after applying BDT selection is shown in figure 3 (right). The top mass was reconstructed from the lepton,  $\cancel{E}_T$  and the highest  $p_T$  b-tagged jet. The W-boson mass was constrained to be 80.4 GeV to obtain two solutions for neutrino kinematics and the one with the smaller  $p_z$  was selected. The statistical uncertainty is 5.7% while the total uncertainty is 22% as shown in Table 4.

Table 5: Final event yield after the cut on BDT discriminator at  $1\text{fb}^{-1}$ .

Process	t-channel	s-channel	Wt-channel	$t\bar{t}$	W+jets	Wbb	$S/B$
$N(1\text{fb}^{-1})$	542	3	15	184	201	10	1.31

#### 4.4 Sensitivity at $1\text{fb}^{-1}$ and the measurement of $|V_{tb}|$

Although the estimated systematic uncertainty of the cut-based analysis is rather large (44.7%), it has been shown that this can be reduced by rejecting the  $t\bar{t}$  background using boosted decision trees. The total uncertainty decreases as the  $S/B$  ratio increases and the estimated uncertainty at  $1\text{fb}^{-1}$  is

$$\frac{\Delta\sigma}{\sigma} = \pm 5.7\%_{\text{stat}} \pm 22\%_{\text{sys}} = \pm 23\%. \quad (3)$$

The t-channel cross section is proportional to  $|f_L V_{tb}|^2$ , where the parameter  $f_L$  is the weak left-handed coupling and  $f_L = 1$  in the Standard Model. In the theory predictions, the product  $|f_L V_{tb}|^2$  is always set to unity. Thus, if one measures the cross section, and then divides by the theoretical cross section, one obtains a measurement of  $|V_{tb}|^2$ , making the Standard Model assumption that  $f_L = 1$  [27].

The relative uncertainty on  $V_{tb}$  is the relative uncertainty on  $|V_{tb}|^2$  divided by two since  $\delta|V_{tb}|/|V_{tb}| = \delta|V_{tb}|^2/2|V_{tb}|^2$ . However, there are additional systematic uncertainties in the  $V_{tb}$  measurement due to the presence of the theoretical cross section in the denominator. Here, we quote the uncertainty calculated in [7], in which a theoretical uncertainty of  $+3.8 - 4.1\%$  is reported including the contributions due to the strong scale, PDF and top quark mass uncertainties. We use the average of the positive and the negative uncertainties. Therefore, the estimated uncertainty on the measured value of  $V_{tb}$  is

$$\frac{\Delta|V_{tb}|}{|V_{tb}|} = \pm 11\%_{stat+sys} \pm 4\%_{theo} = \pm 12\%. \quad (4)$$

#### 4.5 Summary

The cross section measurement of the single top quark t-channel was studied in this chapter. The characteristics of the signal and background were investigated in detail and an analysis strategy was developed first using simple cuts and then using boosted decision trees.

While a cut-based event selection can achieve a statistical precision of a few percent at an integrated luminosity of  $1 \text{ fb}^{-1}$ , the  $t\bar{t}$  background is difficult to reduce. This results in large systematic uncertainties coming from both experimental and theoretical origins. Uncertainties in the jet energy scale, b-tagging and luminosity all affect the measurement considerably. The uncertainty on the background cross section is also rather large though we expect that it will be constrained at higher accuracy with the data. This is also true for the QCD background, which is not included in our current analysis. The results shown are obtained on samples without any pile-up and no systematic uncertainty was associated to it. Data-driven background estimation methods should be developed once data is available. Among the theoretical issues, the ISR/FSR uncertainty degrades the measurement more significantly than other theoretical effects such as the PDF and the Monte Carlo generator model.

A multivariate background discrimination method is very effective in reducing the background and thus reducing the total uncertainty to nearly a half of the cut-based analysis. We conclude that multivariate analysis tools are highly effective for a t-channel cross section measurement and further studies of these techniques will be very beneficial for the improvement of the analysis in the future. However, to reach a precision at a few percent level, studies of systematic uncertainties and an excellent understanding of the detector response will be necessary.

### 5 Measurement of the s-channel cross section

The measurement of the single top quark s-channel appears the most delicate of the three main single-top quark processes. Suffering from a low cross section compared to the main backgrounds, the event topology makes this channel very sensitive to the presence of both  $t\bar{t}$  and  $W$ +jets events. Because of the low jet multiplicity of such events, the analysis is also expected to be sensitive to dijet production, despite the tight requirements on the presence of at least two b jets. The s-channel is however one of the most interesting because the production of  $tb$  final state events is directly sensitive to contributions from extra W-bosons or charged Higgs bosons as predicted in two Higgs doublet model (2HDM) [28].

The event selection is presented in three steps. A first one makes use of a standard cut-based analysis, and will serve as a reference with the early data. In a second step, likelihood functions designed to improve the discrimination against specific backgrounds are presented together with the sets of discrim-

inant variables that enter their definition. Finally, the selection criteria applied on those likelihoods are defined so that the total uncertainty affecting the cross section determination is minimized.

### 5.1 Sequential cut analysis

After applying the common preselection described in Section 3, only two b-tagged jet events with  $p_T$  above 30 GeV are selected, and a jet veto is applied on any other jet with a transverse momentum above 15 GeV. This strong requirement is used to reject  $t\bar{t}$  events which represent the dominant background to our signal at this stage. This set of requirements also reduces the W+jets and QCD multijet contamination, since those events feature much softer b jets or no b jets at all. The selection also requires the opening angle  $\Delta R$  between the two jets to be between 0.5 and 4.0, the scalar sum of total jet transverse momenta  $H_T(\text{jet})$  to be above 80 and below 220 GeV and finally the sum of the transverse missing energy ( $\cancel{E}_T$ ) and lepton transverse momentum ( $p_T$ ) to be in the range between 60 and 130 GeV.

Selected event yields are reported in Table 6 for the three single top quark processes, and all  $t\bar{t}$  and W+jets backgrounds. When adding all contributions, the overall signal efficiency is about 1.1% in the electron channel and 1.6% in the muon channel. This corresponds to a total of about 25 selected candidates for an integrated luminosity of  $1 \text{ fb}^{-1}$ . The signal to background ratio is about 10%. The dominant background is composed of the  $t\bar{t}$  events which account for about 60% of the total background yield. Among those, the  $t\bar{t}$  in the lepton+jets mode, including  $\tau$  decays, contribute about 40%. The remaining backgrounds originate from the  $Wb\bar{b}$ +jets production, which constitutes about 14% of the background yield, and almost equally from the single top quark t-channel (11%) and W+jets (9%) events. As expected, W+jets events are removed due to the requirement of b-tagged jets, with a final yield depending upon the mistag rate. Diboson contributions (WW and WZ) are found to be negligible.

Table 6: Event yield for signal and background for the cut-based analysis in the 2-jet multiplicity bin for  $1 \text{ fb}^{-1}$ . Uncertainties come from Monte Carlo statistics only. The convention  $l = e, \mu$  is used.

Events in $1\text{fb}^{-1}$	e channel	$\mu$ channel	e + $\mu$ combined
s-channel	$10.3 \pm 0.8$	$14.5 \pm 1$	$24.8 \pm 1.3$
t-channel	$17.0 \pm 5.7$	$13.6 \pm 5.1$	$30.6 \pm 7.9$
Wt-channel	$6.5 \pm 1.9$	$2.4 \pm 1.2$	$8.9 \pm 2.3$
$t\bar{t} \rightarrow l + \text{jets}$	$18.8 \pm 4.3$	$20.5 \pm 5.3$	$39.3 \pm 5.3$
$t\bar{t} \rightarrow ll$	$29.0 \pm 5.5$	$15.4 \pm 5.0$	$44.4 \pm 7.4$
$t\bar{t} \rightarrow l\tau$	$20.5 \pm 5.6$	$40.9 \pm 6.9$	$61.4 \pm 8.9$
$Wb\bar{b}$ +jets	$18.9 \pm 2.0$	$19.7 \pm 2.0$	$40.6 \pm 2.5$
W+jets	$14.8 \pm 1.4$	$11.0 \pm 2.2$	$25.8 \pm 2.3$
Total Bkg	$125.5 \pm 10.3$	$123.5 \pm 10.6$	$251.0 \pm 14.2$
$S/B$	8.2%	11.7%	9.8%
$S/\sqrt{B}$	0.9	1.3	1.6
$\sqrt{S+B}/S$	1.1	0.8	0.7

## 5.2 Likelihood selection

The cut based analysis shows that a simple approach to select single top quark s-channel events is hampered by a high level of background. The use of a likelihood discriminator is aimed at improving the performance of the discrimination against backgrounds in order to purify the selected signal samples. This approach assumes that the distributions entering the definition of likelihood functions are well known and validated on data itself. This result can be achieved by cross-checking at every step the agreement between data and Monte Carlo distributions on selected sub-samples where a high level of  $t\bar{t}$  and W+jets background is expected. In the following, only pre-selected events with exactly two jets, both of which are b tagged are considered. A jet veto on any other jet is applied.

### 5.2.1 Definition of the likelihood functions

The main background processes to our signal show very distinct features in the final state and topology that lead us to define several likelihood functions each devoted to the discrimination of a specific process: three likelihood functions are devoted to  $t\bar{t}$  events in the dilepton, the  $l + \tau$  and the  $l$ -jets decay modes and two likelihood functions have been developed to discriminate against W+jets and t-channel events. Due to the limited Monte Carlo statistics, these likelihood discriminators have been defined by combining both muon and electron channels.

The list of variables entering a likelihood function is derived from a procedure of optimization that selects only the variables that bring a significant discrimination between signal and the considered background. The discriminating power of a given variable is computed using the selection efficiencies for both signal and background in the plane  $(\varepsilon_S, \varepsilon_B)$ . When the discriminating power of a variable is low, the variation of the background efficiency  $\varepsilon_B$  follows that of the signal  $\varepsilon_S$ . On the contrary, a high discriminating variable results in a larger decrease of  $\varepsilon_B$  compared to the variation seen in  $\varepsilon_S$ . This variation, computed for each  $\varepsilon_S$  and integrated over the full range of  $\varepsilon_S$  can thus be seen as an estimator of the discriminating power of the variable. In this analysis, the variable is selected if the discriminating power is about a few percent. The use of higher thresholds results in a degradation of the performance due to the loss of discriminating power of the formed likelihoods. The set of discriminant variables is built from 16 relevant kinematical variables:

- the opening angles between the lepton and the jets  $\Delta R(l, b_1), \Delta R(l, b_2)$
- the angles  $\cos \Delta \Phi(l, b_1)$  and  $\cos \Delta \Phi(l, b_2)$ ;
- the opening angle between the two b tagged jets  $\Delta R(b_1, b_2)$ ;
- the pseudo-rapidity of the b tagged jets  $\eta_{b1}$  and  $\eta_{b2}$ ;
- the invariant mass formed by the systems of the two b tagged jets  $M_{\text{inv}}(b_1, b_2)$
- the invariant mass formed by the reconstructed W leptonic boson and the b tagged jets  $M(W_{\text{lep}}, b_1)$  and  $M(W_{\text{lep}}, b_2)$ ;
- the transverse momentum of the reconstructed top quark candidates  $p_T(\text{top}_1)$  and  $p_T(\text{top}_2)$
- the sum of the missing transverse energy and lepton transverse momentum  $\cancel{E}_T + p_T(l)$ ;
- the transverse mass of the leptonic W-boson candidate  $M_T(W_{\text{lep}})$ ;
- the scalar sum of the jet transverse momenta  $H_T(\text{jets})$ ;
- global event shape variables: sphericity, aplanarity and centrality.

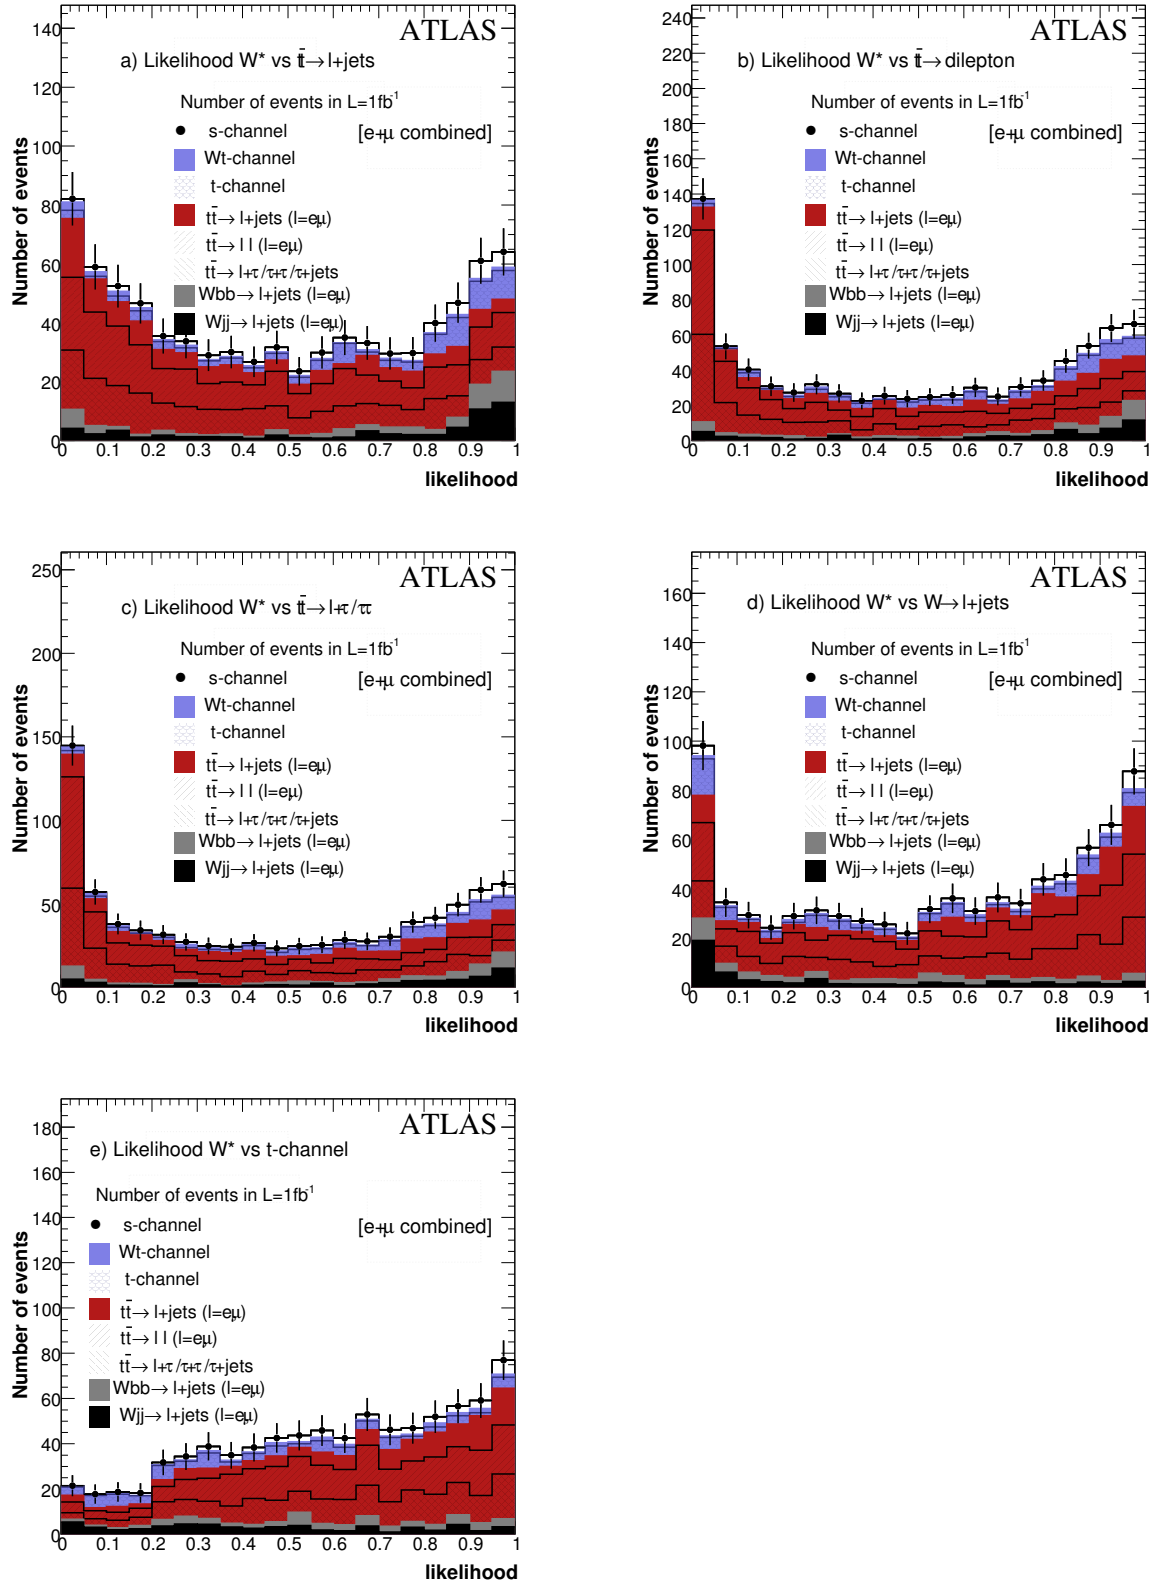

Figure 4: Distributions of the five likelihood functions for an integrated luminosity of  $1\text{fb}^{-1}$ . a) Likelihood against  $t\bar{t}$  in the  $l+jets$  channel; b) Likelihood against  $t\bar{t}$  in the dilepton channel; c) Likelihood against  $t\bar{t}$  in the  $l+\tau$  channel; d) Likelihood against  $W+jets$  events; e) Likelihood against t-channel

### 5.2.2 Optimization of the likelihood selection

The likelihood function distributions corresponding to an integrated luminosity of  $1 \text{ fb}^{-1}$  are shown in Figure 4. Thresholds have been applied on each of the 5 likelihood values. In the present analysis, the thresholds on the likelihood values have been set so that the total uncertainty affecting the cross section measurement is minimized. The total uncertainty was calculated as described in Section 4.2.3. The main sources of systematic errors taken into account are the b-tagging efficiency, jet energy scale, luminosity and uncertainties on the background level, for which central values are provided in Section 5.3. Note that we consider the errors as fully correlated between signal and background for jet energy scale, b-tagging, and luminosity.

The thresholds set on the five likelihood outputs resulting from the minimization of the total uncertainty are listed below:

$$\begin{aligned}\mathcal{L}_{\bar{t}t}/\text{lepton+jets} &> 0.34, \\ \mathcal{L}_{\bar{t}t}/\text{dilepton} &> 0.56, \\ \mathcal{L}_{\bar{t}t}/\tau+\text{lepton} &> 0.80, \\ \mathcal{L}_{W+\text{jets}} &> 0.32, \\ \mathcal{L}_{t\text{-channel}} &> 0.46\end{aligned}$$

Table 7 reports the number of events expected for all signal and backgrounds for an integrated luminosity of  $1 \text{ fb}^{-1}$ . The overall signal to background ratio is improved significantly compared to the sequential cuts analysis with a purity increased from 9.8% to 18.7%. This is an expected outcome of the optimization procedure since the main source of errors comes from the uncertainties in the background.

Table 7: Numbers of expected events for an integrated luminosity of  $1 \text{ fb}^{-1}$  expected from the likelihood analysis in the two jet final state events. The results are shown separately for the electron and muon channels. Statistical uncertainties correspond to the Monte Carlo statistics only. The convention  $l = e, \mu$  is used.

Events in $1\text{fb}^{-1}$	e channel	$\mu$ channel	e + $\mu$ combined
s-channel	$6.3 \pm 0.7$	$9.1 \pm 0.8$	$15.4 \pm 1.0$
t-channel	negl.	$1.7 \pm 1.7$	$1.7 \pm 1.7$
Wt-channel	$1.8 \pm 1.0$	negl.	$1.8 \pm 1.0$
$\bar{t}t \rightarrow l + \text{jets}$	$7.6 \pm 2.6$	$7.7 \pm 3.5$	$15.3 \pm 4.4$
$\bar{t}t \rightarrow ll$	$6.0 \pm 2.6$	$6.0 \pm 2.6$	$12.0 \pm 3.8$
$\bar{t}t \rightarrow l + \tau$	$6.8 \pm 3.4$	$14.5 \pm 4.1$	$21.3 \pm 5.3$
Wbb+jets	$10.0 \pm 3.2$	$7.0 \pm 2.6$	$17.0 \pm 4.1$
W+jets	$6.2 \pm 1.2$	$7.3 \pm 2.1$	$13.5 \pm 2.4$
WZ + WW	negl.	negl.	negl.
Total Bkg	$36.8 \pm 5.8$	$45.9 \pm 6.6$	$82.7 \pm 8.6$
$S/B$	17.3%	19.8%	18.7%
$S/\sqrt{B}$	1.0	1.3	1.7
$\sqrt{S+B}/S$	1.0	0.8	0.6

The dominant background comes from  $t\bar{t}$  production, which contributes about 60% of the total event yield. Among those events, the main contribution originates from the  $l + \tau$  decay modes ( $l=e, \mu$ ), which corresponds to 45% of the  $t\bar{t}$  yield, followed by the dilepton and the  $l$ +jets channels. The production of  $Wb\bar{b}$ +jets represents about 20%, while the  $W$ +jets events still contribute 16% of the total background yield. Finally, the contamination originating from the other single top quark channels is smaller than the signal expected event yield with a contribution of 4% from the sum of  $t$ - and  $Wt$ - channels. The results show a similar statistical sensitivity compared to the standard cut-based analysis, with an improved signal to background ratio.

As described in Section 4.1 the presence of pile-up affects the reconstruction of the objects selected in the event. The use of events with pile-up results in a decrease of about 9% for signal events, and 15% for  $t\bar{t}$  events. No systematic uncertainty is associated to this difference, as  $t\bar{t}$  events completely dominate the selected sample. Dedicated studies with data will be used to tune all Monte Carlo generators.

### 5.3 Systematic uncertainties

The systematic uncertainties have been evaluated on the likelihood analysis. We follow the procedures defined in Section 4.2.

#### 5.3.1 Experimental systematic uncertainties

The uncertainties on the  $b$ -tagging efficiency and the mistag rates have been estimated by varying the  $b$  weight cut value corresponding to a change of  $\pm 5\%$  in the  $b$ -tag efficiency with respect to the reference value of 60%. Table 8 shows the impact of such effects on signal and background events. As the  $b$ -tag efficiency is varied by  $+5\%$  and  $-5\%$ , the signal selection efficiency is shifted by 7.1% and -7.7% respectively. For background events, the impact of such variations result in both cases in an increase of the background level which reaches  $+15\%$  and  $+5\%$  respectively because of the change affecting the mistag rates. Table 9 reports the impact on the total cross-section determination. The understanding of the  $b$ -tagging performance completely drives the analysis strategy.

Table 8: Effect of the main systematic effects,  $b$ -tag efficiency and mistag rate variation and of the jet energy scale variation on the number of expected events for an integrated luminosity of  $1 \text{ fb}^{-1}$  expected from the likelihood analysis in the two jet final state events. Numbers in parentheses are the relative variations.

Events in $1\text{fb}^{-1}$	$b$ -tag -5%	$b$ -tag +5%	JES -5%	JES +5%
s-channel	14.2 (-7.7%)	16.5( +7.1%)	16.9 (+9.7%)	15.4 (negl.)
$t$ and $Wt$ -channel	6.9 (+97%)	3.5 (negl.)	5.1 (+45%)	5.1 (+45%)
$t\bar{t}$ combined	47.8 (-1.6%)	58.1 (+19.5%)	49.5 (+1.8%)	46.9 (-3.5%)
$Wb\bar{b}$ +jets	15.5 (-8.8%)	16.4 (-3.5%)	17.0 (negl.)	17.0 (negl.)
$W$ +jets	17.0 (+26%)	17.0 (+26%)	15.4 (+14%)	15.1 (+11.8%)
Total bkg	87.2 (+5.4%)	94.9 (+14.8%)	87.7 (+6%)	84.9 (+2.6%)

A variation of  $-5\%$  and  $+5\%$  of the jet energy scale has been propagated to the jet reconstruction and the selection efficiencies were re-assessed. Backgrounds change by about 6% and 3% respectively, while the signal acceptance is found to vary by about  $\pm 10\%$ . Again, in both cases the background is

increased with any change of the jet energy scale. Indeed, as the jet scale factor is decreased, top quark pair events in the dilepton and l+jets modes tend to have a lower multiplicity, resulting in an increased contamination. As the scale factor goes up, the low multiplicity events are favored while top quark pair production is almost not affected. Table 8 shows the effects of the jet energy scale variation on the signal and background event yield.

The impact of the trigger efficiency and lepton identification uncertainties has been estimated as explained in the t-channel Section. This reflects as an uncertainty of 6% on the total cross-section measurement. Table 9 reports the impact on the total cross-section determination.

Table 9: Summary of all uncertainties that affect the measured cross section. Data statistics is the Poisson error one would expect from real data while MC Statistics is the uncertainty on the estimated quantities due to MC statistics.

Source of uncertainty	Analysis for $1 \text{ fb}^{-1}$		Analysis for $10 \text{ fb}^{-1}$	
	Variation	$\Delta\sigma/\sigma$	Variation	$\Delta\sigma/\sigma$
Data Statistics		64%		20%
MC Statistics		29%		
Luminosity	5%	31%	3%	18%
b-tagging	5%	44%	3%	25%
JES	5%	25%	1%	5%
Lepton ID	1%	6%	1%	6%
Bkg x-section	10.3%	47%	3%	16%
ISR/FSR	9%	52%	3%	17%
PDF	2%	16%	2%	16%
b-fragmentation	3.6%	19%	3.6%	19%
Total Systematics		95%		48%

### 5.3.2 Theoretical and Monte Carlo systematic uncertainties

In the present analysis, uncertainties on the background estimates come from the theoretical uncertainties associated with their cross section. The main background contributions are  $t\bar{t}$  (60%),  $Wb\bar{b}+\text{jets}$  (20%) and  $W+\text{jets}$  (16%), so 10% uncertainties on the  $t\bar{t}$  cross-section prediction and 20% on the  $W+\text{jets}$  and  $Wb\bar{b}+\text{jets}$  events lead to a total of 10.3% uncertainty on the total background. The understanding of the background level is thus a crucial point for a precise cross-section determination. Note that despite very distinct topologies, the selections of the s-, t- and Wt- channels analyses are not orthogonal. However it is believed that correlations can be properly addressed with dedicated study and enough statistics.

The selection of a 2-jet final state is very sensitive to the presence of extra jets originating from gluon radiation. Any uncertainty in the ISR/FSR modeling is thus expected to have a significant impact on the selection efficiencies, in particular for the s-channel and the  $t\bar{t}$  events. Specific Monte Carlo samples have been generated with ISR/FSR settings leading to the largest cross section variations. Variations of 5% of the signal selection efficiencies are expected, and are due to the change in the jet multiplicity. The uncertainties however reach large values for the  $t\bar{t}$  production, with variations of 17.8% between the two extreme cases. Note that these variations have been assessed with non-calibrated jets, although there is a high expected correlation between jet energy scale and ISR/FSR gluon modeling. An overall

9% uncertainty corresponding to half the variation is quoted. Note that the s-channel being produced via quark-antiquark annihilation, some constraints coming from the use of W-boson events should allow the tuning of the showering interfaces.

Another uncertainty is related to the choice of the PDFs. The procedures used to assess the impact of such choice is presented in Section 4.2.2. The expected bias on the signal is below 3% while this number is below 2% for  $t\bar{t}$  events.

Finally the effect of the b-fragmentation parametrization has also been investigated using fast simulation. The b quark fragmentation is performed according to the Peterson parametrization, with one free parameter  $\epsilon_b$ . Varying the default value from  $\epsilon_b = -0.006$  by  $\pm 0.0025$  [29] and taking the difference as a systematic uncertainty leads to a change of 3.6% in the  $t\bar{t}$  and signal selection efficiencies.

Table 9 lists all sources of uncertainties and reports their impact on the cross-section determination. Two cases are considered: one defined by the level of uncertainty in the b-tagging, JES, luminosity that will presumably characterize the early data taking period and a second one assuming a reasonable improvement on those effects with an integrated luminosity of  $10 \text{ fb}^{-1}$ . The assumptions made in the latter case are the same as the ones listed in Section 4.2.3.

## 5.4 Summary

The determination of the s-channel cross section constitutes a challenging measurement, due to the presence of large backgrounds from the  $t\bar{t}$  production and from the W+jets channels. With an expected signal to background ratio of 18% the measurement will be hampered not only by a significant statistical uncertainty but also by the systematic effects affecting both signal and background. The measurement with an integrated luminosity of  $1 \text{ fb}^{-1}$  is thus both statistically and systematically limited, with about 60% of statistical and 90% of systematic uncertainties.

Given the present limitation on the background knowledge, early measurements will have to be devoted to the understanding of the background, in terms of shape and absolute normalization. For this purpose, specific studies performed on enriched background samples can be used. In this area, the knowledge of the effects of the ISR/FSR gluon radiation will need dedicated studies, in particular in  $t\bar{t}$  events. The constraint from data itself will thus be very important, and a tuning *à la* CDF [30] will be crucial for the understanding of these radiations. From the detector side, a reliable cross-section measurement requires a good knowledge of the b-tagging tools performance, since double-tag events are considered. A good determination of the jet energy scale is also mandatory for the selection, at the level of better than 5%. PDF and b-fragmentation effects are expected to have a significant impact only at higher luminosity.

In this context, the use of sophisticated statistical methods appears mandatory to discriminate the signal from the background and to establish convincing evidence for a signal. Their use however requires an a priori good understanding of the background normalization and shapes. With an improved situation for the b-tagging and jet energy scale, with a background normalization determined from the data and a better ISR/FSR knowledge, evidence at  $3 \sigma$  should be achievable with  $30 \text{ fb}^{-1}$ .

## 6 Measurement of the Wt-channel cross section

The Wt-channel is characterized by the associated production of a top quark and a W-boson. At the LHC, this single top quark process is the second highest cross-section after t-channel production, with an expected cross section of 66 pb. The final state features two W-bosons and a b jet, making this channel experimentally very close to top quark pair production, from which it differs by the absence of a second b jet in the final state. With a cross section 15 times larger than the Wt-channel processes, top quark pair events will thus constitute the dominant source of backgrounds and drive the definition of the selection

criteria in higher jet multiplicity events. On the other hand, low jet multiplicity events will suffer from W+jets contamination. In this report, we consider only the case where one of the two bosons decays into leptons while the other decays into jets. Two approaches have been used to estimate the sensitivity to the Wt-channel cross section measurement: a sequential cut-based analysis, which will provide reference numbers, and an analysis based on the use of Boosted Decision Trees.

### 6.1 Sequential cuts analysis

The common preselection defined for all three single top quark processes has been extended further to account for the specific topology of Wt-channel events. Selected events must have exactly one high  $p_T$  b-tagged jet above 50 GeV. A veto on any other b tagged jet above 35 GeV is applied in order to reject  $t\bar{t}$  events. This b-tag veto utilizes a looser b-tag weight cut which has been optimized according to the signal over  $t\bar{t}$  background ratio: a ratio of 18% is reached in 2- and 3- jet final states events while 14% is found in 4-jet events. The corresponding efficiency is about 30% on signal events and 10% on  $t\bar{t}$  events. For events containing more than three high  $p_T$  jets, the selection requires that the invariant mass of the two highest  $p_T$  non b-tagged jets to be between 50 and 125 GeV. The number of selected events is reported in Table 10 for signal and backgrounds.

Table 10: Number of expected events for an integrated luminosity of  $1 \text{ fb}^{-1}$  as function of the jet multiplicity and for the electron and muon channel combined in the sequential cut-based analysis. Errors shown are statistical only. The convention  $l = e, \mu$  is used.

Events in $1 \text{ fb}^{-1}$	2 jets (1b1j)	3 jets (1b2j)	4 jets (1b3j)
Wt-channel	$435 \pm 16$	$164 \pm 10$	$40 \pm 5$
t-channel	$1218 \pm 47$	$94 \pm 13$	$58 \pm 11$
s-channel	$42 \pm 2$	$5 \pm 0.6$	$0.6 \pm 0.2$
$t\bar{t} \rightarrow l + \text{jets}$	$1260 \pm 38$	$664 \pm 27$	$240 \pm 16$
$t\bar{t} \rightarrow \text{dilepton}$	$291 \pm 18$	$50 \pm 7$	$17 \pm 4$
$t\bar{t} \rightarrow l + \tau$	$428 \pm 22$	$55 \pm 8$	$17 \pm 5$
W+jets	$2983 \pm 71$	$207 \pm 19$	$38 \pm 6$
Wbb+jets	$137 \pm 33$	$13 \pm 3$	$6 \pm 2$
TOTAL bkg	$6359 \pm 232$	$1088 \pm 74$	$377 \pm 42$
$S/B$	6.8%	15.0%	10.6%
$S/\sqrt{B}$	5.4	5.0	2.1
$\sqrt{S+B}/S$	0.19	0.21	0.51

In two jet events (labeled as ‘1b1j’), the signal yield is about 430 signal events for an integrated luminosity of  $1 \text{ fb}^{-1}$ , with a signal to background ratio of 6.8%, combining both electron and muon channels. The W+jets production is the dominant background with more than 45% of the total background yield. The  $t\bar{t}$  contamination in the 1+jets channel constitutes about 20% of the background, while the other  $t\bar{t}$  modes combined contribute 11%. In this low jet multiplicity bin, the single top quark t-channel contamination is significant and represents 19% of the total.

In the three jet final state events (labeled as ‘1b2j’), 160 signal events are expected in  $1 \text{ fb}^{-1}$ , with a signal to background ratio close to 15%. In this final state, the use of the hadronic W boson mass

constraint helps improve the rejection of W+jets and the other single top quark events. The background is made up of  $t\bar{t}$  events which represent 70% of the total background yield, and of about 20% of W+jets events. Among the  $t\bar{t}$  events, the l+jets mode is dominant and constitutes about 85% of the total.

The four jet final state events (labeled as ‘1b3j’) only bring a marginal improvement to the analysis. The number of expected Wt-channel single top quark events is small and expected to be 40 for  $1 \text{ fb}^{-1}$  with a signal to background ratio of 10.6%. In this high jet multiplicity bin, the main background comes from the  $t\bar{t}$  events in the l+jets mode, which constitute 64% of the background. The rest originate mostly from the single top quark t-channel and from W+jets events, each being of the same order as the signal.

## 6.2 Boosted decision tree analysis

As in the s-channel analysis, several multivariate discriminators have been defined to optimize the discrimination against backgrounds. Two Boosted Decision Tree (BDT) functions are defined to separate signal and  $t\bar{t}$  events, one devoted to the discrimination from the dominant l+jets channel  $\mathcal{D}_{t\bar{t}/l+jets}$ , and the other against the dilepton channels  $\mathcal{D}_{t\bar{t}/dilepton}$  including  $\tau$ 's. A function  $\mathcal{D}_{W+jets}$  has been formed to separate signal from the W+jets sample, defined as the total contribution from light and heavy flavor jets. Another BDT discriminator is devoted to the separation of the signal and the single top quark t-channel events  $\mathcal{D}_{t-channel}$ . The analysis being based upon events with jet multiplicity between two and four, specific BDTs have been defined in each jet multiplicity bin for each background. The electron and muon channels are being treated in a combined way, thus leading to the definition of 3 (jet multiplicity) x 4 (background) ie: 12 BDT discriminators in total.

### 6.2.1 Definition of the discriminant variables

The set of discriminant variables is derived from the same procedure of optimization as the one explained for the s-channel analysis. The final set of discriminant variables is built from 25 relevant kinematical variables:

- the opening angles between the lepton and the jets  $\Delta R(l, b)$ ,  $\Delta R(l, j_1)$ ,  $\Delta R(l, j_2)$  where  $j_1$ ,  $j_2$  and  $j_3$  are the non b-tagged  $p_T$  ordered jets
- the opening angle between the jets  $\Delta R(b, j_1)$ ,  $\Delta R(b, j_2)$ ,  $\Delta R(j_1, j_2)$ ;
- the angles  $\cos \Delta \Phi(j_1, j_2)$  and the pseudo-rapidity of the non b-tagged jets  $\eta_{j2}$  and  $\eta_{j3}$ ;
- the invariant mass formed by the sum of all jets  $M_{inv}(jets)$  and by the reconstructed W-boson and top quark candidates  $M(W + t)$ ;
- the mass of the hadronic W-boson candidate  $M(W_{had})$ ;
- the sum of the missing transverse energy and lepton transverse momentum  $\cancel{E}_T + p_T(l)$ ;
- the transverse mass of the leptonic W-boson candidate  $M_T(W_{lep})$
- the transverse mass of the systems formed by the b jet and the reconstructed W-bosons  $M(b, W_{had})$  and  $M(b, W_{lep})$ ;
- the scalar sum of the jet transverse momenta  $H_T(jets)$  and of all objects in the events  $H_T(tot)$ ;
- the transverse jet momenta  $p_T(b)$ ,  $p_T(j_1)$ ,  $p_T(j_2)$ ;
- the longitudinal momentum of the neutrino solution computed with the top quark mass;

- the global event shape variables, sphericity, aplanarity and centrality.

The BDT output distributions associated to each of the four backgrounds are represented in Figure 5 for the 3 jet final state analysis for the electron+muon channels for  $1 \text{ fb}^{-1}$ .

Figure 5: Distributions for the four BDT defined in the 3 jet ('1b2j') final state analysis. a) BDT against  $t\bar{t}$  in the 'l+jets' channel; b) BDT against W+jets events; c) BDT against  $t\bar{t}$  in the dilepton lepton (+tau) channel; d) BDT against single top quark t-channel events.

### 6.2.2 Results with the Boosted Decision Trees

Several selections can be designed, allowing for different levels of signal purity. In this analysis as in the s-channel, the cuts on the discriminant BDTs have been set so that the total uncertainty affecting the cross section measurement is minimized.

The thresholds set on the three BDT outputs are:

$$\begin{aligned}\mathcal{D}_{t\bar{t}j} &> 0.6 \\ \mathcal{D}_{t\bar{t}\tau} &> -0.36 \\ \mathcal{D}_{W\text{jet}} &> 0.30 \\ \mathcal{D}_{t\text{-chan}} &> 0.18\end{aligned}$$

The number of events for signal and the different backgrounds is reported in Table 11 for an integrated luminosity of  $1 \text{ fb}^{-1}$ . In two jet events ('1b1j'), the signal yield is about 60 with a signal to background ratio of 35%, combining electron and muon analyses. This result represents an improvement by a factor 6 compared to the cut-based analysis. This feature is important since one of the main sources of systematic uncertainty originate from the imperfect knowledge of the background levels. Regarding the composition of the background, the W+jets production constitutes the dominant background and contributes 58% of the background yield.  $t\bar{t}$  production in the l+jets mode represents about 40% of the total. The only remaining single top quark events originate from the t-channel which accounts for 6% of the total background yield. The statistical significance for this final state analysis alone is  $4.5\sigma$ .

Table 11: Number of expected events for an integrated luminosity of  $1 \text{ fb}^{-1}$  as function of the jet multiplicity after the BDT analysis. The convention  $l = e, \mu$  is used.

Events in $1\text{fb}^{-1}$	2 jet (1b1j)	3 jet (1b2j)	4 jet (1b3j)
Wt-channel	$58.0 \pm 5.8$	$20.9 \pm 3.5$	$6.6 \pm 2.0$
t-channel	$10.2 \pm 4.2$	negl.	$1.7 \pm 1.7$
s-channel	$1.4 \pm 0.3$	negl.	negl.
$t\bar{t} \rightarrow \text{all jet}$	negl.	negl.	negl.
$t\bar{t} \rightarrow l + \text{jet}$	$56.3 \pm 8.2$	$41.8 \pm 6.3$	$13.7 \pm 3.4$
$t\bar{t} \rightarrow \text{dilepton}$	$1.7 \pm 1.2$	negl.	negl.
$t\bar{t} \rightarrow l + \tau$	negl.	negl.	negl.
W+jets	$92.1 \pm 8$	$3.2 \pm 1.4$	$0.2 \pm 0.1$
Wbb+jets	$3.9 \pm 3.9$	negl.	negl.
Total bkg	$165.6 \pm 9.2$	$45.1 \pm 6.3$	$15.6 \pm 3.4$
$S/B$	35.0%	46%	36.2%
$S/\sqrt{B}$	4.5	3.1	1.7
$\sqrt{S+B}/S$	0.25	0.39	0.71

In three jet final state events ('1b2j'), about 20 signal events are expected with  $1 \text{ fb}^{-1}$ , with a signal to background ratio of 46%. Again, one notices a gain of more than a factor 3 compared to the cut-based analysis. The background events are made up almost exclusively (95%) of  $t\bar{t}$  events in the lepton+jets events. The use of the jet-jet invariant mass reduces the W+jets background to a few percent. The selection in this final state alone provides a signal statistical significance of  $3.1 \sigma$ .

In the four jet final state channel ('1b3j'), the number of expected Wt-channel single top quark events is 7 with  $1 \text{ fb}^{-1}$ . In this bin, the signal to background ratio is about 36%, which corresponds to a gain of a

factor 4 compared to the sequential cut analysis. In this jet multiplicity bin, the only competing processes is the  $t\bar{t}$  events in the 1+jets. The signal significance remains small, around  $1.7\sigma$  with a corresponding statistical precision of 72%.

The effect of pile-up has been investigated with signal and  $t\bar{t}$  samples produced with a pile-up corresponding to a  $10^{32} \text{ cm}^2 \text{ s}^{-1}$  luminosity run. The results show decreases of 18%, 47% and 26% of the signal event yield in the 2, 3 and 4 jet final states. For backgrounds, similar variations of 16%, 39% and 20% in the 2, 3 and 4 jet final states are seen. As expected the increase of the number of light jets seen in the events directly impacts the tight selection of 2- and 3- jet final states. No systematic uncertainty is associated to this effect, as for the two previous analyses, as only dedicated studies using data itself will be used to tune all Monte Carlo signal and background generators.

### 6.3 Systematic uncertainties

The systematic uncertainties have been evaluated on the BDT analysis. We follow the procedures defined in Section 4.2.

#### 6.3.1 Experimental systematic uncertainties

The b-tagging uncertainties affect the Wt-channel selection because of the requirement of one b-tagged jet on one side, and the use of a veto for any second b tagged jet on the other side. The variation by 5% of the b tagging efficiency and the corresponding mistag rate results in a 7% change of the signal selection efficiency in the 2 jet final state. The sensitivity is higher in the higher multiplicity bins, with effects of 10% seen in the 3 jet bin. Regarding backgrounds, the impact of this uncertainty increases with the jet multiplicity, with  $t\bar{t}$  events being the dominant background. Variations of 3% and 5% are seen respectively in 3 jet and 4 jet final states. Table 12 reports the relative changes in signal and background events. Table 13 reports the impact on the total cross section determination, all final states combined.

Table 12: Effect of the b-tag efficiency and mistag rate variation and of the jet energy scale variation on the number of expected events for an integrated luminosity of  $1 \text{ fb}^{-1}$  expected from the BDT analysis.

Process	Events in $1\text{fb}^{-1}$	b-tag $\pm 5\%$	JES $\pm 5\%$
2-jet events			
- signal	58.0	$\pm 7.0\%$	$\pm 0.5\%$
- total bkg	165.6	$\pm 3.0\%$	$\pm 3.1\%$
3 jet events			
- signal	20.9	$\pm 10.1\%$	$\pm 7.0\%$
- total bkg	45.1	$\pm 3.2\%$	$\pm 3.0\%$
4 jet events			
- signal	6.6	$\pm 3.1\%$	$\pm 7.9\%$
- total bkg	15.6	$\pm 5.1\%$	$\pm 4.0\%$

The precise knowledge of the jet energy scale is important for the Wt-channel analysis because of the requirements made on the mass reconstruction and  $p_T$  thresholds used to select jets. A 5% variation

of the jet energy scale has been propagated to the jet reconstruction and the selection efficiencies are re-assessed. Table 12 shows the impact of the jet energy scale variation on signal and background event yields. In two jet events, the effects of the scale variation is about 1% on the signal events and 3% on the sum of all backgrounds. In three jet events a variation of 7% of the signal event yield is observed, with a change of 3% in the backgrounds. In four jet events, variations of 8% and 4% are seen in signal and background respectively. Table 13 reports the impact on the total cross section determination.

An uncertainty of 1% in the lepton identification or in the trigger efficiency would impact the number of selected events. Such an uncertainty would reflect in an uncertainty of 2.6% on the total cross section measurement, which is negligible with respect to the others.

### 6.3.2 Theoretical and Monte Carlo uncertainties

Uncertainties on the background estimates come from the theoretical uncertainties associated to the cross sections. An uncertainty of 10% is quoted for the  $t\bar{t}$  events while 20% is associated to the  $W$ +jets and  $Wb\bar{b}$ +jets events. This translates into a total of 12.5% in the 2 jet final state and 10% in the higher jet multiplicity bins where  $t\bar{t}$  events completely dominate the background. Note that despite very distinct topologies, the selections of the  $Wt$ - and the  $t$ - channels analyses are not orthogonal. However it is believed that correlations can be properly addressed.

Table 13: Summary of all uncertainties that affect the measured cross section. Data statistics is the Poisson error one would expect from real data while MC Statistics is the uncertainty on the estimated quantities due to MC statistics. (\*) background to 2j (12.5%) and 3j and 4j final states (10%)

Source of uncertainty	Analysis for 1 fb <sup>-1</sup>		Analysis for 10 fb <sup>-1</sup>	
	Variation	$\Delta\sigma/\sigma$	Variation	$\Delta\sigma/\sigma$
Data Statistics		20.6%		6.6%
MC Statistics		15.6%		
Luminosity	5%	20%	3%	7.9%
b-tagging	5%	16%	3%	6.6%
JES	5%	11%	1%	1.5%
Lepton ID	1%	2.6%	1%	2.6%
Bkg x-section	12.5/10%(*)	23.4%	3%	9.6%
ISR/FSR	9%	24.0%	3%	7.8%
PDF	2%	5.2%	2%	5.2%
b-fragmentation	3.6%	9.4%	3.6%	9.4%
Total Systematics		48%		19.4%

The selection of a low jet multiplicity final state is very sensitive to the presence of extra jets originating from gluon radiations. Any uncertainty in the ISR/FSR modelling is thus expected to have a significant impact on the selection efficiencies, in particular for the  $Wt$ -channel and top quark pair events. We quote an overall 9% uncertainty due to the modelling of gluon radiation in the  $t\bar{t}$  events.

The uncertainties in the PDF may affect the topologies as well as the momentum distributions of the final state objects, hence impacting the determination of the selection efficiency for both signal and backgrounds. The procedure to estimate the impact of the choice of the PDF to the selection efficiency is

detailed in Section 4.2.2. Complete studies have been performed in each final state and a 2% uncertainty is quoted for signal and  $t\bar{t}$  events.

Finally the effect of the b-fragmentation parametrization has also been investigated following a similar procedure of that defined in Section 5.3.2 from fast simulation. The relative uncertainties of the different channel and final state selection efficiencies due to the b-fragmentation uncertainty is found to be 3.6%.

Table 13 lists all sources of uncertainties and reports their impact on the cross section determination. Two cases are considered: one defined by the level of uncertainty in the b-tagging, jet energy scale and luminosity that will presumably characterize the early data taking period; another assuming reasonable improvements on those effects with an integrated luminosity of  $10 \text{ fb}^{-1}$ . The assumptions made in the latter case are listed in Section 4.2.3.

## 6.4 Summary

The determination of the  $Wt$ -channel cross section constitutes a challenging measurement with the early data, due to the presence of important  $t\bar{t}$  and  $W$ +jets backgrounds. This measurement makes use of the events with a jet multiplicity between two and four jets. With a signal to background ratio of about 30-40%, the analysis requires a good knowledge of the  $W$ +jets production in the lower multiplicity bins, and of the  $t\bar{t}$  process in higher bins. The estimates of the shapes and normalization of those processes will have to rely upon the use of data. Strategies exist for QCD and  $W$ +jets events, but the discrimination against  $t\bar{t}$  events remains a challenge.

As for the  $t$ -channel single top quark analysis, the cross section determination will very early be dominated by systematic uncertainties. The dominant effect is constituted by the background uncertainties, followed by the modeling of the gluon radiation. From the detector side, the dominant source of uncertainty is the b-tagging because of the imperfect knowledge of the b-tag and b-tag veto efficiencies as well as of the mistag rates. Another source is the determination of the jet energy scale, which affects the reconstruction of the  $W$ -boson mass and all the jet energies used in the analysis. Note that the determination of the luminosity to better than 5% is required in order to ensure a good measurement, or the use of ratio of different  $Wt$ -channel final states [31] can be used as well with higher luminosity. A  $3\sigma$  evidence can be reached with a few  $\text{fb}^{-1}$  of data taking and a precision of 20% on the cross section measurement is achievable with about  $10 \text{ fb}^{-1}$  provided that improvements are made in both the experimental aspects of the detection (backgrounds from data, b-tagging, jet energy scale and luminosity) and from the theoretical side.

## 7 Conclusion

At the LHC the production of single top quark events accounts for about a third of the  $t\bar{t}$  production, which leads to about 2.5 million events per year during a run at  $10^{32} \text{ cm}^2 \text{ s}^{-1}$ . Similarly to the situation at the Tevatron, the selection of single top quark events will suffer from the presence of both  $W$ +jets and  $t\bar{t}$  backgrounds, which are produced at much higher rates. Thus, careful approaches devoted to the understanding of these backgrounds in terms of shape and normalization performed directly from data will have to be defined. Besides, except for the  $s$ -channel, single top quark analyses will be very early dominated by the systematic uncertainties, and will require a good control of b-tagging tools and a reliable determination of the jet energy scale.

In a context of low signal over background ratio, the use of sophisticated tools like genetic algorithms, likelihoods and Boosted Decision Trees appears very useful if one wants to establish the signal or to determine its cross section precisely. These techniques, which are now in common use at the Tevatron, will require the use of reliable event samples for modeling signal and backgrounds, that will presumably

be produced from the data. The analyses should also be optimized with respect to the total level of systematic uncertainty, which will be the main limiting factor for  $30 \text{ fb}^{-1}$  measurements.

Finally, a precise determination of single top quark cross sections can be achieved for a few  $\text{fb}^{-1}$  in the t-channel and the  $Wt$ -channel, while for the s-channel, higher statistics will be required. Their possible interpretation in terms of new physics should thus come at a later stage, once the systematic effects are under control.

# Top Quark Mass Measurements

## Abstract

This note summarizes studies performed in order to estimate the potential of ATLAS to measure the top quark mass from the first few hundred  $\text{pb}^{-1}$  of data. The analyses shown here, based on fully simulated events, have been performed for the channel where the top quarks decay into one lepton plus a number of jets, using various methods to extract the top quark mass. The performance of the detector has been evaluated, including triggering, particle identification, and jet reconstruction. For each method, the expected background, statistical and systematic uncertainties, and linearity have been studied. This work shows that the precision on the top quark mass depends mainly on the jet energy scale uncertainty: a precision of the order of 1 to 3.5 GeV should be achievable with  $1 \text{ fb}^{-1}$ , assuming a jet energy scale uncertainty of 1 to 5%.

## 1 Introduction

At the LHC, top quarks will be produced mainly in pairs through the hard processes  $gg \rightarrow t\bar{t}$  (90%) and  $q\bar{q} \rightarrow t\bar{t}$  (10%). The corresponding cross section, at next-to-leading order, is 833 pb [1]; therefore, we expect roughly 800 000  $t\bar{t}$  pairs to be produced with an integrated luminosity of  $1 \text{ fb}^{-1}$ , corresponding to about two weeks at a luminosity equal to  $10^{33} \text{ cm}^{-2}\text{s}^{-1}$ . In contrast to earlier measurements of the top quark mass [2], which concentrated on preserving as much of the signal as possible in order to minimize the statistical uncertainty, the LHC will produce so many top quark pairs that rather stringent requirements can be imposed, to restrict the measurement to regions in which the systematic uncertainties can be well-controlled. With  $1 \text{ fb}^{-1}$  of data, the measurement will already be completely dominated by systematic uncertainties of the order of 1 GeV. The dominant contribution to the systematic uncertainty is expected to be the jet energy scale. In-situ calibration methods will allow the light jet energy scale to be known to the percent level precision after  $1 \text{ fb}^{-1}$  of collected data [3]. This high precision can be, at least in part, translated to the  $b$ -jet energy scale, although differences are expected. Detailed studies with the data will be necessary to reach the desired precision.

The top quark mass measurements described here are based on finding the peak in the invariant mass distribution of the top quark's decay products: a  $W$  boson and a  $b$ -quark jet. This closely corresponds to the pole mass of the top quark. Because of fragmentation effects, it is believed that the top quark mass determination in a hadronic environment is inherently ambiguous by an amount proportional to  $\Lambda_{\text{QCD}}$  [4]: the intrinsic ambiguity is of the order of 100 MeV.

This note describes several ways to measure the top quark mass in the semi-leptonic channel, which corresponds to a  $t\bar{t}$  final state where one  $W$  boson decays leptonically while the other one decays into two jets. The primary results rely on a full reconstruction of the final state, with the mass estimator taken as the invariant mass of the three jets from the hadronically-decaying top quark. This has been studied for two cases. In the first case, both  $b$ -jets are identified via displaced vertices, and two different mass measurement methods are presented. In the second case, fewer  $b$ -jets are identified. This latter case is expected to be important during early running, before the detector is fully calibrated. An analysis which relies on a kinematic fit is also presented. Other  $t\bar{t}$  decay channels can also be used, but have not been considered in this note.

Another possibility relies on the determination of the mean distance of travel of  $b$ -flavoured hadrons from top quark decays [5]. The top quark mass can be inferred from the averaged lifetime

in the laboratory frame of the b-flavoured hadron, since the bottom quark’s boost directly impacts the lifetime of the b-flavoured hadron. Rather than measuring the lifetime, the transverse decay length of the b-flavoured hadron is used in this method. The mean of the transverse decay length distribution is determined for different assumed top quark masses, providing an estimator for the experimental data in the mean decay length as a function of the top quark mass. Since this analysis relies mainly on tracking, the systematic uncertainties are mostly uncorrelated with those of other methods; in particular, the influence of the jet energy scale as a source of uncertainty is negligible. Work is ongoing on this method, which is not shown here.

A last possibility is to estimate the top quark mass from the measured  $t\bar{t}$  production cross section. The errors on these quantities are related, in the Standard Model, via  $\Delta\sigma_{t\bar{t}}/\sigma_{t\bar{t}} \sim 5\Delta m_{\text{top}}/m_{\text{top}}$  [6]. This would allow a determination of  $m_{\text{top}}$  independent of the kinematic reconstruction. In addition, it would be clear that the top quark mass is the one used in the perturbative calculations (i.e. the pole mass). However, even without considering experimental uncertainties, the achievable precision would already be limited to 2 GeV due to the uncertainty of the theoretical calculations. The scale dependence, which is the dominant source of uncertainty, might be reduced to the order of 6 % by performing the computation at higher orders, including the resummation of next-to-leading logarithmic corrections (NLL). This scale dependence can also be reduced by using a different mass definition such as the running mass<sup>1</sup>. This method is not considered further in this note.

## 2 Motivations for a precise top quark mass measurement

Electroweak precision observables in the Standard Model and the Minimal Supersymmetric Standard Model (MSSM) depend on the value of the top quark mass. Therefore, a precise measurement of the top quark mass is important for consistency tests of the Standard Model, to constrain the Higgs boson mass within the Standard Model, and to increase the sensitivity to physics beyond the Standard Model.

The most important dependency of the electroweak observables on the top quark mass arises via the one-loop radiative correction term  $\Delta r$  [9], which is related to the  $W$  boson mass through the relation  $m_W^2 = \frac{\pi\alpha}{\sqrt{2}G_F \sin^2\Theta_W}(1 + \Delta r)$  ( $\Theta_W$  being the weak mixing angle,  $\alpha$  the fine structure constant and  $G_F$  the Fermi coupling constant). The top quark mass is present in  $\Delta r$  as terms proportional to  $m_{\text{top}}^2/m_Z^2$ , while the Higgs boson mass is present only in terms proportional to  $\log(m_H/m_Z)$ . Therefore, the dependence on the Higgs boson mass is much weaker than the dependence on the top quark mass.

The precision of the indirect prediction of the Higgs boson mass depends mainly on the uncertainty on the following quantities: the hadronic contribution to the electromagnetic coupling at the scale  $m_Z$   $\Delta\alpha_{\text{had}}$ ,  $\sin^2\Theta_W$ ,  $W$  boson mass and top quark mass. For the current value of the top quark mass ( $m_{\text{top}} = 172.6 \pm 1.4$  GeV) [10],  $m_H = 87_{-27}^{+36}$  GeV, implying  $m_H < 160$  GeV at 95% C.L [11]. In order to ensure a similar contribution to the indirect prediction of the Higgs mass, the precision on  $m_W$  and  $m_{\text{top}}$  must satisfy  $\Delta m_W \simeq 0.07\Delta m_{\text{top}}$ . At the LHC, we expect to reach an accuracy of 15 MeV on  $m_W$  [12] and 1 GeV on  $m_{\text{top}}$ . With these precision measurements, the relative precision on a Higgs boson mass of 115 GeV would be of the order of 18% [13].

---

<sup>1</sup>The dependency of the perturbative calculations convergence on the quark mass definition has been observed in other observables in which the running mass has led to better results [7, 8]. This would allow as well a determination of the top running mass.

### 3 Top quark mass measurement in the semi-leptonic channel with the standard ATLAS $b$ -tagging

In this section we investigate the determination of the top quark mass using the standard ATLAS  $b$ -tagging.

#### 3.1 Physics background

The major sources of background, listed in Table 1, are single top events ( $Wt$  and  $t$  channels) and  $W$  boson production ( $W$  boson with  $W \rightarrow l\nu$  decay,  $W+b\bar{b}$  and  $W+c\bar{c}$ ). It has been shown that backgrounds from  $Z$ +jet events with  $Z \rightarrow ll$ ,  $WW$ ,  $WZ$ , and  $ZZ$  gauge boson pair production have much smaller contributions [14]: therefore, their contribution has not been re-evaluated here. Backgrounds from QCD multi-jets and  $b\bar{b}$  production have not been investigated with full simulation. Nevertheless, studies performed on fast simulation have shown that these backgrounds are negligible after leptonic cuts (lepton  $p_T$ ,  $\cancel{E}_T$ ) [14].

Another source of background comes from  $t\bar{t}$  events themselves (fully leptonic or fully hadronic channels). Moreover,  $t\bar{t}$  events in which the  $W$  boson decays into  $\tau\nu_\tau$  are classified in the following way:  $\tau$  decaying leptonically belong to signal events, whereas  $\tau$  decaying hadronically belong to background (fully hadronic  $t\bar{t}$ ).

Before any selection requirements, the signal to background ratio is of the order of  $\frac{800pb}{80mb}$ , i.e.  $10^{-8}$ .

Table 1: Main backgrounds to the semi-leptonic ( $\ell = e, \mu$ ) signal listing the number of events in  $1 \text{ fb}^{-1}$  before and after the selection cuts (samples used here have comparable weights).

Process	Number of events	1 isolated lepton $p_T > 20 \text{ GeV}$ and $\cancel{E}_T > 20 \text{ GeV}$	$\geq 4$ jets $p_T > 40 \text{ GeV}$	2 b-jets $p_T > 40 \text{ GeV}$
Signal	313200	132380	43370	15780
$W$ boson backgrounds	$9.5 \times 10^5$	154100	9450	200
all-jets (top pairs)	466480	1020	560	160
di-lepton (top pairs)	52500	16470	2050	720

single top, $W t$ channel	9590	8430	770	170
single top, $s$ channel	720	640	11	5

#### 3.2 Combinatorial background

When a  $t\bar{t}$  semi-leptonic decay is reconstructed, one must choose which jets in the event to associate with the hadronic  $W$  boson decay and also which jets correspond to each of the two  $b$ -jets. When at least one of these choices is wrong, the event is classified as combinatorial background.

### 3.3 Jets

All particles (electrons, muons, jets) forming the  $t\bar{t}$  final state are required to lie within  $|\eta| < 2.5$ , since  $b$ -jets cannot be tagged and muons are not reconstructed for higher values of  $|\eta|$ . See Ref. [15] for a description of the features of jet selection that are common to all top quark analyses; only the points specific to the analyses in this note are discussed below.

#### 3.3.1 Jet calibration

This analysis uses jets defined as in [15]. The jet calibration effects are removed by performing a jet calibration to the parton level using the Monte Carlo information. This allows jet calibration to be disentangled from other effects on the top quark mass measurement from the other effects (selection, reconstruction, measurement methods). This is done by matching jets to partons before radiation (requiring  $\Delta R(\text{quark}, \text{jet})$  lower than 0.2) and deriving the difference between reconstructed jet energy and the parton energy as a function of the parton energy. This is performed separately for  $b$ -quark jets with and without muons and for light jets. This procedure leads to a perfect and unbiased jet energy scale.

Uncertainties on the top quark mass measurement arising from the jet energy scale uncertainties will be assessed here by applying miscalibration factors to the calibrated jets.

Jet scales on data will be obtained in a different way. The light jet energy scale determination is explained in detail in a separate note [3]; the  $b$ -jet energy scale will be measured using  $Z$ +jets samples. The  $Z$  + jets yield will be low at the start of LHC running; therefore, the  $b$ -jet scale will probably be derived from the measured light jet scale, together with a Monte Carlo correction term modelling the difference between the two jet energy scales.

#### 3.3.2 Jet labelling

A jet is called purely electromagnetic if the distance  $\Delta R$  to the nearest electromagnetic cluster is lower than 0.2 and the ratio between the cluster and jet energies is greater than 0.8. Only 0.15% of jets produced by hadronisation pass these cuts. Such objects are ignored for the remainder of the analysis.

A jet is tagged as a  $b$ -jet if its  $b$ -weight is larger than 6 (the weight is defined by the three-dimensional space  $b$ -tagging, described in the introduction of this chapter [15]). The  $b$ -tagging efficiency for this weight in  $t\bar{t}$  events is equal to 62% and the light (i.e.  $u$ ,  $d$  and  $s$  flavoured) jet rejection to 130 for isolated ( $\Delta R(\text{jet}, \text{jet}) > 0.8$ ) jets with  $p_T$  greater than 15 GeV (Fig. 1).

All remaining jets (i.e. non  $b$ -tagged jets nor purely electromagnetic jets) are called light jets. Therefore, a  $b$ -jet which is not tagged by the  $b$ -tag algorithm is considered as a light jet.

#### 3.3.3 Jet multiplicity

- The light jet multiplicity, for signal events, is illustrated in Fig. 2.(a), for all light jets, and for light jets above the  $p_T$  cut applied (40 GeV). The multiplicity is often higher than two (47% of events, for jets above the  $p_T$  cut), due to the presence of initial and final state radiation. This has of course an impact on the combinatorial background size and shape.
- The  $b$ -jet multiplicity, illustrated in Fig. 2.(b), reflects the  $b$ -tagging efficiency.

Figure 1:  $b$ -tagging efficiency as a function of light (i.e. u, d and s flavoured) jet rejection in  $t\bar{t}$  events, for isolated ( $\Delta R(\text{jet}, \text{jet}) > 0.8$ ) jets with  $p_T$  greater than 15 GeV.

### 3.4 Event selection

#### 3.4.1 Trigger

The following Event Filter trigger [16] selections have been applied:

- At least one isolated electron with  $p_T$  greater than 25 GeV (“e22i”). This trigger is satisfied by 53% of  $t\bar{t} e + \text{jets}$  events, and 71% of  $e + \text{jets}$  with  $p_T(e)$  greater than 25 GeV pass.
- At least one isolated muon with  $p_T$  greater than 20 GeV (“mu20”). This trigger is satisfied by 59 % of  $t\bar{t} \mu + \text{jets}$  events, and 74% of  $\mu + \text{jets}$  with  $p_T(\mu)$  greater than 20 GeV pass.

#### 3.4.2 Standard cuts

A sequence of consecutive cuts is applied in order to reduce the contribution from physics background.

- Exactly one isolated lepton, with  $p_T > 20$  (25) GeV for muons (electrons) and  $|\eta| < 2.5$ . This cut corresponds to the trigger selection. Moreover, the isolation criteria reject a large fraction of the leptonic  $b$ -decays in the all-jets channel: 99.6% of the  $t\bar{t}$  events with both  $W$  bosons decaying hadronically are rejected by this first selection step.
- Missing transverse energy cut:  $\cancel{E}_T > 20$  GeV. Together with the lepton requirement, this cut reduces QCD background.
- At least four jets with  $p_T > 40$  GeV. Below 40 GeV, jets are known to be less precisely calibrated; the jet energy scale will be discussed later on, as a source of systematic uncertainty. Therefore, they are removed in order to improve the precision of the top quark mass measurement [3]. Only 34% of hadronically-decaying  $W$  bosons have both jets passing this requirement. If it is relaxed so that one jet can have  $p_T$  down to 20 GeV, 88% of these  $W$  bosons pass, but

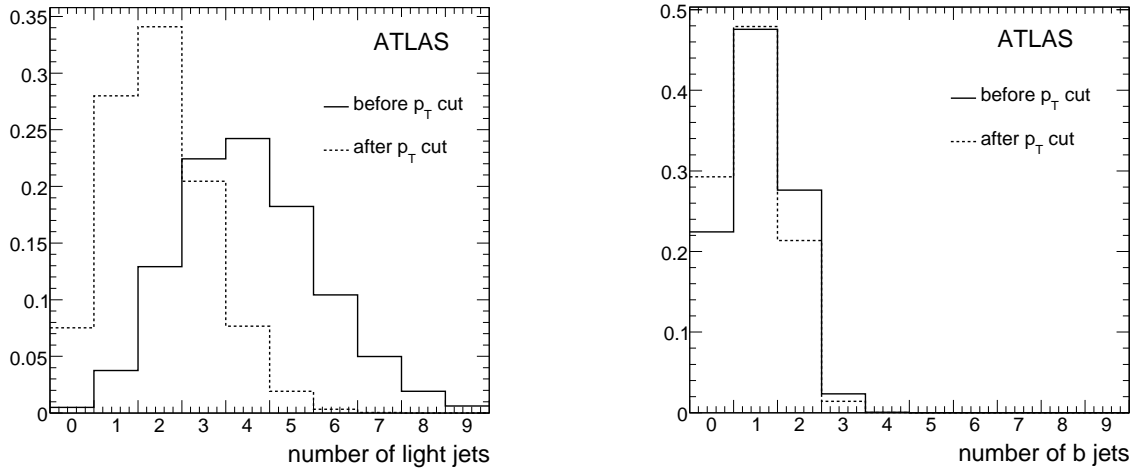

Figure 2: a) Light jet and b)  $b$ -jet multiplicity in semi-leptonic  $t\bar{t}$  events before (solid line) and after (dashed line) requiring that the jet  $p_T$  be greater than 40 GeV (plots are normalised to unity).

the combinatorial and physical backgrounds increase. Moreover, due to initial and final state radiation (ISR, FSR), 30% of the signal events have more than two light jets with  $p_T > 40$  GeV. Therefore, no requirement is made on the number of light jets.

- Among these jets, exactly two must be  $b$ -tagged.

### 3.4.3 Purity definition

When a  $t\bar{t}$  semi-leptonic decay is reconstructed, one must choose which jets in the event to associate with the hadronic  $W$  boson decay and also which jets correspond to each of the two  $b$ -jets. The success of an algorithm for making such a choice is quantified as its *purity*, the fraction of events in which this choice is correct, based on looking at the Monte Carlo parentage information. For this purpose, jets are matched to the closest Monte Carlo parton with  $\Delta R < 0.25$ . Purities are defined for identifying the hadronically-decaying  $W$  boson (both light jets chosen are within 0.25 from the quark stemming from the  $W$  boson), the hadronic  $b$ -quark, and the hadronically-decaying top quark. Note that the top quark purity is not the product of the other two due to correlations.

## 3.5 Hadronic $W$ boson mass reconstruction

Several algorithms have been tried to choose the two light jets from the hadronically-decaying  $W$  boson. Three have been identified that give the best compromise between efficiency and purity:

- the  $\chi^2$  minimization method,
- the geometric method: this method consists in choosing the two closest jets,
- choosing the two light jets that give the mass closest to the known mass of the  $W$  boson [14].

The first and last methods are quite similar, but the first one contains in addition an event-by-event rescaling. Therefore, the last method will not be described here.

Figure 3: Invariant mass of light jet pairs for events with only two light jets (the contribution of physics background is shown in black, the one from combinatorial background, in grey).

Figure 4: Hadronic  $W$  boson mass after  $\chi^2$  minimization (the contribution of physics background is shown in black, the one from combinatorial background, in grey).

### 3.5.1 Hadronic $W$ boson mass reconstruction with $\chi^2$ minimization method

Events kept after the selection described above have at least two light jets above the  $p_T$  threshold (50% of the events have more than two). Figure 3 shows the distribution of the invariant mass of the light jet pairs, in events with only two light jets. As a first step, we select the hadronic  $W$  boson candidates in a mass window of ( $\pm 30$  GeV) around the peak value of this distribution (82 GeV).

The energy scale of the jets may be shifted, due to effects that include the energy lost out of the jet cone and initial and final state radiation effects, not taken into account in the default jet energy calibration [17]. Moreover, the effects of the jet  $p_T$  cut applied during event selection (explained in [3], section 3.3) contribute to the jet energy scale shift. To reduce the effect of such shifts on the final measured top quark mass, the jets are rescaled by constraining the pair to the known  $W$  boson mass using a  $\chi^2$  minimization. The quantity to be minimized is shown in Eq. (1). The first term constrains the jet pair mass  $M_{jj}$  to the  $W$  boson mass and width from the Particle Data Group [18] ( $M_W^{\text{PDG}}, \Gamma_W^{\text{PDG}}$ ). The other two terms are the usual  $\chi^2$  terms for scaling the jets with multiplicative constants  $\alpha_{E_{j1,j2}}$ ;  $\sigma_{1,2}$  are the light jet energy resolutions<sup>2</sup>.

$$\chi^2 = \frac{(M_{jj}(\alpha_{E_{j1}}, \alpha_{E_{j2}}) - M_W^{\text{PDG}})^2}{(\Gamma_W^{\text{PDG}})^2} + \frac{(E_{j1}(1 - \alpha_{E_{j1}}))^2}{\sigma_1^2} + \frac{(E_{j2}(1 - \alpha_{E_{j2}}))^2}{\sigma_2^2}. \quad (1)$$

This  $\chi^2$  is minimized, event by event, for each light jet pair. The pair with the smallest  $\chi^2$  is kept as the hadronic  $W$  boson candidate. This minimization procedure also gives the corresponding energy correction factors  $\alpha_{E_{j1}}$  and  $\alpha_{E_{j2}}$ , shown in Fig. 5. Given the jet energy resolution, the first term in Eq. (1) dominates the  $\chi^2$ . Therefore, the hadronic  $W$  boson mass reconstructed with the light jets chosen

<sup>2</sup>The light jet energy resolution has been estimated from the gaussian fit of the difference between a light jet energy and the corresponding quark energy. The expression thus obtained is the following:  $\sigma_E = E * \sqrt{(a^2/E) + b^2}$ , where  $a = 0.989 \text{ GeV}^{1/2}$  and  $b = 0.075$ .

by this  $\chi^2$  minimization is very narrow, as shown in Fig. 4. Further on, only the hadronic  $W$  boson candidates within a mass window of  $\pm 2 \Gamma_{M_W}$  ( $\Gamma_{M_W}^{\text{PDG}} = 2.1 \text{ GeV}$ ) are kept; this cut is called **C0**.

Figure 5: Energy correction factors estimated by the  $\chi^2$  minimization.

### 3.5.2 Hadronic $W$ boson mass reconstruction with geometric method

In this method, the light jet pair with the smallest  $\Delta R$  distance between the two jets is taken as the hadronic  $W$  boson candidate. This method is simple and does not depend on the accuracy of the jet energy scale. The resulting  $W$  boson mass distribution is shown in Fig. 6. Only hadronic  $W$  boson candidates within a mass window of  $\pm 2 \sigma_{M_W}$  ( $\sigma_{M_W} = 10.4 \text{ GeV}$ ) around the peak value of the invariant mass distribution of all light jet pairs are kept; this cut is called **C1**.

## 3.6 Leptonic $W$ boson mass reconstruction

The main difficulty in reconstructing the leptonic  $W$  boson comes from the kinematics of the neutrino. The missing transverse momentum  $\cancel{E}_T$  is used as an estimate of the neutrino transverse momentum. This is, however, only an approximation, illustrated in Fig. 7, as there may be other, softer, neutrinos in the event, such as from leptonic  $b$ -decay. With this hypothesis,  $p_T^\nu$  is underestimated by more than 2% (miscalibration of  $\cancel{E}_T$  and fake missing  $\cancel{E}_T$  also contributes to this shift).

Using the known  $W$  boson mass, four-momentum conservation for the  $W \rightarrow \ell + \nu$  decay gives a quadratic equation for the longitudinal component of the neutrino momentum  $p_z^\nu$  ( $\ell$  stands for lepton and  $\nu$  stands for neutrino):

Figure 6: Hadronic  $W$  boson mass with the geometric method (the contribution of physics background is shown in black, the one from combinatorial background, in grey).

Figure 7: Ratio of  $E_T$  to the generated neutrino transverse momentum, after C0 cut. The neutrino considered here is the one from the leptonic  $W$  boson decay.

$$M_W^2 = m_1^2 - 2(p_x^1 p_x^v + p_y^1 p_y^v) + 2E_1 \sqrt{\cancel{E}_T^2 + (p_z^v)^2} - 2(p_z^1 p_z^v).$$

This equation has no solution if the measured  $\cancel{E}_T$  fluctuates such that the neutrino-lepton invariant mass is above the  $W$  boson mass; this happens in 30% of the remaining events after the C0 cut. In this case,  $p_T^v$  is reduced until a solution is found, with the restriction that the transverse  $W$  boson mass remain below 90 GeV (see Fig. 8). Only 11% of the events still have no solution after this procedure. Otherwise, the equation has two solutions. The choice among the two  $p_z^v$  is performed together with the association of the  $b$ -jet to the corresponding  $W$  boson: the combination giving the smaller difference between the hadronic and leptonic top quark masses is kept.

Figure 8: Transverse  $W$  boson mass (distributions are normalized to unity). On the left, the Jacobian peak is clearly seen at the generator level (solid line); events for which no  $p_z^v$  solution is found (dashed line) can be distinguished from events for which a solution is found (dotted line). On the right, the effect of the  $p_T^v$  modification for events for which no  $p_z^v$  solution is found, before (dashed line) and after (solid line) modification: a fraction of these events are recovered.

### 3.7 Top quark reconstruction

The two methods used for the hadronic  $W$  boson reconstruction lead to two methods for the top quark mass reconstruction. Moreover, additional cuts are applied in order to increase the purity of the selected sample; their relevance is illustrated below.

Once the hadronic  $W$  boson is reconstructed, the next step is to choose from the two  $b$ -jets the one to associate with the hadronic  $W$  boson in order to reconstruct the hadronic top quark. Several methods have been investigated:

- choose the  $b$ -jet that maximizes the hadronic top quark  $p_T$ .
- Choose the  $b$ -jet closest to the hadronic  $W$  boson.
- Choose the  $b$ -jet furthest from the leptonic  $W$  boson.

All three methods give similar results, but the second method has a slightly higher purity, so that one has been chosen. The remaining  $b$ -jet and the leptonic  $W$  boson then define the leptonic top quark.

The performance of the analyses before any additional cuts is summarized in Tables 2 and 3, in a full top quark mass window and within  $\pm 3 \sigma_{m_{\text{top}}}$ , where  $\sigma_{m_{\text{top}}} = 10$  GeV.

Table 2: Efficiency of cuts applied and final purities (full top quark mass window and within  $\pm 3 \sigma_{m_{\text{top}}}$ , where  $\sigma_{m_{\text{top}}} = 10$  GeV), with respect to  $t\bar{t}$  semi-leptonic sample (e, $\mu$ ), for both methods.

Cuts applied	Efficiency (%)	W boson purity (%)	b purity (%)	top purity (%)
$\chi^2$ minimization method				
Cut C0	$2.22 \pm 0.03$	$59.4 \pm 0.8$	$61.6 \pm 0.8$	$40.2 \pm 0.8$
Cut C0 within $\pm 3 \sigma_{m_{\text{top}}}$	$1.40 \pm 0.04$	$70.4 \pm 0.8$	$77.3 \pm 0.8$	$60.7 \pm 0.8$
Cuts C0, C2 and C3	$1.25 \pm 0.04$	$59.3 \pm 0.8$	$82.2 \pm 0.8$	$56.5 \pm 0.8$
Cuts C0, C2 and C3 within $\pm 3 \sigma_{m_{\text{top}}}$	$0.90 \pm 0.03$	$74.9 \pm 0.9$	$91.1 \pm 0.9$	$73.6 \pm 0.9$
Cuts C0, C2, C3, C4 and C5	$0.91 \pm 0.05$	$80.1 \pm 0.8$	$92.8 \pm 0.8$	$77.1 \pm 0.8$
Geometric method				
Cut C1	$1.26 \pm 0.03$	$68.8 \pm 0.8$	$69.7 \pm 0.8$	$53.8 \pm 0.9$
Cut C1 within $\pm 3 \sigma_{m_{\text{top}}}$	$1.01 \pm 0.04$	$77.6 \pm 0.8$	$77.7 \pm 0.8$	$65.9 \pm 0.8$
Cuts C1, C2 and C3	$0.85 \pm 0.03$	$68.7 \pm 0.9$	$84.7 \pm 0.8$	$66.1 \pm 0.9$
Cuts C1, C2 and C3 within $\pm 3 \sigma_{m_{\text{top}}}$	$0.70 \pm 0.03$	$79.4 \pm 0.9$	$90.7 \pm 0.7$	$78.1 \pm 0.9$
Cuts C2, C3, C4 and C5	$0.57 \pm 0.05$	$86.9 \pm 0.9$	$94.0 \pm 0.6$	$86.4 \pm 0.9$

Table 3: Number of events in  $1 \text{ fb}^{-1}$  (signal and background) after selection cuts (full top quark mass window and within  $\pm 3 \sigma_{m_{\text{top}}}$ , where  $\sigma_{m_{\text{top}}} = 10$  GeV), for both methods.  $\tau$  + jets events correspond to: hadronic W boson  $\rightarrow \tau\nu$  and  $\tau$  decays hadronically. Leptonic  $\tau$  decays are counted together with the signal.

Number of events for $1 \text{ fb}^{-1}$	signal	W + jets	$\tau \rightarrow \text{jets}$	di-lepton	all-jets	single top
$\chi^2$ minimization method						
Cut C0	6946	19	14	191	51	148

### 3.7.1 Additional cuts

Additional cuts can be applied in order to increase the final top purity (combinatorial background rejection).

- **Cut C2:** the invariant mass of the hadronic  $W$  boson and the  $b$ -jet associated to the leptonic  $W$  boson must be greater than 200 GeV.
- **Cut C3:** the invariant mass of the lepton and the  $b$ -jet associated to the leptonic  $W$  boson must be lower than 160 GeV.

These cuts are illustrated in Figs. 9 and 10. Their effects on efficiency and purity are shown in Tables 2 and 3.

Figure 9: Invariant mass of the hadronic  $W$  boson and the leptonic  $b$ -jet for events satisfying C1. The vertical line corresponds to  $M_{jjbl} = M(W_{\text{had}}, b_{\text{lep}}) > 200$  GeV.

Figure 10: Invariant mass of the lepton and the leptonic  $b$ -jet for events satisfying C1 and C2. The vertical line corresponds to  $M_{lbl} = M(l, b_{\text{lep}}) < 160$  GeV.

The combinatorial background can be further suppressed with two more cuts [19]. These are defined based on the following variables, where  $E^*$  denotes the energy of a particle in the top quark rest frame:

$$X_1 = E_W^* - E_b^* = E_{j1}^* + E_{j2}^* - E_b^* = \frac{M_W^2 - M_b^2}{M_{\text{top}}}, \quad (2)$$

$$X_2 = 2E_b^* = \frac{M_{\text{top}}^2 - M_W^2 + M_b^2}{M_{\text{top}}}. \quad (3)$$

We call the peak and width of the  $X_{1,2}$  distributions  $\mu_{1,2}$  and  $\sigma_{1,2}$ , as is found from simulated  $t\bar{t}$  events with  $m_{\text{top}} = 175$  GeV that satisfy all previous requirements. Then the two following cuts are defined:

- **Cut C4:**  $|X_1 - \mu_1| < 1.5 \sigma_1$ ,
- **Cut C5:**  $|X_2 - \mu_2| < 2 \sigma_2$ .

These cuts are illustrated in Figs. 11 and 12. With respect to C2 and C3, these cuts reduce the efficiency by 30% but increase the purity to 85%, as shown in Tables 2 and 3. The numbers are identical in the full top quark mass window and within  $\pm 3 \sigma_{m_{\text{top}}}$ , since C4 and C5 restrict the top quark mass to a more stringent window than  $\pm 3 \sigma_{m_{\text{top}}}$  around the peak value.

Table 4 summarizes the cuts applied in these analyses.

Figure 11: Distribution of  $X_1 \equiv E_W^* - E_b^*$  for events passing C2 and C3. Vertical lines correspond to the bounds of the **C4** cut.

Figure 12: Distribution of  $X_2 \equiv 2E_b^*$  for events passing C2, C3, and C4. Vertical lines correspond to the bounds of the **C5** cut.

Table 4: Additional cuts applied, after the event selection, for both methods ( $X_i$ ,  $\mu_i$  and  $\sigma_i$  are defined in the text of this section).

Cut label	Description
Cut C0 ( $\chi^2$ minimization)	$ M_W^{\text{rec}} - M_W^{\text{PDG}}  < 2\Gamma_{M_W}^{\text{PDG}}$ ( $M_W^{\text{rec}}$ is the reconstructed hadronic W and $\Gamma_{M_W}^{\text{PDG}} = 2.1$ GeV)
Cut C1 (geometric method)	$ M_W^{\text{rec}} - M_W^{\text{peak}}  < 2\sigma_{M_W}$ ( $\sigma_{M_W} = 10.4$ GeV)
Cut C2 (both methods)	$M(W_{\text{had}}, b_{\text{lep}}) > 200$ GeV
Cut C3 (both methods)	$M(\text{lepton}, b_{\text{lep}}) < 160$ GeV
Cut C4 (both methods)	$ X_1 - \mu_1  < 1.5\sigma_1$
Cut C5 (both methods)	$ X_2 - \mu_2  < 2\sigma_2$

### 3.8 Top quark mass measurement

In Fig. 13, the hadronic top quark mass reconstructed with the  $\chi^2$  minimization method is fit to the sum of a Gaussian and a polynomial (third degree). For  $1 \text{ fb}^{-1}$ , the fit Gaussian has its mean at  $175.0 \pm 0.2 \text{ GeV}$  and a width of  $11.6 \pm 0.2 \text{ GeV}$  ( $\chi^2/\text{dof} = 137/67$ ). It is seen that C2 and C3 do not significantly shift the top quark mass:  $m_{\text{top}} = 174.8 \pm 0.3 \text{ GeV}$  with a width equal to  $11.7 \pm 0.4 \text{ GeV}$  ( $\chi^2/\text{dof} = 82/67$ : C2 and C3 improve significantly this value).

Figure 13: The hadronic top quark mass reconstructed with the  $\chi^2$  minimization method, fit with a sum of a Gaussian and a third order polynomial, scaled to  $1 \text{ fb}^{-1}$ . Left, after C0:  $m_{\text{top}} = 175.0 \pm 0.2 \text{ GeV}$ , with a width equal to  $11.6 \pm 0.2 \text{ GeV}$ . Right, after C2 and C3:  $m_{\text{top}} = 174.8 \pm 0.3 \text{ GeV}$  with a width equal to  $11.7 \pm 0.4 \text{ GeV}$

Figure 14 shows the result of the hadronic top mass reconstruction using the geometric method, fit to the sum of a Gaussian and a threshold function<sup>3</sup>(left,  $\chi^2/\text{dof} = 97/75$ ) and to a pure Gaussian (right,  $\chi^2/\text{dof} = 38/24$ ). After all cuts, the Gaussian mean fits to  $175.0 \pm 0.4 \text{ GeV}$  with a width of  $14.3 \pm 0.3 \text{ GeV}$ . The width is larger than with the  $\chi^2$  minimization method since no attempt is made to perform an event-by-event rescaling of the light jets. Nevertheless, the contribution of the light jets to the top quark mass resolution can be removed to first order by computing the top quark mass as  $m_{\text{top}} = M_{\text{jib}} - M_{\text{jj}} + M_{\text{W}}^{\text{peak}}$ . The results of this geometric method with rescaling are shown in Fig. 15. The width decreases to  $10.6 \text{ GeV}$ , consistent with the results from the  $\chi^2$  minimization method.

Table 5 summarizes the fit results from all the methods discussed here.

<sup>3</sup>The formula of the threshold function used is the following:

$$A \cdot e^{-\frac{1}{2} \left( \frac{x - M_{\text{top}}}{\sigma_{\text{top}}} \right)^2} + CstBdf \cdot (x - \text{threshold})^b \cdot e^{-c(x - \text{threshold})} \quad (4)$$

Figure 14: The hadronic top quark mass reconstructed with the geometric method, fit with a sum of a Gaussian and a threshold function (left) and with a pure Gaussian (right), scaled to  $1 \text{ fb}^{-1}$ . Left, after C1, C2, and C3:  $m_{\text{top}} = 174.6 \pm 0.5 \text{ GeV}$ , with a width equal to  $11.1 \pm 0.5 \text{ GeV}$ ; right, after C2, C3, C4, and C5:  $m_{\text{top}} = 175.0 \pm 0.4 \text{ GeV}$ , with a width equal to  $14.3 \pm 0.3 \text{ GeV}$ .

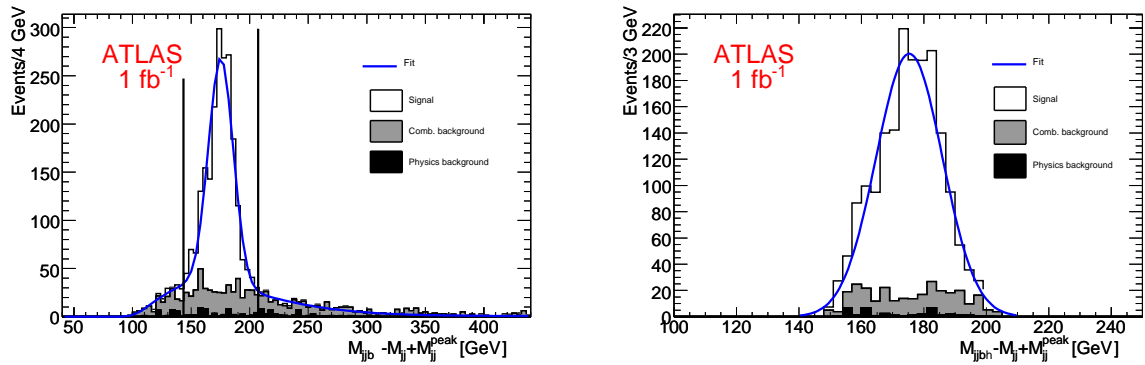

Figure 15: The hadronic top quark mass reconstructed with the geometric method with rescaling, fit with a sum of a Gaussian and a threshold function, scaled to  $1 \text{ fb}^{-1}$ . Left, after C1, C2, and C3:  $m_{\text{top}} = 175.4 \pm 0.4 \text{ GeV}$ , with a width equal to  $10.6 \pm 0.4 \text{ GeV}$  ( $\chi^2/\text{dof} = 109/73$ ); right, after C2, C3, C4, and C5:  $m_{\text{top}} = 175.3 \pm 0.3 \text{ GeV}$ , with a width equal to  $10.6 \pm 0.2 \text{ GeV}$  ( $\chi^2/\text{dof} = 43/16$ ).

Figure 16:  $\chi^2$  distribution (with combinatorial background), with cuts **C2** and **C3** applied.

Figure 17: Top quark mass as a function of  $\chi^2$ . The points are fitted by a linear function to extract  $m_{\text{top}} = m_{\text{top}}^{\text{fit}}(\chi^2 = 0)$

### 3.9 Kinematic fit

The top quark mass can be extracted from a kinematic fit using a  $\chi^2$  based on the entire final state, as defined in equation (5). The terms in the first line consist of the usual  $\chi^2$  terms<sup>4</sup>, while the last four constrain the object masses. The resolutions are extracted from Monte Carlo. The  $\chi^2$  is calculated event by event and the resulting  $\chi^2$  distribution, shown in Fig. 16, exhibits a higher purity for lower  $\chi^2$  values. The purity of the final sample could be improved by cutting on the  $\chi^2$ .

$$\begin{aligned} \chi^2 = & \sum_{\text{jets}} \left( \left( \frac{\eta_i^m - \eta_i^f}{\sigma_{\eta}^i} \right)^2 + \left( \frac{\phi_i^m - \phi_i^f}{\sigma_{\phi}^i} \right)^2 \right) + \sum_{\text{jets, lepton}} \left( \frac{E_i^m - E_i^f}{\sigma_E^i} \right)^2 + \sum_{x,y,z} \left( \frac{p_{iv}^m - p_{iv}^f}{\sigma_{iv}^i} \right)^2 \\ & + \left( \frac{m_{ij} - M_W^{\text{PDG}}}{\sigma_W} \right)^2 + \left( \frac{m_{lv} - M_W^{\text{PDG}}}{\sigma_W} \right)^2 + \left( \frac{m_{ijb_h} - m_{\text{top}}^{\text{fit}}}{\sigma_t} \right)^2 + \left( \frac{m_{lvb_l} - m_{\text{top}}^{\text{fit}}}{\sigma_t} \right)^2. \end{aligned} \quad (5)$$

The  $\chi^2$  minimization provides a high constraint on the jets from  $W$  boson. In an earlier study [14], it has been shown that the accuracy of the determination of the top quark mass depends on the  $\chi^2$ . For events in which the b-quark jets are well measured and extra final state effects are small, the  $\chi^2$  of the fit is close to 0 and produces a top quark mass value reflecting the Monte Carlo generated top quark mass. For larger  $\chi^2$  value, this top quark mass value decreases while the fraction of b-quarks with a large gluon radiation increases. This observation can be used by performing a linear fit to the extracted top quark mass as a function of the  $\chi^2$ . The fit is shown on Fig. 17 where the top mass distribution is fitted by a gaussian for each  $\chi^2$  slice. The most accurate estimate of the top quark mass is obtained by extrapolating this linear fit to  $\chi^2 = 0$ . This procedure should lead to a lower sensitivity to final state radiation effects of the extracted top quark mass, which is found to be  $m_{\text{top}} = 174.8 \pm 0.4$  GeV, where the uncertainty is statistical.

This method is more computationally intensive than the others to assess the systematics, and is not considered further in this note.

<sup>4</sup>The  $m$  index stands for measured quantities and the  $f$  index, for fitted quantities.  $E$ ,  $\eta$  and  $\phi$  are respectively the energy, pseudo-rapidity and polar angle of the considered objects.

Table 5: Fitted peaks for the hadronic top quark mass and corresponding widths for several methods. From simulated events with  $m_{\text{top}} = 175$  GeV, for  $1 \text{ fb}^{-1}$ .

Method	Cuts	Top quark mass [GeV]	$\sigma$ [GeV]	Pull bias	Pull width
$\chi^2$ minimization	<b>C0</b>	$175.0 \pm 0.2$	$11.6 \pm 0.2$	$-0.3$	$1.23$
$\chi^2$ minimization	<b>C0, C2, and C3</b>	$174.8 \pm 0.3$	$11.7 \pm 0.4$	$-0.2$	$1.11$
$\chi^2$ minimization	<b>C0, C2, C3, C4, and C5</b>	$174.8 \pm 0.3$	$11.8 \pm 0.4$	$-0.5$	$1.00$

Kinematic fit		$174.8 \pm 0.4$			

### 3.10 Statistical uncertainties

Figure 18: Pull distributions for the top quark mass measurement. Left,  $\chi^2$  minimization method and right, geometric method. Both plots after C2, C3, C4, and C5.

The statistical uncertainties quoted have been evaluated using a single simulated experiment with statistics corresponding to  $1 \text{ fb}^{-1}$ . To evaluate the reliability of these estimates, a bootstrap resampling technique has been used [20].

The pull distributions for the top quark mass measurement  $(M_i - M_{\text{gen}})/\sigma_{M_i}$  have been produced for each method using 1200 pseudo-experiments. The biases and widths are reported in Table 5 for all the analyses shown in this note. Fig. 18 shows the pull distributions for the  $\chi^2$  minimization method and for the geometric method, after cuts **C2** through **C5**. All pull mean values are of size 0.5 or less: this indicates that the biases induced by the methods of measuring the top quark mass are of the order of 0.1 to 0.2 GeV depending on the cuts applied. The pull widths are slightly larger than 1; this indicates that the statistical uncertainty of the fit is slightly underestimated.

### 3.11 Systematic uncertainties

The statistical uncertainty on the top quark mass being negligible with a few  $\text{fb}^{-1}$  of collected data, the total uncertainty will quickly be dominated by the systematic uncertainties. All the contributions are listed below and summarized in Table 6.

Table 6: Systematic uncertainties on the top quark mass measured in the semi-leptonic channel.

Systematic uncertainty	$\chi^2$ minimization method	geometric method
Light jet energy scale	0.2 GeV/%	0.2 GeV/%
b jet energy scale	0.7 GeV/%	0.7 GeV/%
ISR/FSR	$\simeq 0.3$ GeV	$\simeq 0.4$ GeV
b quark fragmentation	$\leq 0.1$ GeV	$\leq 0.1$ GeV
Background	negligible	negligible
Method	0.1 to 0.2 GeV	0.1 to 0.2 GeV

#### 3.11.1 Jet energy scale (JES)

The effect of the uncertainty of the jet energy scale on the top quark mass measurement has been estimated by multiplying separately the light jet and  $b$ -jet momenta by several rescaling factors (20 factors, between  $-10\%$  and  $+10\%$ ). Neither the event selection nor the  $\cancel{E}_T$  have been changed after this jet energy rescaling.

The resulting top quark mass depends linearly on the rescaling factor. The related systematic uncertainty on the top quark mass can therefore be expressed as a percentage of the light jet and  $b$ -jet energy scale miscalibration.

- The uncertainty in the  $b$ -jet energy scale produces an uncertainty in the top quark mass of 0.7 GeV/%. The  $b$ -jet scale will ultimately be determined with data from  $Z + \text{jets}$ . However, at the start of LHC running, the  $Z + \text{jets}$  statistics will be low, so the  $b$ -jet scale will be derived from the measured light jet scale together with a Monte Carlo correction term modelling the difference between the two jet energy scales. The systematic uncertainty associated with these methods has not been yet evaluated.
- The uncertainty in the light jet energy scale produces an uncertainty in the top quark mass of 0.2 GeV/%. The reduced dependence compared to that of the  $b$ -jet energy scale is due to the  $W$  boson mass constraint used in the rescaling ( $\chi^2$  minimization method or kinematical fit) or the definition of the top quark mass estimator (geometric with rescaling method). It has been shown that the light jet energy scale should be known with a precision of 1% in  $1 \text{ fb}^{-1}$  of data [3]: the corresponding uncertainty on the top quark mass would therefore be 0.2 GeV.

#### 3.11.2 Initial and final state radiation (ISR and FSR)

The study of the effect of initial and final state radiation on the top quark mass measurement is still preliminary. Several samples have been simulated for this study, corresponding to different sets of parameters:

Table 7: Top quark mass measured with several ISR/FSR parameters ( $\chi^2$  minimization method, after cut C0 and jet calibration).

Sample	Top quark mass [GeV]	$\sigma$ [(GeV)]
1	$176.6 \pm 0.4$	$13.4 \pm 0.6$
2	$176.3 \pm 0.7$	$13.7 \pm 0.8$
3	$176.3 \pm 0.5$	$12.7 \pm 0.6$

- Sample 1: AcerMC  $t\bar{t}$  events, with maximum reconstructed top quark mass (half the default value of  $\Lambda(\text{QCD})$  for FSR; twice the default value of  $\Lambda(\text{QCD})$  for ISR).
- Sample 2: AcerMC  $t\bar{t}$  events, with default ISR and FSR parameters.
- Sample 3: AcerMC  $t\bar{t}$  events, with minimum reconstructed top quark mass (twice the default value of  $\Lambda(\text{QCD})$  for FSR, half the default value of  $\Lambda(\text{QCD})$  for ISR).

For each sample, a specific jet calibration has been applied (separately for  $b$ -jets and light jets).

The measured top quark masses are summarised in Table 7. A shift on the top quark mass is observed. A first estimate of the systematic uncertainty due to initial and final state radiation can be estimated from the relative difference between these three top quark mass values: it is approximately equal to 0.3 GeV (more statistics would be necessary for a more precise estimate).

This preliminary study shows the impact on the top quark mass measurement of a given change of ISR/FSR parameters, but the estimate of the systematic uncertainty due to ISR or FSR will benefit from a measurement of these effects with ATLAS data. Figure 19 shows, for example, that the jet multiplicity could help to determine the size of the initial and final state radiation contribution. Initial state radiation could be measured with Drell-Yan events, as has been done at the Tevatron.

Figure 19: Light and  $b$ -jet multiplicity for several values of the ISR/FSR parameters ( $p_T(\text{jet}) > 40$  GeV).

### 3.11.3 $b$ -quark fragmentation

The effect of  $b$ -quark fragmentation has been estimated by varying the Peterson parameter within its uncertainty (study performed on fast simulation [14]).

Figure 20: Reconstructed top quark mass with 2  $b$ -tagged jets as a function of the generated top quark mass (left:  $\chi^2$  minimization method, after C0 cut; right: geometric method after C1 cut). The method has good linearity.

The resulting uncertainty is lower than 0.1 GeV.

### 3.11.4 Background estimate

Variations in the size of the background have no noticeable effect on the extracted top quark mass. Nevertheless, it is important to extract the shape of the background from data.

## 3.12 Linearity of the method

The analysis leading to the top quark mass measurement has been applied to samples corresponding to several values of generated top quark mass. Figures 20 and 21 show that both methods have good linearity. The reconstructed top quark mass lies above the generated one by an average offset equal to 0.2% of  $m_{\text{top}}$ . This comes from the  $p_T$  jet spectrum which is different for each sample with a different generated top quark mass [3]. The jet energy scale is then a little bit different in each sample due to the  $p_T$  cut applied on jets.

## 4 Top quark mass measurement in the semi-leptonic channel with relaxed requirements on the $b$ -tagging

At the start of LHC running, the detector will not be optimized and will require a commissioning phase with first data to calibrate its sub-components. This is particularly true for the pixel detector and its capability to tag  $b$ -jets. Thus, it could be useful to have a top quark mass measurement analysis in which the use of  $b$ -tagging is reduced. This is addressed in this section by performing a first analysis in which exactly one  $b$ -jet is  $b$ -tagged (the assumed  $b$ -tagging efficiency is the same as before:  $\epsilon_b \simeq 60\%$ ). This sample has no events in common with the sample used in section 3. In a second analysis,  $b$ -tagging is not used in the reconstruction of the  $t\bar{t}$  events. Even if not used, this sample contains events with 0, 1, or 2  $b$ -tagged jets and overlap with the other two samples.

Figure 21: Difference between the reconstructed and generated top quark mass, as a function of the latter (left:  $\chi^2$  minimization method, after C0 cut; right: geometric method after C1 cut).

#### 4.1 Displaced vertex $b$ -tagging, 1 $b$ -tagged jet

The sample is here limited to events with no more than five jets. In this case, the best method to select the two light jets from the  $W$  boson is the one which minimizes  $M_{jj} - M_W^{\text{peak}}$ . The  $b$ -jet associated with the hadronic top quark decay is then chosen among the remaining light jets and the tagged  $b$ -jet. The best choice is the one which minimizes  $\sqrt{(X_1 - \mu_1)^2 + (X_2 - \mu_2)^2}$  (see equations (2) and (3)).

A large fraction of the non-hadronic  $b$ -jets is removed by requiring the  $b$ -jet to be closer to the reconstructed  $W$  boson than the lepton originating from the leptonic top quark decay:

- cut **C6** :  $\Delta R(\text{lepton}, b_{\text{had}}) - \Delta R(W, b_{\text{had}}) > 1$

As in previous sections, the purification cuts **C1** and **C3** are applied. Harder purification cuts (**C4** and **C5**) could also be applied. The top quark mass spectra derived after applying the two sets of purification cuts are shown in Fig. 22.

Table 8 summarizes the reconstruction efficiency and purity related to this reconstruction method for both sets of cuts.

Table 8: Single  $b$ -tagged sample: efficiency of cuts applied and final purities (within  $\pm 3 \sigma_{m_{\text{top}}}$ ), with respect to semi-leptonic events.

Cuts	Efficiency (%)	$W$ boson purity (%)	$b$ purity (%)	top purity (%)	Number of events
<b>C1+C3+C6</b>	$0.54 \pm 0.02$	$70 \pm 1$	$69 \pm 1$	$62 \pm 1$	1063
<b>C3+C4+C5+C6</b>	$0.52 \pm 0.02$	$71 \pm 1$	$70 \pm 1$	$63 \pm 1$	1016

The systematic uncertainties on the top quark mass measurement, determined in the same way as in the previous section, are summarized in Table 9.

The top quark mass values obtained are shown in Table 10 together with the pull distribution results. The single-tag sample can be added to the double-tagged sample to perform a top quark mass measurement with 50% more signal events.

Figure 22: Events with only 1  $b$ -tagged jet:  $m_{\text{top}} = M_{\text{j}bh} - M_{\text{j}j} + M_{\text{j}j}^{\text{peak}}$  with the geometric method and rescaling, after purification cuts (left, **C1**, **C3**, and **C6** cuts:  $m_{\text{top}} = 176.0 \pm 0.7$  GeV, with a width equal to  $9.4 \pm 0.8$  GeV ( $\chi^2/\text{dof} = 58/52$ ); right, **C3**, **C4**, **C5**, and **C6** cuts:  $m_{\text{top}} = 174.0 \pm 0.4$  GeV, with a width equal to  $12.7 \pm 0.4$  GeV ( $\chi^2/\text{dof} = 27/13$ )).

Table 9: Systematic uncertainties on the top quark mass with rescaling measured in the semi-leptonic channel, with 1  $b$ -tagged jet and no  $b$ -tagging, using the geometric method.

Systematic uncertainty	1 $b$ -tagged jet	No $b$ -tagging
Light jet energy scale	0.3 GeV/%	0.4 GeV/%
$b$ jet energy scale	0.7 GeV/%	0.7 GeV/%
ISR/FSR	$\simeq 0.4$ GeV	$\simeq 0.4$ GeV
$b$ quark fragmentation	$\leq 0.1$ GeV	$\leq 0.1$ GeV
Background	$< 1$ GeV	1 GeV

Table 10: Fitted top quark mass value and corresponding widths for 1  $b$ -tag and no  $b$ -tag samples, in  $1 \text{ fb}^{-1}$ . Pull bias and width are also given.

Geometric method with rescaling	Cuts	Top quark mass [GeV]	$\sigma$ [GeV]	pull bias	pull width
1 $b$ -tagged jet	<b>C1</b> , <b>C3</b> and <b>C6</b> cuts	$176.0 \pm 0.7$	$9.4 \pm 0.8$	-0.48	1.17
1 $b$ -tagged jet	<b>C3</b> , <b>C4</b> , <b>C5</b> and <b>C6</b> cuts	$174.0 \pm 0.4$	$12.7 \pm 0.4$	-0.05	1.07
No $b$ -tagged jet	<b>C1</b> and <b>C3</b> cuts	$175.0 \pm 0.4$	$11.7 \pm 0.5$	0.40	1.12
No $b$ -tagged jet	<b>C3</b> , <b>C4</b> and <b>C5</b> cuts	$175.2 \pm 0.5$	$12.4 \pm 0.8$	-0.15	0.94

## 4.2 Top quark mass measurement in the semi-leptonic channel assuming no $b$ -tagging

The same analysis is performed with no use of  $b$ -tagging information. The main difference with the two  $b$ -tagged analysis comes from the larger contribution of the combinatorial and physics background.

The corresponding top mass spectra are given in Fig. 23 for both sets of cuts. Table 11 summarizes the efficiency and purity related to this method.

Figure 23: Events without  $b$ -tagging:  $m_{\text{top}} = M_{\text{j}jb} - M_{\text{j}j} + M_{\text{W}}^{\text{peak}}$  with the geometric method, after purification cuts (left, **C1** and **C3** cuts:  $m_{\text{top}} = 175.0 \pm 0.4$  GeV, with a width equal to  $11.7 \pm 0.5$  GeV ( $\chi^2/\text{dof} = 130/69$ ); right, **C3**, **C4** and **C5** cuts:  $m_{\text{top}} = 175.2 \pm 0.5$  GeV, with a width equal to  $12.4 \pm 0.8$  GeV ( $\chi^2/\text{dof} = 41/24$ )).

Table 11: Efficiency of cuts applied and final purities (within  $\pm 3 \sigma_{m_{\text{top}}}$ ), with respect to semi-leptonic ( $e, \mu$ ) events, assuming no  $b$ -tagging.

Cuts	Efficiency (%)	W boson purity (%)	b purity (%)	top purity (%)	Number of events
<b>C1+C3</b>	$1.59 \pm 0.03$	$49.5 \pm 0.9$	$46.8 \pm 0.9$	$58.4 \pm 0.9$	3115
<b>C3+C4+C5</b>	$1.48 \pm 0.03$	$51.1 \pm 0.9$	$49.0 \pm 0.9$	$58.9 \pm 0.9$	2916

The systematic uncertainties on the top quark mass measurement are summarized in Table 9. The obtained top quark mass values together with the pull distribution results are shown in Table 10.

For the second set of cuts (right plot of Fig. 23), the background contribution ( $\simeq 45$  % of the sample) is peaked exactly below the signal contribution, preventing a fit using a parametrization like gaussian function (signal) + polynomial function (background). An event mixing technique has been used to fix the background shape in the parametrization. The event mixing technique consists in replacing one of the two jets momentum associated to the W with a simulated jet whose energy,  $\phi$  and  $\eta$  distribution is randomly selected according to the global energy,  $\phi$  and  $\eta$  distributions observed for the jets associated to the W. This technique looks very promising as shown in Fig. 24 comparing data and event mixing samples for the two jet and three jet invariant masses after preselection.

Figure 24: Events without  $b$ -tagging: comparison between background and event mixing samples for two jets (left) and three jets (right) invariant mass.

## 5 Conclusion

Several methods have been investigated in order to perform an accurate top quark mass measurement with  $1 \text{ fb}^{-1}$  of collected data, in the  $t\bar{t}$  semi-leptonic channel. The best top quark mass determination is achieved with two  $b$ -tagged events and a top mass estimator taken as the invariant mass of the three jets from hadronically-decaying top quark; the uncertainty on the top quark mass measurement with this analysis will be dominated by systematics, the statistical uncertainty being already small ( $\leq 0.4 \text{ GeV}$ ). The precision on the top quark mass relies mainly on the jet energy scale uncertainty: a precision of the order of 1 to 3.5 GeV should be achievable with  $1 \text{ fb}^{-1}$ , assuming a jet energy scale uncertainty of 1 to 5%.  $W$  boson sample can be extracted from the  $t\bar{t}$  sample in order to constrain the light jet energy scale. The main uncertainty on the top quark mass measurement will come from the  $b$ -jet energy scale.

Events with one or no  $b$ -tagged jets lead also to an interesting measurement if the background (physical and combinatorial) shape is constrained from data. The estimated precision on the top quark mass value is below 2 GeV (assuming a jet energy scale uncertainty of the order of the percent), with a very good signal over background ratio. These samples are thus very useful for jet energy scale or  $b$ -tagging studies during the commissioning phase with early data.

# Top Quark Properties

## Abstract

The ATLAS potential for the study of top quark properties and physics beyond the Standard Model in the top sector, is reviewed in this paper. Measurements of the top quark charge, the spin and spin correlations, the Standard Model decay ( $t \rightarrow bW$ ), rare top quark decays associated to flavour changing neutral currents ( $t \rightarrow qX, X = \gamma, Z, g$ ) and  $t\bar{t}$  resonances are discussed. The expected sensitivity of the ATLAS experiment is estimated for an integrated luminosity of  $1 \text{ fb}^{-1}$  at the LHC. For the Standard Model measurements the expected precision is presented. For the tests of physics beyond the Standard Model, the  $5\sigma$  discovery potential (in the presence of a signal) and the 95% confidence level limit (in the absence of a signal) are given.

## 1 Introduction

Several properties of the top quark have already been explored by the Tevatron experiments, such as the mass, charge and lifetime, the rare decays through flavour changing neutral currents (FCNC) and the production cross-sections. The structure of the  $Wtb$  vertex and the main top quark decay mode ( $t \rightarrow bW$ ) within the Standard Model were also investigated together with the measurements of the W-boson helicity fractions. Many of these studies were performed by reconstructing  $t\bar{t}$  pairs in the semileptonic, dileptonic and fully hadronic decay modes. Given the current Tevatron luminosity, most of these studies are limited by the statistics acquired.

The electric charge of the top quark is one of its fundamental properties and will be probed with high statistics at the LHC. The measurement of the top quark charge can be performed either by identifying the charge of its decay products in the main decay channel  $t \rightarrow bW$  or by studying radiative top quark processes. At the Tevatron the D0 [1] and CDF [2] collaborations have already initiated the study of the top quark charge and, with the available statistics, they showed that the data gives preference to the Standard Model top quark hypothesis (with a charge of  $+2/3$ ) over the scenario with an exotic quark (XM) of charge  $-4/3$  and mass  $\approx 170 \text{ GeV}$ , fully consistent with the present precision electroweak data [3, 4]. The D0 and CDF exclude the exotic quark hypothesis with 92 and 87 % confidence, respectively.

As the top quark decays before it can form hadronic bound states, a consequence of its high mass, the spin information of the top quark is propagated to its decay products. This unique behaviour among quarks allows direct top quark spin studies, as spin properties are not washed out by hadronization. Through the measurement of the angular distributions of the decay products the information of the top quark spin can be reconstructed. Top quark spin polarization and correlations in  $t\bar{t}$  events produced at the LHC are precisely predicted by the Standard Model and are sensitive to the fundamental interactions involved in the top quark production and decay. By testing only the top quark decay, the W-boson polarization measurement complements top quark spin studies, helping to disentangle the origin of new physics, if observed. The W-boson polarization states can be measured through the longitudinal ( $F_0$ ), left-handed ( $F_L$ ) and right-handed ( $F_R$ ) helicity fractions. At the present, the most stringent limits on the W-boson helicity fractions were obtained at the Run-II of the Tevatron [5–13]. Analysing  $1.9 \text{ fb}^{-1}$  of data, the CDF experiment measured [5]  $F_0 = 0.62 \pm 0.11$  with  $F_R$  fixed to zero and  $F_R = -0.04 \pm 0.05$  with  $F_0$  fixed to the Standard Model expectation for  $m_t = 175 \text{ GeV}$ . For  $2.7 \text{ fb}^{-1}$ , the D0 experiment measured [10]  $F_0 = 0.490 \pm 0.106(\text{stat}) \pm 0.085(\text{syst})$  with  $F_R$  fixed to zero, and  $F_R = 0.110 \pm 0.059(\text{stat}) \pm 0.052(\text{syst})$  with  $F_0$  fixed to the Standard Model value.

Within the Standard Model, the  $Wtb$  coupling is purely left-handed (at the tree level), and its size is given by the Cabibbo-Kobayashi-Maskawa (CKM) matrix element  $V_{tb}$ . In Standard Model extensions,

Table 1: The values of the branching ratios of the FCNC top quark decays, predicted by the SM, the quark-singlet model (QS), the two-higgs doublet model (2HDM), the minimal supersymmetric model (MSSM) and SUSY with R-parity violation are shown [30–36].

Process	SM	QS	2HDM	MSSM	$\tilde{R}$ SUSY
$t \rightarrow uZ$	$8 \times 10^{-17}$	$1.1 \times 10^{-4}$	—	$2 \times 10^{-6}$	$3 \times 10^{-5}$
$t \rightarrow u\gamma$	$3.7 \times 10^{-16}$	$7.5 \times 10^{-9}$	—	$2 \times 10^{-6}$	$1 \times 10^{-6}$
$t \rightarrow ug$	$3.7 \times 10^{-14}$	$1.5 \times 10^{-7}$	—	$8 \times 10^{-5}$	$2 \times 10^{-4}$
$t \rightarrow cZ$	$1 \times 10^{-14}$	$1.1 \times 10^{-4}$	$\sim 10^{-7}$	$2 \times 10^{-6}$	$3 \times 10^{-5}$
$t \rightarrow c\gamma$	$4.6 \times 10^{-14}$	$7.5 \times 10^{-9}$	$\sim 10^{-6}$	$2 \times 10^{-6}$	$1 \times 10^{-6}$
$t \rightarrow cg$	$4.6 \times 10^{-12}$	$1.5 \times 10^{-7}$	$\sim 10^{-4}$	$8 \times 10^{-5}$	$2 \times 10^{-4}$

departures from the Standard Model expectation  $V_{tb} \simeq 0.999$ <sup>1</sup> are possible [14, 15], as well as new radiative contributions to the  $Wtb$  vertex [16, 17]. These deviations might be observed in top quark production and decay processes at LHC. The most general  $Wtb$  vertex for on mass shell W-boson, top quark and b quark, containing terms up to dimension five can be written as

$$\mathcal{L} = -\frac{g}{\sqrt{2}}\bar{b}\gamma^\mu(V_L P_L + V_R P_R)t W_\mu^- - \frac{g}{\sqrt{2}}\bar{b}\frac{i\sigma^{\mu\nu}q_\nu}{M_W}(g_L P_L + g_R P_R)t W_\mu^- + \text{h.c.}, \quad (1)$$

with  $q = p_t - p_b$  the W-boson momentum and  $P_{R(L)}$  the chirality projectors. Additional  $\sigma^{\mu\nu}k_\nu$  and  $k^\mu$  terms, where  $k = p_t + p_b$ , can be absorbed into this Lagrangian using Gordon identities. If the W-boson is on its mass shell or it couples to massless fermions  $q^\mu \varepsilon_\mu = 0$ , and terms proportional to  $q^\mu$  can be dropped from the effective vertex. The new constants  $V_R$ ,  $g_L$  and  $g_R$  [18, 19], are vector like ( $V_R$ ) and tensor like ( $g_L$  and  $g_R$ ) anomalous couplings, can be related to  $f_1^R$ ,  $f_2^L$  and  $f_2^R$  in Ref. [20] (and references therein) as  $f_1^R = V_R$ ,  $f_2^L = -g_L$  and  $f_2^R = -g_R$ . If we assume CP is conserved, these couplings can be taken to be real. Within the Standard Model  $V_L \equiv V_{tb} \simeq 0.999$  and the other couplings ( $V_R$ ,  $g_L$ ,  $g_R$ ) vanish at the tree level, while nonzero values are generated at higher orders [21, 22]. Indirect limits on the  $Wtb$  vertex anomalous couplings can be inferred from radiative B-meson decays and  $B\bar{B}$  mixing [23]. Taking into account the current world average [23],  $\text{BR}(\bar{B} \rightarrow X_s \gamma) = (3.55 \pm 0.24_{-0.10}^{+0.09} \pm 0.03) \times 10^{-4}$ , varying one parameter at a time, the 95% C.L. bounds on  $V_R$ ,  $g_L$  and  $g_R$  are in the range  $[-0.0007, 0.0025]$ ,  $[-0.0015, 0.0004]$  and  $[-0.15, 0.57]$ , respectively [22, 24].

Flavour Changing Neutral Currents are strongly suppressed in the Standard Model due to the Glashow-Iliopoulos-Maiani (GIM) mechanism [25]. Although absent at tree level, small FCNC contributions are expected at one-loop level, determined by the CKM mixing matrix [26–29]. For the top quark within the framework of the Standard Model, these contributions limit the FCNC decay branching ratios to the gauge bosons,  $\text{BR}(t \rightarrow qX, X = Z, \gamma, g)$ , to below  $10^{-12}$ . There are however extensions of the SM, like supersymmetry (SUSY) [30], multi-Higgs doublet models [31] and models with exotic (vector-like) quarks [32–34], which predict the presence of FCNC contributions already at tree level and significantly enhance the FCNC decay branching ratios compared to the Standard Model predictions [35, 36]. The branching ratio for the different models are shown in Table 1. FCNC processes associated with the production and decay of top quarks have been studied at colliders and the observed upper limits on the branching ratios at 95% C.L., from the direct searches, are shown in Table 2.

Since the top quark mass is much larger than the other quarks, the top quark may play a privileged role in the electroweak symmetry breaking (EWSB) mechanism. Any new physics connected to the EWSB could be preferentially coupled to the top quark sector. This would lead to deviations from the

<sup>1</sup>Three generations of quarks and unitarity of the CKM matrix are assumed.

Table 2: Experimental observed upper limits on the branching ratios at 95%C.L. for the FCNC top quark decays.

	LEP	HERA	Tevatron
BR( $t \rightarrow qZ$ )	7.8% [37–41]	49% [42]	3.7% [43]
BR( $t \rightarrow q\gamma$ )	2.4% [37–41]	0.75% [42]	3.2% [44]
BR( $t \rightarrow qg$ )	17% [45]	13% [42,46,47]	0.1 – 1 % (estimated from [46,48])

expected Standard Model  $t\bar{t}$  production rate and could distort the top quark kinematics. New resonances and gauge bosons strongly coupled to the top quark are expected in a large variety of models, in particular those with strong EWSB [49–51]. The  $t\bar{t}$  final states are also interesting for leptophobic  $Z'$  bosons which can appear in Grand Unification Models [52]. These new particles could reveal themselves in the  $t\bar{t}$  invariant mass distribution. At the Tevatron experimental upper limits were set at 95 %C.L. for the  $\sigma(p\bar{p} \rightarrow Z') \times \text{BR}(Z' \rightarrow t\bar{t})$  with  $Z'$  masses between 450 GeV and 900 GeV. A topcolor leptophobic  $Z'$  is ruled out below 720 GeV and the cross section of any narrow  $Z'$  decaying to a  $t\bar{t}$  is less than 0.64 pb at 95%C.L., for  $Z'$  masses above 700 GeV [53].

In this note the ATLAS potential for the study of the top quark properties and tests of physics beyond the Standard Model in the top quark sector are reviewed for an expected luminosity of  $1 \text{ fb}^{-1}$  at the LHC. The note is organized as follows: the basic event selection and the trigger used are reminded in Section 2. In Sections 3, 4, 5 and 6 the studies of the top quark charge, the W-boson and top quark polarisation studies and the  $Wtb$  anomalous couplings, the top quark FCNC decays and the production of  $t\bar{t}$  resonances are discussed respectively. The summary and conclusions are presented in Section 7. The top quark mass, one of the most important top quark properties, is not investigated here as a separate note is devoted to this issue [54].

## 2 Basic event selection

As most of the studies performed in this paper are related to either the semileptonic ( $t\bar{t} \rightarrow WWb\bar{b} \rightarrow l\nu l'j_2b\bar{b}$  with  $l = e, \mu$ ) or the dileptonic ( $t\bar{t} \rightarrow WWb\bar{b} \rightarrow l\nu l' \nu' b\bar{b}$  with  $l, l' = e, \mu$ ) decays of  $t\bar{t}$  events, basic criteria for the event selection were defined for each one of these final state topologies. Changes to the criteria are to be expected depending on the type of top quark property under study. For the background studies several sources were considered,  $t\bar{t}$ ,  $W$ +jets,  $Wb\bar{b}$ +jets,  $Wc\bar{c}$ +jets,  $Z$ +jets,  $WW$ ,  $ZZ$ ,  $WZ$  and single top events (see the introduction of the Top Chapter for a full list of backgrounds). The backgrounds are also described in more detail separately for each section of the note. All signal and background events were required to pass the single lepton trigger requirements for electrons and muons. The triggers considered were L1\_EM18I (L1\_MU20, L1\_MU40) for electrons (muons) at L1, e22i (mu20) for electrons (muons) at L2 and e22i (mu20) for electrons (muons) at the Event Filter (EF) [55].

Different selection criteria are applied for the top quark FCNC analyses, as the final state topology is different from those considered above. These criteria are explained in Section 5.

### *Semileptonic topology*

In the semileptonic topology, signal events have a final state with one isolated lepton (electron or muon), at least four jets (two of them from the hadronization of  $b$  quarks and labelled  $b$ -jets) and large transverse missing energy from the undetected neutrino. More information on the signal can be found in the introduction of the Top Chapter. The basic selection criteria were defined by requiring that the events should have:

Table 3: Cumulative efficiencies of the standard top quark selection criteria for the semileptonic and dileptonic type of events with electrons and muons for the pseudorapidity range  $|\eta| \leq 2$ .

criterion	$\varepsilon(\%)$	criterion	$\varepsilon(\%)$
Semileptonic events	100	Dileptonic events	100
1 isol.lept. ( $p_T > 25/20$ GeV)	58.9	2 isol.lept. ( $p_T > 25/20$ GeV)	35.5
$\geq 4$ jets ( $p_T > 30$ GeV)	34.2	$\geq 2$ jets ( $p_T > 30$ GeV)	31.8
$\geq 2$ b-tagged	10.5	$= 2$ b-tagged	8.3
missing $E_T > 20$ GeV	8.5	missing $E_T > 30$ GeV	6.5

- exactly one isolated electron (muon) with  $|\eta| < 2.5$  and  $p_T > 25$  GeV ( $p_T > 20$  GeV);
- at least 4 jets with  $|\eta| < 2.5$  and  $p_T > 30$  GeV;
- at least 2 jets tagged as b-jets;
- missing transverse energy above 20 GeV.

#### *Dileptonic topology*

In the dileptonic topology, signal events have a final state with two isolated leptons (electrons and/or muons), at least two jets (tagged as b-jets) and large transverse missing energy from the two undetected neutrinos. The basic selection criteria were defined by requiring that the events should have:

- exactly two isolated electrons (muons) with  $|\eta| < 2.5$  and  $p_T > 25$  GeV ( $p_T > 20$  GeV);
- at least 2 jets with  $|\eta| < 2.5$  and  $p_T > 30$  GeV;
- 2 jets tagged as b-jets;
- missing transverse energy above 30 GeV.

#### *Selection efficiency*

The efficiency of the basic selection criteria was examined using  $\approx 450\,000$  events from the  $t\bar{t} \rightarrow bWbW \rightarrow bqqb\ell\nu, b\ell\nu b\ell\nu$  signal sample. The results are presented in Table 3.

The effect of the trigger efficiency is investigated separately for the individual analysis.

### 3 Top quark charge reconstruction

There are several techniques to determine the electric charge of the top quark at hadron collider experiments [56–58]. The top quark charge measurement presented here is based on the reconstruction of the charges of the top quark decay products. As the dominant decay channel of the top quark is  $t \rightarrow W^+b$  ( $\bar{t} \rightarrow W^- \bar{b}$ ), the top quark charge determination requires the measurement of both the W boson and the b quark charges. While the charge of the W boson can be determined through its leptonic decay, the b quark charge is not directly measurable due to quark confinement in hadrons. In this note two possible ways to determine the b quark charge were investigated:

- The charge weighting technique: this approach is based on finding a correlation between the b quark charge and the charges of the tracks belonging to the b-jet [59, 60].
- The semileptonic b-decay approach: in this case the b quark charge is determined using the semileptonic b-decays ( $b \rightarrow c, u + W^-$ ,  $W^- \rightarrow \ell^- + \bar{\nu}_\ell$ ), where the sign of the soft lepton indicates the sign of the b quark charge.

Two major issues have to be addressed. The first one is to find the selection criteria to perform the correct pairing of the lepton and the b-jet originated in the same top quark decay. In the Standard Model a b-jet, coming from a b quark, should be associated with a positive lepton ( $\ell^+$ ), while in the exotic case it should be associated with a negative one ( $\ell^-$ ). The second issue is the assignment of a charge to the b-jet selected by the pairing criterion. While the former issue is common for both the approaches, the latter one is tackled in different ways.

### 3.1 Event generation and selection

The standard  $t\bar{t} \rightarrow W^+bW^-\bar{b}$  samples were used as signal events in both the semileptonic and the dileptonic channels (only electrons and muons are taken as signal). For the background studies, the  $W$ +jets sample was used. The  $t\bar{t}$  all jets channels as well as the semileptonic and dileptonic channels of  $\tau$  leptons were analysed as they can contribute to background (all jets channel) and to signal (events with the leptonic decays of  $\tau$  leptons). In the present analysis the common selection criteria were used, as defined in Section 2. In addition, for each approach, specific criteria were applied to the events.

### 3.2 The lepton and b-jet pairing algorithm

The lepton and b-jet pairing was done using the invariant mass distribution of the lepton and the b-tagged jet,  $m(l, b_{\text{jet}})$ . If the assignment is correct,  $m(l, b_{\text{jet}})$  is limited by the top quark mass, otherwise there is no such restriction, as can be seen in Figure 1, where the signal sample with the standard cuts applied was analysed. To find the connection between the b-quarks and reconstructed b-jets and the parton level leptons and reconstructed leptons, the MC truth was used: the matching was treated as successful if the cone difference,  $\Delta R$  between b-quark and b-jet was less than 0.4 (in the lepton case  $\Delta R < 0.2$ ). For double b-tagged events, only the b-jets that satisfy

$$m(l, b_{\text{jet}}^{(1,2)}) < m_{\text{cr}} \quad \text{and} \quad m(l, b_{\text{jet}}^{(2,1)}) > m_{\text{cr}} \quad (2)$$

were accepted. In the di-lepton case both leptons should fulfill the condition (2). The optimal value for the pairing mass cut,  $m_{\text{cr}} = 155$  GeV, is a trade-off between the efficiency ( $\epsilon$ ) and purity ( $P$ ) of the pairing method. The factor  $\epsilon(2P - 1)^2$  was maximised to find the optimum working point. As this criterion requires events with two b-tagged jets and one combination for the lepton and b-jet invariant mass must be below  $m_{\text{cr}}$  and the other one above  $m_{\text{cr}}$ , the efficiency of the method is small. On the other hand, this criterion gives a high purity sample as is shown in Section 3.5.1. In the analysis two variants of b-tagged events treatment were considered. In the first one exactly two b-jets were required while in the second one two and more b-jets were allowed (the two with the highest  $p_T$  treated as true b-jets). Slightly better results were obtained for the former variant and the results presented here correspond to this case. To suppress the background some additional cuts were tried:  $W$  boson mass ( $M_W$ ) window, top quark mass ( $m_{\text{top}}$ ) window, etc. By using the combined  $W$  boson and top quark mass window the background can be reduced by factor more than 10 at the expense of a factor 2 loss in signal. The  $M_W$  window requires that at least one pair of non b-tagged jets should have an invariant mass within 10 GeV of the  $W$  boson mass. The  $m_{\text{top}}$  window requires that the reconstructed  $W$  boson can be combined with a b-jet (not previously paired with a high- $p_T$  lepton) to give an invariant mass within 40 GeV of the top

Figure 1: Lepton - b-jet invariant mass spectra for the lepton and b-jet pairs from the same top quark (full line) and from different top quarks (dashed line).

quark mass. This extra mass cut was applied by default in the whole top quark charge analysis using the weighting approach.

### 3.3 The jet track charge weighting approach

The determination of the average b-jet charge was done using a weighting technique in which the b-jet charge is evaluated as the weighted sum of the b-jet track charges:

$$Q_{\text{bjet}} = \frac{\sum_i q_i |\vec{j}_i \cdot \vec{p}_i|^\kappa}{\sum_i |\vec{j}_i \cdot \vec{p}_i|^\kappa} \quad (3)$$

where  $q_i(p_i)$  is the charge (momentum) of the  $i^{\text{th}}$  track inside the jet and  $\vec{j}$  is the b-jet axis unit vector. The  $\kappa$  parameter was optimised for the best separation between b- and  $\bar{\text{b}}$ -jets and the optimum value was found to be  $\kappa = 0.5$ . In addition, for the charge weighting technique, it was further required, using only tracks with  $p_T > 1.5$  GeV, that at least two tracks must be found within a cone with  $\Delta R < 0.4$  with respect to the jet axis. For b-jets with more than seven such tracks, only the seven with the highest  $p_T$  are used. The parameters of the weighting procedure are the result of a maximisation of the difference between the mean values of the b- and  $\bar{\text{b}}$ -jet charge distributions - these mean values were found for a set of the parameters values ( $\kappa$  and track  $p_T$ ) and compared. For the procedure optimisation the signal  $t\bar{t}$ -sample was used.

### 3.4 Semileptonic b-decay approach

In this approach the pairing procedure described in Section 3.2 is also used. But in this case the b quark charge is determined through its semileptonic decay. The sign of the b-jet charge is determined by the lepton charge within the b-jet,

$$\text{b} \rightarrow \text{c}, \text{u} + \ell^- + \bar{\nu}, \quad \bar{\text{b}} \rightarrow \bar{\text{c}}, \bar{\text{u}} + \ell^+ + \nu.$$

The lepton from the b-decay will be identified as a non-isolated lepton inside the corresponding b-jet, and its charge ( $Q_{\text{nonIs}}$ ) defines the b quark charge. The non-isolated lepton is searched for among the tracks pointing to the treated b-jet and originating in the corresponding secondary vertex. Several processes can lead to an incorrect b quark charge assignment with this approach. Semileptonic decays of D mesons produced in the B decay chain, and the  $\text{B}^0$ - $\bar{\text{B}}^0$  mixing are examples of such processes. To

suppress the contribution from D mesons, the non-isolated lepton transverse momentum with respect to the b-jet axis,  $p_T^{\text{rel}}$ , can be used. The fact that the lepton  $p_T^{\text{rel}}$  from b-decays is, on average, higher than from D meson decays can be used to diminish this contamination. The  $p_T^{\text{rel}}$  cut was optimised using a sample of  $\approx 555000$  signal  $t\bar{t}$  events and the value of 1 GeV has been found as the optimum cut. An additional source of wrong b quark charge assignments is mistagging, i.e. light jets incorrectly tagged as b-jets.

The main drawback of this approach is that, from all the selected lepton plus b-jet pairs, only those with a b-jet containing a non-isolated lepton can be used in the analysis. In addition to that, due to difficulties in selecting a pure sample of electrons from within jets, only muons were taken as the non-isolated leptons.

### 3.5 Results

In both approaches, the Standard Model scenario of top quark production and decay is assumed. The corresponding results are discussed in the following sections.

#### 3.5.1 Weighting technique approach results

As a first step, the efficiency and purity of the lepton b-jet pairing was investigated. Using the events which passed the selection criteria, the obtained pairing efficiency is  $\varepsilon = 30.5\%$  and the pairing purity is  $P = 85.6\%$ . The purity of pairing is defined as  $P = N_{\text{good}}/N_{\text{all}}$ , where  $N_{\text{good}}$  ( $N_{\text{all}}$ ) is the number of correctly paired lepton – b-jet pairs (all treated pairs) and the Monte Carlo truth is used to find  $N_{\text{good}}$ .

The b-jet charge spectra reconstructed using the Monte Carlo truth and invariant mass pairing procedure for the signal  $t\bar{t}$  events are presented in Figure 2, left and right respectively. From Figure 2, the shift of the b-jet charges associated with  $\ell^+$ ,  $Q_{\text{bjet}}^{(+)}$ , and  $\ell^-$ ,  $Q_{\text{bjet}}^{(-)}$ , (or with b and  $\bar{b}$  quark in the Monte Carlo case) is clearly seen. The obtained b-jet charge purity, defined as the percentage of b-jets with the correct charge ( $Q_{\text{bjet}}^{(+)} < 0$  and  $Q_{\text{bjet}}^{(-)} > 0$ ), is  $P \approx 62\%$ . In addition to that, the  $Q_{\text{comb}}$  b-jet charge spectrum, defined as  $Q(\ell) \times Q_{\text{bjet}}^{(\ell)}$ , has been reconstructed. The influence of trigger was also investigated, namely the lepton level 1 and level 2 triggers as well as the event filter (EF). The results with and without trigger are summarised in Table 4. No significant impact of the trigger is observed. A small asymmetry in favour of the positive b-jet charge, as was revealed by the analysis, is due to the dominance of positive charge in the initial state (two colliding protons).

Note that the peaks at  $\pm 1$  in Fig. 2 correspond to the cases when all the tracks pointing to a b-jet have the same charge sign - in this case the weighting procedure (2) gives  $Q_{\text{bjet}} = \pm 1$ .

Table 4: The mean b-jet charge associated with positive ( $Q_+$ ) and negative ( $Q_-$ ) lepton and combined b-jet charge ( $Q_{\text{comb}}$ ) without (no) and with (yes) EF trigger; two b-tags required.

trigger	$Q_+$	$Q_-$	$ Q_{\text{comb}} $	Nevent	efficiency
no	$-0.092 \pm 0.006$	$0.103 \pm 0.006$	$0.097 \pm 0.004$	7129	100.0
yes	$-0.095 \pm 0.006$	$0.106 \pm 0.006$	$0.101 \pm 0.004$	6130	86.0

The main background processes for the top quark charge measurement in the semileptonic mode are:  $W$ + jets production (the most important background in this mode), QCD multi-jets, di-boson and single top quark production. The single top production is not a genuine background as it gives the same sign of the b-jet charge asymmetry as the signal. For the selection criteria that were used, the ratio of the accepted semileptonic  $t\bar{t}$  events to the accepted single lepton ones is more than 15:1. In the dileptonic

Figure 2: The b-jet charge associated with positive (full line) and negative (dashed line) lepton using the Monte Carlo truth (left) and invariant mass criteria (right) for the  $\ell b$ -pairing.

mode, the background is composed of Drell-Yan pairs (the most significant background), multi-jet QCD processes and di-boson production [2].

The background studies for this analysis require large Monte Carlo samples (in addition to the standard cuts the invariant mass criterion is highly restrictive) not available at present. The ideal way to determine the basic background parameters, the S:B ratio and background charge asymmetry, is to use the W+jets (dominant background) samples. However, after applying the selection criteria to the available W+jets samples, only a few events remained (20 lepton b-jet pairs). It is clear that due to poor statistics the samples are not suitable for a valuable background analysis. Nonetheless, combining the b-jet charge spectra, obtained for the individual W+jets channels ( $W+n\times\text{jets}$  and  $Wb\bar{b}$ ,  $Wc\bar{c} + n\times\text{jets}$ ) scaled according to their cross sections to 1 fb, a S:B ratio of  $\approx 38 \pm 8$  was obtained. To fix the S:B ratio we need to include other backgrounds and take a regard for the poor statistics. Taking into account only the standard cuts with a loose  $M_W$  window ( $\pm 30$  GeV) a value of 7:1 was obtained for the S:B ratio which is compatible with that of the CDF background studies [2]. As a result, a nominal S:B ratio of 30:1 has been assumed, with 7:1 as a very conservative lower limit for studying systematic uncertainties related to the background.

The poor statistics of the available W+jets samples does not enable the background b-jet charge asymmetry to be determined precisely, the obtained value being  $\approx -0.02 \pm 0.05$ . On the other hand, as it was shown by CDF [2], no marked background asymmetry is expected. For this reason, as a background, we use the signal events but without the pairing of leptons and b-jets. As a consequence the obtained b-jet charge spectrum is not correlated with the high  $p_T$  lepton charge and should not have any charge asymmetry. Assuming the nominal S:B ratio, the spectrum is normalized to 1/30 of the signal statistics. The analysis showed that this background exhibits practically no asymmetry. For the systematics studies, a background corresponding to S:B=7:1 was also considered.

To find a realistic b-jet charge distribution, the signal and background distributions are combined. In Figure 3 (left) the expected b-jet charge ( $Q_{\text{comb}}$ ) distribution combining the signal with the background (full line) and the background itself (dashed line) are shown. From the reconstructed b-jet charge spectra using the two treated backgrounds, the expected mean b-jet charge (assuming the Standard Model) is:

$$Q_{\text{comb}} = -0.094 \pm 0.0042 \text{ (stat).}$$

The  $Q_{\text{comb}}$  value is obtained as the mean value of the signal plus background (S+B) distribution combining signal with the background.

In conclusion,  $\approx 6000$   $\ell b$  combinations could be selected for the top quark b-jet charge analysis, using the  $1 \text{ fb}^{-1}$  sample. The expected combined b-jet charge purity,  $N(Q_{\text{bjet}} < 0)/N_{\text{all}}$ , is  $\approx 0.62 \pm 0.01$  for the Standard Model case.

Figure 3: Left: the full S+B b-jet charge ( $Q_{\text{comb}}$ ) distribution (full line) and the background itself (dashed line); right: the reconstructed top quark charge ( $Q_t^{\text{comb}}$ ) (full line) and its background (dashed line).

Taking into account the statistical uncertainty of the obtained mean b-jet charge ( $Q_{\text{comb}}$ ) it can be stated that the obtained value will differ from 0 by more than  $20\sigma$ . Using a simple statistical treatment it is easy to show that for a reliable determination of  $Q_{\text{comb}}$  ( $\geq 5\sigma$ ) a sample of  $\approx 0.1 \text{ fb}^{-1}$  should be sufficient. In addition to that the analysis has revealed that the reconstructed b-jet charge is more influenced by the size of the S:B ratio than by the background asymmetry: going from the pure signal b-jet charge spectrum to that of the 7:1 mixture of signal and background, the mean b-jet charge decreased by 14%, while a replacement of the symmetric background by the asymmetric one with an asymmetry 1/4 of the signal one, leads to only 3% change of the charge at the 7:1 S:B ratio.

The direct reconstruction of the top quark charge can be done relying on the obtained value of  $Q_{\text{comb}}$  (see above). Using the Standard Model value of the b quark charge ( $Q_b = -1/3$ ) and the mean reconstructed value of the b-jet charge ( $Q_{\text{comb}}$ ), the b-jet charge calibration coefficient  $C_b = Q_b/Q_{\text{comb}}$  is  $3.54 \pm 0.16$  and the top quark charge then reads:

$$Q_t = Q(\ell^+) + Q_{\text{bjet}}^{(+)} \times C_b, \quad Q_t = Q(\ell^-) + Q_{\text{bjet}}^{(-)} \times C_b \quad (4)$$

where  $Q(\ell^\pm) = \pm 1$  is the lepton charge and  $Q_{\text{bjet}}^{(\pm)}$  is as above.

The reconstructed top quark charge is shown in Figure 3 (right) for the sample of  $1 \text{ fb}^{-1}$ . The absolute value of top quark charge obtained by combining  $Q_t$  and  $Q_{\bar{t}}$  for the above mentioned sample is  $Q_t^{\text{comb}} = 0.67 \pm 0.06 \text{ (stat)} \pm 0.08 \text{ (syst)}$ . The statistical error assumes that the relative error of  $C_b$  is the same as that of  $Q_{\text{comb}}$ . The systematic error of  $Q_t^{\text{comb}}$  can be studied comprehensively only by using experimental data<sup>2</sup>. In this case the main source of the systematic error is the weighting procedure that influences the coefficient  $C_b$ , that should be determined independently on the investigated b-jet charge, as well as the mean b-jet charge. In our case only the systematics stemming from determination of the mean b-jet charge were taken into account.

### 3.5.2 Semileptonic b-decay approach results

The charge of the non-isolated lepton found within the b-jet provides discrimination between the Standard Model and the exotic hypotheses on a statistical basis. Figure 4 shows the number of b-jets, which have been paired with positive (left) and negative (right) high  $p_T$  lepton and which contain inside a non-isolated lepton, as a function of the charge ( $Q_{\text{nonIs}}$ ) of the contained non-isolated lepton. The mean values

<sup>2</sup>The reconstructed b-jet charge or coefficient  $C_b$  for an experimental sample, e.g. dijet  $b\bar{b}$  data, should be compared with the corresponding Monte Carlo one to look for a possible difference in the b-jet track topology between Monte Carlo and real data.

of the non-isolated lepton charge obtained from these figures are:

$$\bar{Q}_{\text{nonIs}}^{(+)} = \frac{N(\ell^+) - N(\ell^-)}{N(\ell^+) + N(\ell^-)} = -0.32 \pm 0.05, \quad \bar{Q}_{\text{nonIs}}^{(-)} = \frac{N(\ell^+) - N(\ell^-)}{N(\ell^+) + N(\ell^-)} = 0.30 \pm 0.05,$$

where  $\bar{Q}_{\text{nonIs}}^{(+)}$  ( $\bar{Q}_{\text{nonIs}}^{(-)}$ ) is the mean charge of the non-isolated leptons in the b-jets paired with the positive (negative) high  $p_T$  lepton.  $N(\ell^-)$  ( $N(\ell^+)$ ) is the number of b-jets with a negative (positive) charged lepton. The quantity  $Q(\ell) \times Q_{\text{nonIs}}^{(\ell)}$ , where  $Q(\ell)$  is the charge of the lepton paired with the b-jet containing a non-isolated lepton, can be used to combine both histograms. The obtained mean combined charge in the Standard Model is  $\bar{Q}_{\text{nonIs}}^{(\text{comb})} = -0.31 \pm 0.04$ , showing a potential to distinguish between the Standard model and exotic hypothesis even with  $1 \text{ fb}^{-1}$  of data, as in the case of the exotic scenario the opposite value of  $\bar{Q}_{\text{nonIs}}^{(\text{comb})}$  is expected.

Figure 4: Number of b-jets, containing a non-isolated lepton inside, associated with positive (left) and negative (right) high  $p_T$  lepton vs the charge of the non-isolated lepton. The contribution of different sources of leptons are marked by different shading styles.

### 3.6 Systematic uncertainties

The systematic studies have been done following the prescription described in Section 6 of Chapter 1. The resulting systematic errors are summarised in Table 5. The systematic uncertainty caused by the top quark mass was estimated from the absolute difference between the  $Q_{\text{comb}}$  reconstructed at the nominal value (175 GeV) and  $m_t=160$  and 190 GeV and rescaling to an effective 2 GeV uncertainty. The systematic uncertainty connected with the signal to background ratio was found assuming that this ratio is known with 30% uncertainty. The background asymmetry systematics was estimated assuming that the background charge spectrum asymmetry is at a level of 10% of the signal one.

The systematic uncertainties due to Monte Carlo modeling of  $t\bar{t}$  signal were studied by comparing samples with different fragmentation parameters: an AcerMC/Pythia sample and the standard signal MC@NLO/Herwig one, giving values of  $18 \pm 13\%$  and  $16 \pm 13\%$  for the weighting and semileptonic approaches, respectively. The large uncertainties are due to a limited Monte Carlo statistics, so these values cannot be considered as a reliable estimate of the corresponding systematic uncertainties and are therefore not included in Table 5.

Pileup background affects the weighting technique procedure, as tracks from additional minimum-bias interactions get included in the jet charges. The associated systematic uncertainty was evaluated by comparing the standard sample to a dedicated  $t\bar{t}$  sample including pileup, leading to a shift of  $20 \pm 18\%$ . Since the Monte Carlo statistical error is large, and it is expected that any pileup effect can be minimised

(at least at moderate LHC luminosities) by applying track impact parameter cuts to eliminate tracks from pileup vertices, this value is also not included Table 5.

Table 5: The systematic uncertainties (%) of the mean reconstructed charge,  $Q_{\text{comb}}$ , the weighting technique and b-decay approaches.

Source	Weighting (%)	b-decay (%)
jet scale	0.7	0.3

## 4 Polarization studies in $t\bar{t}$ semileptonic events

The measurements of the W-boson and top quark polarizations in  $t\bar{t}$  events provide a powerful test of the top quark production and decay mechanisms and are a sensitive probe of new physics. W-boson or top quark spin information can be inferred from the angular distributions of the daughter particles in the W-boson or top quark rest frame, respectively. The W-boson can be produced with right, left or longitudinal polarizations, with corresponding partial widths  $\Gamma_R$ ,  $\Gamma_L$ ,  $\Gamma_0$  that depend on new anomalous couplings [61] ( $V_R$ ,  $V_L$ ,  $g_L$  and  $g_R$ ) which can appear at the  $Wtb$  vertex (see Eq. 1).

### 4.1 W-boson polarization and $t\bar{t}$ spin correlation measurements

The probability for the three helicity states of W-boson produced in top quark decay,  $F_0$  (longitudinal),  $F_L$  (left-handed) and  $F_R$  (right-handed), can be extracted from the  $\Psi$  angular distribution [61] :

$$\frac{1}{N} \frac{dN}{d\cos\Psi} = \frac{3}{2} \left[ F_0 \left( \frac{\sin\Psi}{\sqrt{2}} \right)^2 + F_L \left( \frac{1 - \cos\Psi}{2} \right)^2 + F_R \left( \frac{1 + \cos\Psi}{2} \right)^2 \right], \quad (5)$$

where  $\Psi$  is the angle between the W-boson direction in the top quark rest frame and the charged lepton direction in the W-boson rest frame obtained by a boost along the W-boson flying direction in the top quark rest frame. The correlation between the parameter couples  $(F_0, F_L)$ ,  $(F_0, F_R)$  and  $(F_L, F_R)$  are -0.9, -0.8 and 0.4, respectively.

Although, in the Standard Model, top quarks are produced unpolarised in  $t\bar{t}$  events, their spins are correlated [62]. The production asymmetry  $A$  in these events, measures the spin correlation and is defined as

$$A = \frac{\sigma(t_{\uparrow}\bar{t}_{\uparrow}) + \sigma(t_{\downarrow}\bar{t}_{\downarrow}) - \sigma(t_{\uparrow}\bar{t}_{\downarrow}) - \sigma(t_{\downarrow}\bar{t}_{\uparrow})}{\sigma(t_{\uparrow}\bar{t}_{\uparrow}) + \sigma(t_{\downarrow}\bar{t}_{\downarrow}) + \sigma(t_{\uparrow}\bar{t}_{\downarrow}) + \sigma(t_{\downarrow}\bar{t}_{\uparrow})}, \quad (6)$$

where  $\sigma(t_{\uparrow/\downarrow}\bar{t}_{\uparrow/\downarrow})$  denotes the production cross-section of a top quark pair with spins up or down with respect to a selected quantisation axis. It can be extracted from the  $\theta_1$  and  $\theta_2$  angular distributions [62]:

$$\frac{1}{N} \frac{d^2N}{d\cos\theta_1 d\cos\theta_2} = \frac{1}{4}(1 - A|\alpha_1\alpha_2|\cos\theta_1\cos\theta_2), \quad (7)$$

where  $\theta_1$  ( $\theta_2$ ) is the angle between the  $t$  ( $\bar{t}$ ) direction, measured in the  $t\bar{t}$  rest frame, and the direction of the  $t$  ( $\bar{t}$ ) decay product in the  $t$  ( $\bar{t}$ ) rest frame obtained by a boost along  $t$  ( $\bar{t}$ ) direction in the  $t\bar{t}$  rest frame,  $\alpha_i$  is the spin analysing power of the top quark decay product  $i$ , which ranges between  $-1$  and  $1$  and measures the degree to which its direction is correlated with the spin of the parent top quark. The parameter  $A_D$  defined in [20], used to measure the production asymmetry in another basis, is extracted from the  $\Phi$  angular distribution [62] :

$$\frac{1}{N} \frac{dN}{d\cos\Phi} = \frac{1}{2}(1 - A_D|\alpha_1\alpha_2|\cos\Phi), \quad (8)$$

where  $\Phi$  is the angle between the direction of flight of the two spin analysers, defined in the  $t$  and  $\bar{t}$  rest frames respectively.

Table 6: Standard Model values of W-boson polarization parameters( $F_0$ ,  $F_L$ ,  $F_R$ ) at the next-to-leading order and  $t\bar{t}$  spin correlation parameters ( $A$ ,  $A_D$ ) at leading order for a top quark mass of 175 GeV. For  $A$  and  $A_D$  the asterisk superscript means that  $m_{t\bar{t}} < 550$  GeV is applied.

$F_0$	$F_L$	$F_R$	$A^*$	$A_D^*$
0.695	0.304	0.001	0.422	-0.290

The Standard Model predictions for the W-boson polarization ( $F_0$ ,  $F_L$ ,  $F_R$ ), at next-to-leading order, and  $t\bar{t}$  spin correlation ( $A$ ,  $A_D$ ), at leading order, are given in Table 6. The ATLAS sensitivity to these observables has been evaluated with an ATLFAST simulation [20] and a full simulation of a perfect detector [63]. A precision of 1% to 5% should be achievable with  $10 \text{ fb}^{-1}$  of data, dominated by systematic uncertainties (in particular from the b-jet energy scale). This measurement requires a complete reconstruction of the  $t\bar{t}$  system and a reliable Monte Carlo description to correct the distortion induced by trigger, cuts and reconstruction. In this section the robustness of the analysis with a realistic detector simulation including triggering is assessed. Only the semileptonic topology of the  $t\bar{t}$  events ( $t\bar{t} \rightarrow WWb\bar{b} \rightarrow \ell\nu_{j1}j_2b\bar{b}$  with  $\ell = e, \mu$ ) is used as signal (an analysis using  $t\bar{t}$  dilepton events as signal can improve the results of this study, especially for the  $t\bar{t}$  spin correlation measurements). In this case the most powerful spin analysers of the top quark are the charged lepton ( $\alpha_1 = 1$ ) and the least energetic non b-jet in the top quark rest frame ( $\alpha_{\text{jet}} = 0.51$ ) [64], which are chosen afterwards for the spin correlation measurement.

#### 4.1.1 Event simulation and selection

The largest statistics Monte Carlo sample was generated with MC@NLO which does not implement  $t\bar{t}$  spin correlations, so it can only be used to study W-boson polarisation. Spin correlations were studied using the smaller AcerMC sample. In both cases, non-semileptonic  $t\bar{t}$ , semileptonic  $t\bar{t}$  which decay to  $\tau$ , W-boson+jets and single top quark events were considered as background. Semileptonic signal events are characterised by one (and only one) isolated lepton, at least 4 jets, of which at least 2 jets are tagged as b-jets, and missing transverse energy. Following the common criteria for the semileptonic selection, all kinematic cuts are summarised in Table 7 together with the corresponding signal efficiencies.

After kinematic cuts are applied, the event is fully reconstructed, as described below. The angles  $\Psi$ ,  $\theta_1$ ,  $\theta_2$  and  $\Phi$  are computed and the polarization parameters are extracted.

Table 7: Selection cuts used and corresponding efficiencies for semileptonic  $t\bar{t}$  MC@NLO events and  $t\bar{t}$  AcerMC events.

Variables	Cuts	Efficiency (%)	
		MC@NLO	AcerMC
Lepton	exactly 1 identified	57.8	58.7
Jets	at least 4 selected jets	59.3	62.1
b-tagging	at least 2 are tagged as b	32.0	31.0
Missing energy	$p_T^{\text{miss}} > 20$ GeV	92.0	92.2
Cumulative efficiency		9.4	9.8

#### 4.1.2 W-boson and top quark reconstruction

The energies of all jets are calibrated according to the comparison with the energies of corresponding parton level quarks before selection and reconstruction. Then, in the event reconstruction, the light jet pair with invariant mass  $m_{jj}$  closest to the known W-boson mass,  $m_W$ , is selected to reconstruct the W-boson which decays hadronically. This W-boson is then combined with one of the b-jets to reconstruct the top quark. As there are several possible combinations, the one which gives the mass closest to the top quark mass  $m_t$  is assumed to be the correct one. The b-jet which is closest to the lepton in  $\Delta R$  among the remaining b-jets, is reserved for reconstructing the other top quark whose daughter W-boson decays leptonically. To reconstruct the W-boson which decays leptonically, the neutrino  $p_T$  is taken as the missing transverse energy. Its longitudinal component  $p_z$  is determined by constraining  $m_{l\nu}$  to  $m_W$  [63]. When two solutions for  $p_z$  are found, the one giving  $m_{l\nu b}$  closer to  $m_t$  is kept.

Quality cuts  $|m_{jjb} - m_t| < 35$  GeV,  $|m_{l\nu b} - m_t| < 35$  GeV and  $|m_{jj} - m_W| < 20$  GeV are applied to reject badly reconstructed events. At this stage, 2.8% of the signal events are kept for MC@NLO events and 2.7% for AcerMC events, corresponding to 7000 signal events for  $1 \text{ fb}^{-1}$  of data (Table 8). After this event selection, the main background comes from the  $t\bar{t} \rightarrow \tau + X$  events, where the tau decays to electron or muon. The number of events from W-boson+jets and single top quark channels is less than 3% of the selected number of signal events, so we neglect them in the following sections. Due to this cancellation of the background, the S/B ratio can be affected as much as 20%, which is taken as a systematic uncertainty (see Table 10).

After event reconstruction, the angle  $\Psi$  (W-boson polarization) as well as the angles  $\theta_1$ ,  $\theta_2$  and  $\Phi$  ( $t\bar{t}$  spin correlations) are computed using the prescription described at the beginning of Section 4. The measured distributions of  $\cos \Psi$ ,  $\cos \theta_1 \times \cos \theta_2$  and  $\cos \Phi$  are distorted, compared with their distributions at parton level. The detector resolution results in much smaller smearing effect on the final particles than that coming from particle radiation, quark fragmentation-hadronization and final event reconstruction. That is to say, the latter effects dominate the resolution of the reconstructed objects from top quark decay [65]. A correction function, taken from the ATLFAST simulation, is used to recover the distributions at parton level. With ATLFAST data, the correction function is obtained from the ratio between the two normalized distributions of the  $\cos \Psi$  (i.e. after reconstruction of the signal and main background events and at parton level of the pure signal). To correct for the distortion, a weight derived from this function is applied on all the reconstructed  $\cos \Psi$  of full simulation, on an event by event basis, allowing to recover, as much as possible, the shape of the distribution of the  $\cos \Psi$  of the pure signal at parton level. A detailed description of the method can be found in [20].

Table 8: The number of signal (MC@NLO) and the most important background events before (left) and after (right) selection for  $1 \text{ fb}^{-1}$ . \*: in the single top quark decay  $W \rightarrow e/\mu/\tau + \nu$  mode

	Events for $1 \text{ fb}^{-1} (\times 10^3)$	Selected events full simulation
<b>Signal</b> ( $t\bar{t}$ semileptonic)	250	7000
$t\bar{t} \rightarrow \tau + X$	130	710
$W(\rightarrow l\nu) + \text{jets}$	800	[10,55]
Single t ( $Wt$ channel)	25*	90
Single t ( $t$ channel)	80*	55

#### 4.1.3 Impact of the trigger on the analysis

Semileptonic  $t\bar{t}$  events are characterised by a single isolated lepton, which can be used to trigger the events with high efficiency. Applying the trigger selection to events passing the standard selection cuts, 15% of well reconstructed events are lost. The measurement results with and without trigger applied on the data, while keeping all other aspects of the measurement unchanged, were compared. The effect of the trigger on the measurements of the W-boson polarization is almost zero. But the effect on the  $t\bar{t}$  spin correlations is not negligible, and is taken as a systematic error, shown in Table 10.

#### 4.1.4 Measurement of the W-boson polarization

Figure 5 shows the correction function (left) and the reconstructed  $\cos\Psi$  distribution (right) after applying the correction function. This distribution is fitted to Eq. (5) varying  $F_0$ ,  $F_L$  and  $F_R$ , but constrained by  $F_0 + F_L + F_R = 1$ . The fit is restricted to the region  $-0.9 < \cos\Psi < 0.8$ , which is the most extended region where the correction is varying slowly. The results are shown in Table 9.

Figure 5: Left: Correction function taken from ATLFAST simulation fitted with a third order polynomial function. Right: Normalised reconstructed and corrected distribution of  $\cos\Psi$ , the full line corresponds to the fit to Eq. (5). The sample has an integrated luminosity of  $730 \text{ pb}^{-1}$ .

Two complementary methods to extract the W-boson helicity fractions, using the observed angular distribution between the charged lepton direction in the W-boson rest frame and the W-boson direction in the top quark rest frame, are currently under development at ATLAS inspired on Tevatron methods [5,66].

#### 4.1.5 Measurement of $t\bar{t}$ spin correlation

At parton level, before any phase space cut, the two estimators  $C = -9 \times \cos \theta_1 \cos \theta_2$  and  $D = -3 \times \cos \Phi$  are unbiased [20]. Figure 6 shows the reconstructed distributions of  $-9 \times \cos \theta_1 \cos \theta_2/0.51$  and  $-3 \times \cos \Phi/0.51$  after correction. It should be stressed that, in the evaluation of the  $t\bar{t}$  spin correlation parameters, the theoretical value for the spin analyzing power for signal events (0.51) was assumed for both cases. The means of the distributions are unbiased estimators of  $A$  and  $A_D$ , provided corrections for

Figure 6: Left: Reconstructed and corrected distribution of  $-9 \times \cos \theta_1 \cos \theta_2/0.51$ . Right: Reconstructed and corrected distribution of  $-3 \times \cos \Phi/0.51$ . The integrated luminosity of the sample is  $220 \text{ pb}^{-1}$  in each case.

physics effects and detector effects are fully carried out.

Due to the fact that the ATLFASST was used to extract the correction function, an additional systematic uncertainty of 0.25 was derived for the  $A$  spin correlation parameter. This uncertainty reflects the different parametrizations of the Monte Carlo simulations. Preliminary studies suggest that this shift can be removed by using high statistics full simulation samples to derive the correction functions and for this reason this uncertainty was not included in Table 10.

Table 9: W-boson polarization and top quark spin correlation parameters extracted after triggering. The indicated errors are statistical and systematic, respectively.

W-boson polarization	$F_L$	$F_0$	$F_R$
	$0.29 \pm 0.02 \pm 0.03$	$0.70 \pm 0.04 \pm 0.02$	$0.01 \pm 0.02 \pm 0.02$
$t\bar{t}$ spin correlation	$A$	$A_D$	
	$0.67 \pm 0.17 \pm 0.18 \pm 0.25$	$-0.40 \pm 0.11 \pm 0.09$	

#### 4.1.6 Systematic uncertainties

The systematic uncertainties were estimated with ATLFASST simulation for the factorisation scale, structure function, ISR, FSR, b-fragmentation, top quark mass, hadronization scheme and pile-up effects, and with full simulation for the b-tagging efficiency, b-jet energy scale, light jet energy scale and signal to background ratio (S/B scale) as listed in Table 10, for the measurement of the W-boson helicity fractions and top quark pair spin correlations respectively.

With data,  $t\bar{t}$  events can be reconstructed without requiring b-jet tagging on the side of top quark whose daughter W-boson decays leptonically. This can provide a pure sample of b-jets which can be

Table 10: Systematics for W-boson polarization and top quark spin correlation measurement.

Source of uncertainty	$F_L$	$F_0$	$F_R$	$A$	$A_D$
Factorisation	0.000	0.001	0.001	0.029	0.006

Trigger	-	-	-	0.10	0.03
TOTAL	0.03	0.02	0.02	0.18	0.09

used to check the uncertainty on the b-tagging efficiency [67]. The b-jet energy miscalibration can also be obtained from other control samples, such as Z+b-jet events [68].

## 4.2 Anomalous couplings at the Wtb vertex

The W-boson polarisation is sensitive to new anomalous couplings ( $V_L$ ,  $V_R$ ,  $g_L$  and  $g_R$ ) associated with the Wtb vertex. Although the W-boson helicity fractions ( $F_0$ ,  $F_L$  and  $F_R$ ) depend on these couplings, the helicity ratios  $\rho_{R,L} \equiv \Gamma_{R,L}/\Gamma_0 = F_{R,L}/F_0$ , were found to be more sensitive to  $V_L$ ,  $V_R$ ,  $g_L$  and  $g_R$ . The  $\rho_R$  and  $\rho_L$  observables are independent quantities and take the LO values  $\rho_R = 5.1 \times 10^{-4}$ ,  $\rho_L = 0.423$  in the Standard Model. General expressions for  $\rho_{R,L}$  in terms of the new anomalous couplings can be found in Ref. [19]. As for the helicity fractions, the measurement of helicity ratios sets bounds on  $V_R$ ,  $g_L$  and  $g_R$ . A third and simpler method to extract information about the Wtb vertex is through angular asymmetries involving the angle of the charged lepton in the W-boson rest frame and the W-boson direction in the top quark rest frame (introduced in the previous section). For any fixed  $z$  in the interval  $[-1, +1]$ , one can define asymmetries as the difference between the number of events above and below  $z$ , normalised to the total number of events. The most obvious choice is  $z = 0$ , giving the forward-backward asymmetry  $A_{FB}$  [18, 69]. The forward-backward asymmetry is related to the W-boson helicity fractions by  $A_{FB} = \frac{3}{4} [F_R - F_L]$ . Other convenient choices are  $z = \mp(2^{2/3} - 1)$ . Defining  $\beta = 2^{1/3} - 1$ , we have  $A_+ = 3\beta[F_0 + (1 + \beta)F_R]$  and  $A_- = -3\beta[F_0 + (1 + \beta)F_L]$ . Thus,  $A_+$  ( $A_-$ ) only depend on  $F_0$  and  $F_R$  ( $F_L$ ). The LO Standard Model values of these asymmetries are  $A_{FB} = -0.223$ ,  $A_+ = 0.548$ ,  $A_- = -0.840$ . They are sensitive to anomalous Wtb interactions, and their measurement allows to probe this vertex without the need of a fit to the distribution of the angle between the charged lepton direction in the W-boson rest frame and the W-boson direction in the top quark rest frame. In the present analysis the ATLAS sensitivity to the  $\rho_L$ ,  $\rho_R$ ,  $A_{FB}$ ,  $A_+$  and  $A_-$  observables is studied.

### 4.2.1 Event selection

In this section an alternative two-level likelihood analysis is explored for the semileptonic channel, i.e.  $t\bar{t} \rightarrow W^+bW^-\bar{b}$  where one of the W-bosons decays hadronically and the other one decays in the leptonic

channel  $W \rightarrow \ell \nu_\ell$  (with  $\ell = e, \mu$ ). Any other process constitutes a background to this signal. In particular, it should be noticed that the fully hadronic, dileptonic and semileptonic (with one of the W-bosons decaying into  $\tau \nu$ )  $t\bar{t}$  channels are considered backgrounds to the present analysis. Additionally, the following Standard Model processes were considered as background: single top production, W+jets,  $Wb\bar{b}$ +jets,  $Wc\bar{c}$ +jets,  $Z \rightarrow e^+e^-$ ,  $Z \rightarrow \mu^+\mu^-$ ,  $Z \rightarrow \tau^+\tau^-$ , WW, ZZ and WZ. The likelihood analysis is based on the construction of a discriminant variable which uses distributions of some kinematical properties of the events. In the first analysis level (called the pre-selection), the common selection criteria for the semileptonic topology, with the exception of the b-tagging requirement on jets, was applied to the event. The full event reconstruction was performed using a  $\chi^2$ , defined by

$$\chi^2 = \frac{(m_{\ell\nu_{ja}} - m_t)^2}{\sigma_t^2} + \frac{(m_{j_b j_c j_d} - m_t)^2}{\sigma_t^2} + \frac{(m_{\ell\nu} - m_W)^2}{\sigma_W^2} + \frac{(m_{j_c j_d} - m_W)^2}{\sigma_W^2}, \quad (9)$$

where  $m_t = 175$  GeV,  $m_W = 80.4$  GeV,  $\sigma_t = 14$  GeV and  $\sigma_W = 10$  GeV are the expected top quark and W-boson mass resolutions<sup>3</sup>,  $\ell$  represents the selected electron or muon,  $m_{\ell\nu}$  is the invariant mass of the electron (muon) and the neutrino, and  $j_{a,b,c,d}$  corresponds to all the possible combinations among the four jets with highest  $p_T$  (with  $m_{\ell\nu_{ja}}$ ,  $m_{j_b j_c j_d}$  and  $m_{j_c j_d}$  being the corresponding invariant masses). The neutrino was reconstructed using the missing transverse energy and allowing the  $p_z^\nu$  to vary in the range  $[-500, +500]$  GeV. The solution corresponding to the minimum  $\chi^2$  was chosen. The jets used to reconstruct the hadronic W-boson will be labelled “non-b” jets and the remaining two are labelled “b-jets”. It should be stressed that no b-tagging information was used so far. The pre-selection was completed by requiring  $\chi^2 < 16$ . In the second level (the final selection), signal and background-like probabilities were constructed for each event ( $\mathcal{P}_i^{\text{signal}}$  and  $\mathcal{P}_i^{\text{back.}}$ , respectively) using probability density functions (p.d.f.) built from relevant physical variables: the cosine of the angle between the leptonic top quark and the leptonic “b-jet”, the transverse momentum of the hadronic W, the hadronic and leptonic top quark masses, the transverse momentum of the two “b-jets”, the transverse momentum of the lepton and the  $\sqrt{\chi^2}$  distribution. It should be stressed that the objective is to test the sensitivity for new physics exclusion, under the hypothesis that the Standard Model holds, and the simulation was done assuming no anomalous couplings. Signal ( $\mathcal{L}_S = \prod_{i=1}^n \mathcal{P}_i^{\text{signal}}$ ) and background ( $\mathcal{L}_B = \prod_{i=1}^n \mathcal{P}_i^{\text{back.}}$ ) likelihoods (with  $n = 8$ , the number of p.d.f.) are used to define a discriminant variable  $L_R = \log_{10}(\mathcal{L}_S/\mathcal{L}_B)$ . The distribution of this variable is shown in Figure 7(a). The final event selection is done by applying the cut  $L_R > 0.1$  on the discriminant variable. The number of signal and background events (normalised to  $L = 1 \text{ fb}^{-1}$ ) after the pre-selection and final selection are shown in Table 11. After the final selection (including the trigger), the dominant backgrounds are W+jets and semileptonic  $t\bar{t}$  with taus in the final state (corresponding to 49%, and 29% of the total background, respectively, as shown in Table 12).

The effect of the single lepton trigger on the event selection was studied. The results are summarised in Table 11. In what follows, only events passing the trigger are considered.

Once b-tagging is well understood, additional information can be used. In this case only jets with a positive b-tagging weight were considered as “b-jet” candidates for the  $\chi^2$  minimisation method. In addition, the b-tagging weights of these jets were considered as p.d.f.s for the discriminant variable evaluation. In this case, the number of selected signal and background events for  $L = 1 \text{ fb}^{-1}$  is expected to be  $(6.6 \pm 0.1) \times 10^3$  and  $(0.9 \pm 0.1) \times 10^3$ , respectively. The  $t\bar{t}$  background is expected to be dominant (72% of the total background, mainly due to the semileptonic channel with taus in the final state) and the W+jets and single top processes correspond to 15% and 13% of the total background, respectively. The discriminant variables corresponding to the analysis with and without b-tagging are shown in Figure 7.

<sup>3</sup>These resolutions are taken from the top quark mass measurement analyses [70]. It should be noticed that  $\sigma_t$  and  $\sigma_W$  can be interpreted as weights for each term of the  $\chi^2$  definition. By changing their values by a factor  $\sim 2$ , the obtained observables ( $\rho_L$ ,  $\rho_R$ ,  $A_+$  and  $A_-$ ) are the same within the statistical error.

Table 11: Number of signal  $t\bar{t} \rightarrow \ell v b\bar{b} q\bar{q}'$  and background events (and corresponding statistical error), normalised to  $L = 1 \text{ fb}^{-1}$ , after the pre-selection and final selection for the analysis without b-tagging. The effect of the trigger on the event selection is also shown.

#### 4.2.2 Measurement of the angular distribution and asymmetries

The experimentally observed angular distribution, which includes the  $t\bar{t}$  signal as well as the Standard Model background, is affected by detector resolution,  $t\bar{t}$  reconstruction and selection criteria [71]. In order to recover the Standard Model distribution, it is necessary to subtract the background and correct for the effects of the detector, event selection and reconstruction. For this purpose, two different sets of signal and background event samples were used: one “experimental” set, which simulates a possible experimental result, and one “reference” set, which is used to parametrise the effects mentioned, and correct the previous sample. The procedure is as follows. After subtracting reference background samples, the full “experimental” distribution is multiplied by a correction function  $f_c$  in order to recover the Standard Model one. This correction function is determined by assuming that the charged lepton distribution corresponds to the Standard Model. In case that a deviation from Standard Model predictions (corresponding to anomalous couplings) is found, the correction function must be modified accordingly, and the expected distribution recalculated in an iterative process. These issues have been analysed in detail in Ref. [20], where it was shown that this process quickly converges. The correction function is calculated, for each bin of the angular distribution, by dividing the number of generated events by the number of selected events, using the reference sample. In order to avoid non-physical fluctuations due to the limited amount of Monte Carlo statistics, a smoothing procedure was applied to the obtained correction function. The value of  $f_c$  is in the range [0.2,1.4]. Other methods of correcting the angular distribution are under investigation.

The procedure of correcting for detector and reconstruction effects in the asymmetries is similar to that used with the full angular distribution, but using only two or three bins. This has the advantage that the asymmetry measurements are less sensitive to the extreme values of the angular distributions,

Figure 7: Discriminant variables for the Standard Model background (shaded region) and the  $t\bar{t}$  signal (full line), normalised to  $L = 1 \text{ fb}^{-1}$  corresponding to the (a) analysis without b-tagging and (b) analysis using the b-tagging weights of the “b-jets” selected by the  $\chi^2$  minimisation method.

where correction functions deviate from unity. Moreover, it should be noticed that the extreme bins of the angular distribution have a very significant impact on the measurement of the  $\rho_L$  and  $\rho_R$  helicity ratios. The values obtained from a fit to the corrected distribution, as well as the angular asymmetries  $A_{\text{FB}}$ ,  $A_{\pm}$ , are collected in Table 13, with their statistical uncertainties. Although the statistical errors of the observables obtained for the analyses without and with b-tagging are similar, the use of this tool allows to improve the signal to background ratio, leading to smaller systematic uncertainties, as discussed below.

Table 13: Expected values and corresponding statistical errors for the helicity ratios and angular asymmetries. The results for an integrated luminosity of  $1 \text{ fb}^{-1}$  (analyses with and without b-tagging) are shown.

#### 4.2.3 Systematic uncertainties

The study of the systematic uncertainties considered possible errors from different sources: jet energy scale, luminosity, top quark mass, background level, ISR and FSR, Monte Carlo generator and pile-up. The jet calibration used in the present analyses is described in Ref. [70]. As for the reference analyses, full simulation Monte Carlo samples were used for the study of all the systematic sources of uncertainty. Only the simulated sample used as the “experimental” set (which fakes the data) was changed for each systematic source of uncertainty. The correction function and the Monte Carlo sample used to perform the background subtraction were kept unchanged. The impact on the measurements is summarised in Tables 14 and 15. As the background subtraction is based on Monte Carlo simulation, the background estimation required a luminosity value and therefore the corresponding systematic uncertainty was considered. Once the cross-sections for known backgrounds are measured with data, a data-driven normali-

sation will be possible and the luminosity systematic error should be reduced. Moreover, with data it will be possible to compare the discriminant variable distributions for selected events obtained from data and Monte Carlo. This comparison will allow the correction of systematic uncertainties caused by inaccurate description of data by the Monte Carlo simulation.

Table 14: Sources of systematic uncertainties in the determination of the helicity ratios and angular asymmetries (analysis without b-tagging).

#### 4.2.4 Constraints on the anomalous couplings

Using the parametric dependence of the observables on  $V_R$ ,  $g_L$  and  $g_R$  (and considering the correlations between them, which are shown in Table 16), constraints can be set on the anomalous couplings. The helicity ratios  $\rho_{R,L}$  and the asymmetries  $A_{\pm}$  were used as input for the program TopFit [19]. The expected 68% CL allowed regions on the Wtb anomalous couplings for  $L = 1 \text{ fb}^{-1}$  (analyses with and without b-tagging) are shown in Figure 8. In addition to the allowed regions of Figure 8, additional solutions can be found at  $g_R \sim 0.8$ . Such solutions are due to a large cancellation between  $\mathcal{O}(g_R)$  and  $\mathcal{O}(g_R^2)$  terms and can be excluded by the measurement at the LHC of the single top cross-section [72].

Table 16: Correlation matrix for the  $A_{\pm}, \rho_{R,L}$  observables.

	$A_+$	$A_-$	$\rho_L$	$\rho_R$
$A_+$	1	0.16	-0.73	-0.14
$A_-$	0.16	1	-0.10	0.55
$\rho_L$	-0.73	-0.10	1	0.42
$\rho_R$	-0.14	0.55	0.42	1

 Figure 8: Expected 68% CL allowed regions on the  $Wtb$  anomalous couplings for luminosities of  $1 \text{ fb}^{-1}$  (with and without b-tagging), obtained from the  $\rho_{R,L}$  and  $A_{\pm}$  observables using TopFit.

## 5 Rare Top Quark Decays and FCNC

This section discusses the study of rare top quark decays via FCNC ( $t \rightarrow qX, X = \gamma, Z, g$ ) using  $t\bar{t}$  events produced at the LHC. These decays are strongly suppressed in the Standard Model at tree level due to the GIM mechanism. In the effective Lagrangian approach [73, 74] the new top quark decay rates to the gauge bosons can be expressed in terms of the  $\kappa_{tq}^g, \kappa_{tq}^\gamma, (|v_{tq}^Z|^2 + |a_{tq}^Z|^2)$  and  $\kappa_{tq}^Z$  anomalous couplings to the  $g, \gamma$  and  $Z$  bosons respectively, and  $\Lambda$ , the energy scale associated with the new physics.

### 5.1 Event samples

The signal event samples used in this analysis correspond to  $t\bar{t} \rightarrow b\bar{\ell}vqX$ , where  $X = \gamma, Z \rightarrow \ell\bar{\ell}, g$  and  $\ell = e, \mu$ . The following common Standard Model samples were considered as background: fully hadronic, fully leptonic and semi-leptonic  $t\bar{t}$ , all from MC@NLO;  $Wt, s-$  and  $t-$  channels of single top production, all from AcerMC;  $W+\text{jets}, Wb\bar{b}+\text{jets}$  and  $Wc\bar{c}+\text{jets}$ , all from ALPGEN;  $Z \rightarrow e^+e^-, Z \rightarrow \mu^+\mu^-$  and  $Z \rightarrow \tau^+\tau^-$ , all from PYTHIA;  $WW, ZZ$  and  $WZ$ , all from HERWIG.

### 5.2 Event selection

The  $t\bar{t}$  final states corresponding to the different FCNC top quark decay modes lead to different topologies according to the number of jets, leptons and photons. There is however a common characteristic of all channels under study, *i.e.* in all of them one of the top quarks is assumed to decay through the dominant Standard Model decay mode  $t \rightarrow bW$  and the other is forced to decay via one of the FCNC modes  $t \rightarrow qZ, t \rightarrow q\gamma$  or  $t \rightarrow qg$ . The QCD backgrounds at hadron colliders make the search for the signal via the fully hadronic channels (when the  $W$  and the  $Z$  bosons decay to quarks) difficult. For this reason only the

Table 17: Selection cuts applied to the FCNC analyses. For the  $t \rightarrow qg$  channel,  $E_{\text{vis}}$ ,  $p_{Tg}$  and  $m_{qg}$  represent the total visible energy, the transverse momentum of the jet associated with the gluon and the reconstructed mass of the top quark with FCNC decay, respectively (see text for details).

Channel	$t\bar{t} \rightarrow bWq\gamma$	$t\bar{t} \rightarrow bWqg$	$t\bar{t} \rightarrow bWqZ$
Pre-selection	$= 1\ell$ ( $p_T > 25$ GeV) $\geq 2j$ ( $p_T > 20$ GeV) $= 1\gamma$ ( $p_T > 25$ GeV) $p_T > 20$ GeV	$= 1\ell$ ( $p_T > 25$ GeV) $= 3j$ ( $p_T > 40, 20, 20$ GeV) $= 0\gamma$ ( $p_T > 15$ GeV) $p_T > 20$ GeV	$= 3\ell$ ( $p_T > 25, 15, 15$ GeV) $\geq 2j$ ( $p_T > 30, 20$ GeV) $= 0\gamma$ ( $p_T > 15$ GeV) $p_T > 20$ GeV
Final selection	$p_{T\gamma} > 75$ GeV	$E_{\text{vis}} > 300$ GeV $p_{Tg} > 75$ GeV $m_{qg} > 125$ GeV $m_{qg} < 200$ GeV	2 $\ell$ same flavour, oppos. charge
Trigger	e22i, mu20 or g55	e22i or mu20	e22i or mu20

Table 18: The trigger efficiency, in percentage, for the background and signal events after all the other cuts of the FCNC analyses.

	$t \rightarrow q\gamma$		$t \rightarrow qZ$		$t \rightarrow qg$	
	Sig.	Back.	Sig.	Back.	Sig.	Back.
Trigger	99.6	99.5	99.2	95.0	83.2	82.2

leptonic decays of both W and Z to e and  $\mu$  were taken into account. Only isolated muons, electrons and photons separated by  $\Delta R > 0.4$  from other reconstructed objects, were considered. Specific pre-selection and selection cuts were applied for each FCNC channel, as outlined in Table 17. For the  $t \rightarrow q\gamma$  channel, exactly one reconstructed lepton and one reconstructed photon were required in the events. Additionally, at least two jets were required. For the  $t \rightarrow qg$  channel, the events had to have exactly one reconstructed lepton, three jets and no reconstructed photon. Finally, for the  $t \rightarrow qZ$  channel, only the events with at least two jets, exactly three reconstructed leptons and no reconstructed photons were accepted. Therefore, the selection criteria for these channels are orthogonal. The expected number of background events and signal efficiencies after the final selection are shown in Table 19. The effect of the trigger on the background and signal events, after all the other cuts, is shown in Table 18. It should be noticed that the events of the  $t \rightarrow q\gamma$  ( $t \rightarrow qZ$ ) channel can be triggered by the lepton or the photon (one of the three leptons), which results on higher trigger efficiencies, when compared with the  $t \rightarrow qg$  channel with just one lepton. For the  $t \rightarrow q\gamma$  channel, the dominant backgrounds are  $t\bar{t}$ , Z+jets and W+jets events, which correspond to 38%, 30% and 29% of the total background. The total background for the  $t \rightarrow qZ$  channel is mainly composed of  $t\bar{t}$  and Z+jets events (59% and 28% of the total background, respectively), while for the  $t \rightarrow qg$  it is mainly composed of W+jets and  $t\bar{t}$  events (which correspond, respectively, to 64% and 25% of the total background).

For all the channels, the top quark with Standard Model semileptonic decay ( $t \rightarrow b\ell\nu$ ) cannot be directly reconstructed due to the presence of an undetected neutrino in the final state. The neutrino four-momentum was estimated with a method similar to the one used in Section 4.2, by finding the  $p_Z^\nu$  value and the jet combination (and the lepton combination in the case of the qZ topology) which minimizes the following expression:

$$\chi^2 = \frac{(m_t^{\text{FCNC}} - m_t)^2}{\sigma_t^2} + \frac{(m_{\ell_a\nu j} - m_t)^2}{\sigma_t^2} + \frac{(m_{\ell_a\nu} - m_W)^2}{\sigma_W^2} + \frac{(m_{\ell_b\ell_c} - m_Z)^2}{\sigma_Z^2}, \quad (10)$$

Table 19: The expected number of background events and signal efficiencies after the final selection level (the trigger is included) of the analyses for each FCNC channel. The corresponding statistical errors are also shown. The expected background numbers are normalised to  $L = 1 \text{ fb}^{-1}$ .

	e	$\mu$	$\ell$

where  $m_t^{\text{FCNC}}$ ,  $m_{\ell_a \nu j}$ ,  $m_{\ell_a \nu}$  and  $m_{\ell_b \ell_c}$  are, for each jet and lepton combination, the reconstructed mass of the top quark decaying via FCNC, the top quark decaying through the Standard Model, the W-boson from the top quark with Standard Model decay and the Z boson from the top quark FCNC decay, respectively. The last term of Eq. 10 was only used in the  $t \rightarrow qZ$  channel. The following values are used for the constraints:  $m_t = 175 \text{ GeV}$ ,  $m_W = 80.42 \text{ GeV}$ ,  $m_Z = 91.19 \text{ GeV}$ ,  $\sigma_t = 14 \text{ GeV}$ ,  $\sigma_W = 10 \text{ GeV}$  and  $\sigma_Z = 3 \text{ GeV}^4$ . No b-tag information was used to reconstruct the event kinematics. The jet chosen to reconstruct the top quark with Standard Model decay is labeled as b quark. For the  $t \rightarrow q\gamma$  and the  $t \rightarrow qZ$  channels, the other jet, which was used to reconstruct the top quark with FCNC decay, is denoted by q quark. For the  $t \rightarrow qg$  channel, it is assumed that the jet created by the gluon is the most energetic from the two which reconstruct the top quark with FCNC decay and the other is created by the light quark.

Following the selection cuts, a likelihood-based type of analysis was applied, as described in section 4.2. Due to the small statistics of the available full simulation samples, ATLFAST samples were used to obtain the probability density functions (p.d.f.s). The p.d.f.s of the  $t \rightarrow q\gamma$  channel were built based on the following variables: the mass of the top quark with FCNC decay ( $m_t^{\text{FCNC}}$ ); the reconstructed mass of the photon and the b quark ( $m_{b\gamma}$ ) and the transverse momentum of the leading photon ( $p_T^\gamma$ ). For the  $t \rightarrow qZ$  channel, the p.d.f.s were based on the following physical distributions: the mass of the top quark with FCNC decay ( $m_t^{\text{FCNC}}$ ); the minimum invariant mass of the three possible combinations of two leptons ( $m_{\ell\ell}^{\text{min}}$ ); the reconstructed mass of the Z and the b quark ( $m_{bZ}$ ); the reconstructed mass of the two quarks ( $m_{qb}$ ); the transverse momentum of the third lepton ( $p_T^{\ell_3}$ ) and the transverse momentum of the light quark ( $p_T^q$ ). The following variables were used to build the p.d.f.s of the  $t \rightarrow qg$  channel: the mass of the top quark with FCNC decay ( $m_t^{\text{FCNC}}$ ); the mass of the top quark with Standard Model decay ( $m_{\ell_a \nu j}$ ); the reconstructed mass of the light and the b quark ( $m_{qb}$ ); the transverse momentum of the b quark ( $p_T^b$ ); the transverse momentum of the light quark ( $p_T^q$ ) and the angle between the lepton and the gluon ( $\alpha_{\ell g}$ ). The distributions of the discriminant variables are presented in Figure 9. It can be seen that ATLFAST describes the fully simulated distributions fairly well, when there are sufficient statistics to tell.

<sup>4</sup>These resolutions are taken from the top quark mass measurement analyses [70]. The effect of changing their values was considered as one of the systematic source of uncertainties. Its impact on the observables is below the statistical error.

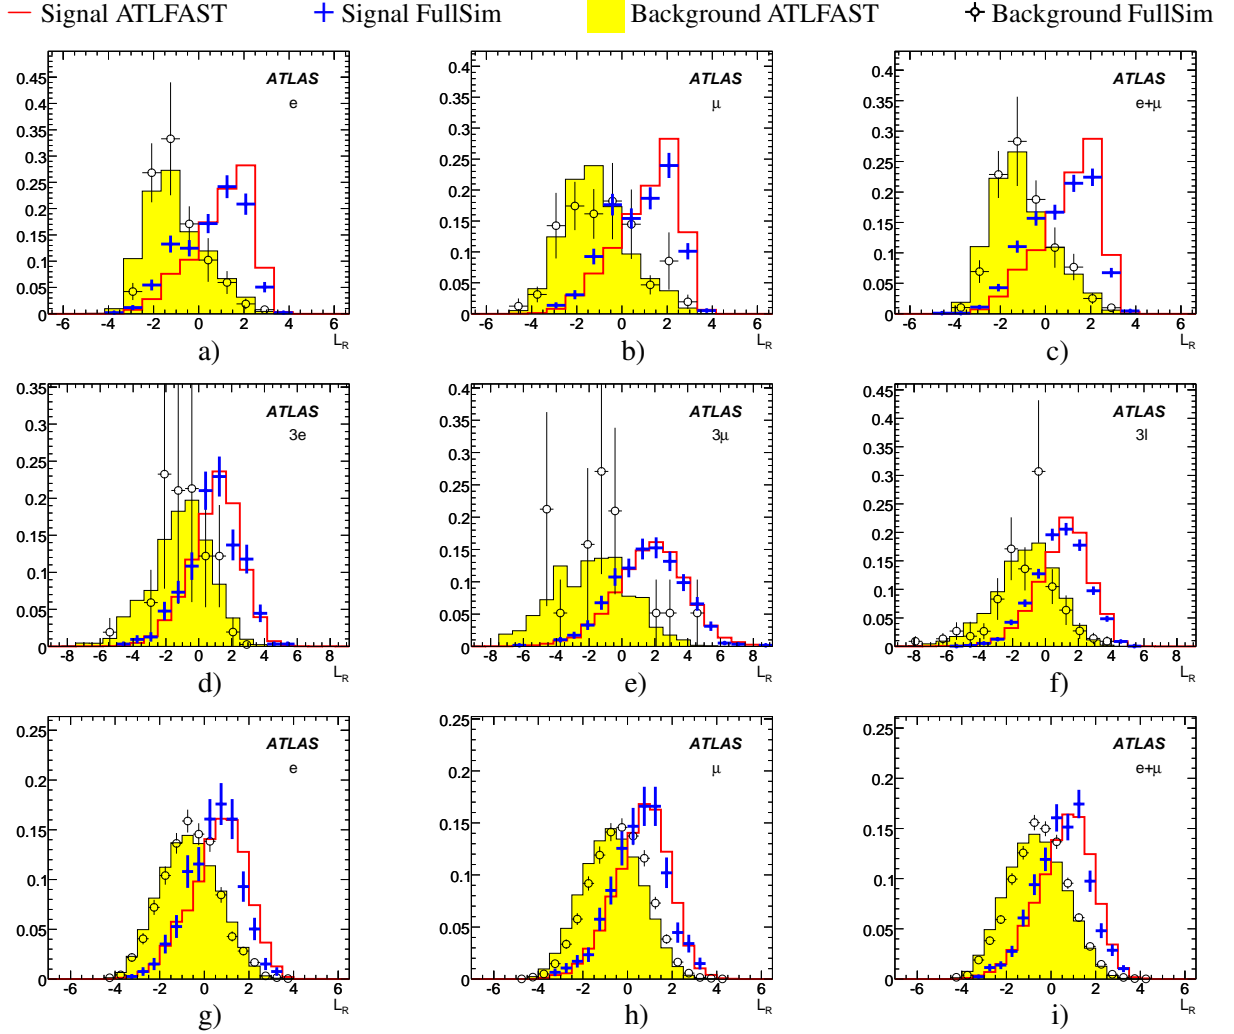

Figure 9: Distributions of the normalised discriminant variables for the expected background and signal after the final selection level of the  $t \rightarrow q\gamma$  channel when the isolated lepton is identified as (a) an electron, (b) a muon and (c) electron or muon; of the  $t \rightarrow qZ$  channel when the 3 isolated leptons are identified as (d) electrons, (e) muons and (f) electrons or muons and of the  $t \rightarrow qg$  channel, when the isolated lepton is identified as (g) an electron, (h) a muon and (i) electron or muon.

Table 20: The expected 95% confidence level limits on the FCNC top quark decay branching ratio, in the absence of signal, are shown for a luminosity of  $L = 1 \text{ fb}^{-1}$ . The central values are represented together with the  $1\sigma$  bands, which include the contribution from the statistical and systematic uncertainties.

### 5.3 Results and systematic uncertainties

In the absence of a FCNC top quark decay signal, expected limits at 95% CL were derived using the modified frequentist likelihood method [75] and the discriminant variables obtained with the full simulation samples. No cuts on the discriminant variables were used. Using the Standard Model  $\bar{t}t$  production cross-section these limits were converted into limits on the branching ratios. The central values of these limits are shown in Table 20. The branching ratio sensitivity for each FCNC channel, assuming a signal discovery with a  $5\sigma$  significance, is on average 3.0 times larger than the central values presented in Table 20.

Several sources of systematic uncertainties were studied following the common criteria used for this note and the results are shown in Table 21. The jet energy scale (the jet calibration used in the present analyses is described in Ref. [70]), the luminosity, the influence of the cross-section values, ISR/FSR, Monte Carlo generator and pile-up effects were studied. For the top quark mass, the full simulation samples were analysed using the values of 170 and 180 GeV (i.e. p.d.f.s, Eq. 10 and limit computation). The systematic error was taken from a linear fit of the values found, for a top quark mass error of  $\pm 2 \text{ GeV}$ . To study the effect of the mass resolutions in Eq. 10, and since no cut is applied to the  $\chi^2$  distribution, the ratio  $\sigma_t/\sigma_W$  was changed by a factor 2. The total systematic uncertainties, computed as the quadratic sum of these individual contributions, are also shown in Table 21. The analysis stability was also cross-checked by varying the kinematic cuts by about 10%, and the maximum relative change on the expected 95% CL limits was 3%, 9% and 5% for the  $t \rightarrow q\gamma$ ,  $t \rightarrow qZ$  and  $t \rightarrow qg$  channels, respectively. Table 20 shows the obtained central values for the BR limits. The  $\pm 1\sigma$  contributions from statistical and systematic uncertainties (added in quadrature) are also shown. The contribution from the luminosity and the absolute value of background level may be reduced with data, by normalising to measured processes.

Figure 10 shows the ATLAS 95% CL expected sensitivity for the first  $\text{fb}^{-1}$  in the absence of signal, for the  $t \rightarrow q\gamma$  and  $t \rightarrow qZ$  channels taking into account the contributions from both the statistical and systematic uncertainties.

Figure 10: The present 95% CL observed limits on the  $BR(t \rightarrow q\gamma)$  vs.  $BR(t \rightarrow qZ)$  plane are shown as full lines for the LEP, ZEUS and CDF collaborations. The expected sensitivity at ZEUS, CDF and ATLAS (together with the statistic plus systematic  $1\sigma$  band) is also represented by the dotted and dashed lines.

Table 21: Maximum changes (with respect to the central values of Table 20) of the expected 95% CL limits for each FCNC top quark decay branching ratio for different systematic error sources.

## 6 $t\bar{t}$ resonances

New resonances or gauge bosons strongly coupled to the top quark could manifest themselves in the  $t\bar{t}$  invariant mass distribution. Due to the large variety of models and their parameters, studies have been done in a model-independent way searching for a “generic” narrow resonance decaying into  $t\bar{t}$  (semileptonic channel) [51, 76]. The ATLAS discovery potential is assessed using the latest available simulations and detector description, performing the  $t\bar{t}$  event reconstruction along the same lines as done for the high precision measurement of the top quark mass in the semileptonic decay channel [54]. Alternative methods are currently under investigation to study the production of high mass resonances ( $m > 2$  TeV), where the decay products of the top quark are close together, so requiring a modified selection.

### 6.1 Event generation and selection

In this study,  $t\bar{t}$  resonances were produced with PYTHIA. The  $Z' \rightarrow t\bar{t}$  channel without interference in the  $Z'$  production has been chosen [77]. Only the semileptonic decay (electrons and muons) of  $t\bar{t}$  pairs is considered. Five samples of  $Z'$  resonances with mass 700 GeV (the lower limit from CDF and DØ measurements [78, 79]), 1000 GeV, 1500 GeV, 2000 GeV and finally 3000 GeV have been produced.

The common  $t\bar{t}$  semileptonic selection criteria were used to accept signal events. Once these criteria are applied, the main source of physical background to be considered in the search for  $t\bar{t}$  resonances comes from Standard Model  $t\bar{t}$  events. The other sources of background, dominated by W+jets events, are negligible [54].

### 6.2 Data characteristics

#### 6.2.1 $t\bar{t}$ reconstruction

Several ways to reconstruct the W-bosons and the top quarks have been investigated [54]. The simplest of them is used here. This method selects, among all jets from light quarks (u,d,c and s), the two jets which are closest in  $\Delta R$  to build the hadronic W-boson. The hadronic top quark is reconstructed combining the nearest b-jet to the hadronic W-boson. For the leptonic side, the constraint on the W-boson mass is used to compute the longitudinal momentum of the neutrino, identifying the missing transverse energy as the neutrino transverse momentum. Among the 2  $p_{z\nu}$  solutions, the one providing the leptonic top quark mass closest to the mean value of the hadronic top quark mass is chosen. To reduce both the physical background and the combinatorial background (which dominates), cuts are applied on the hadronic W-boson mass spectrum, and on both top quark mass spectra. The resulting  $t\bar{t}$  mass distribution, given in Figure 11, is used as a starting point for the discovery potential determination.

This method does not need a well understood jet energy scale and it is also one of the most efficient. More sophisticated methods to select the top quarks, such as a kinematic fits of the  $t\bar{t}$ -pairs (used by the DØ experiment [79]), or a matrix-element motivated method (used by CDF [78]), are not described here. The method used could be considered as a baseline for the  $t\bar{t}$  resonance search.

#### 6.2.2 Event yield

The reconstruction efficiency of Standard Model  $t\bar{t}$  pairs corresponding to the reconstruction scheme and cuts described above is shown in Figure 13. The fact that the produced particles are closer together when the generated  $t\bar{t}$  mass is higher explains the drop of efficiency observed as a function of the  $t\bar{t}$  mass. Part of the efficiency can be recovered if another jet finding algorithm, better at resolving nearby jets (such as a cone jet algorithm with smaller cone radius), is used.

Figure 14 gives the reconstruction efficiency of  $Z'$  resonances as a function of their mass. This reconstruction efficiency is of the same order as for the Standard Model  $t\bar{t}$  pairs. Nevertheless, some

Figure 11: Standard Model  $t\bar{t}$  mass spectrum. The black area represents the combinatorial background where at least one of the selected jets or leptons does not match the corresponding parton.

Figure 12: A 700 GeV  $Z'$  reconstructed mass spectrum. The black area represents the combinatorial background where at least one of the selected jets or leptons does not match the correspondent parton.

Figure 13: Reconstruction efficiency of Standard Model  $t\bar{t}$  pairs as a function of the  $t\bar{t}$  mass.

Figure 14: Reconstruction efficiency of  $Z' \rightarrow t\bar{t}$  resonances as a function of the  $Z'$  mass.

Figure 15:  $Z'$  mass resolution as a function of the  $Z'$  mass.

Figure 16:  $5\sigma$  discovery potential of a generic narrow  $t\bar{t}$  resonance as a function of the integrated luminosity.

small differences arise due to the different production mechanism and spin. Thus, the final result is not completely model-independent. The purity (fraction of well reconstructed events among all selected events) in each  $Z'$  sample is of the order of 80-85%.

### 6.3 Discovery potential

#### 6.3.1 Method and results

The method used to extract the  $5\sigma$  discovery sensitivity consists of counting the number of Standard Model  $t\bar{t}$  events in a sliding mass window over the invariant mass spectrum. The  $5\sigma$  sensitivity means that an effect is seen over the expected background with a deviation at least 5 times the background fluctuation in the mass window. The width of the window is twice the detector resolution for a given resonance mass. Then, the lowest cross section times branching ratio  $\sigma \times Br(Z' \rightarrow t\bar{t})$  is computed for the discovery of a resonance at a given mass.

The produced resonances are expected to have a width smaller than the resolution, leading to a gaussian shape for the reconstructed invariant mass. The discovery potential is thus estimated here only for narrow  $t\bar{t}$  resonances.

This method, explained in detail in [76], requires as input the  $Z'$  mass resolution (Figure 15), the reconstruction efficiency of both Standard Model  $t\bar{t}$  events and resonance events, and the purity of the final samples.

The resulting sensitivity is shown on Figure 16. For example, a 700 GeV  $Z'$  resonance produced with a  $\sigma \times Br(Z' \rightarrow t\bar{t})$  of 11 pb should be discovered with a  $5\sigma$  significance after  $1 \text{ fb}^{-1}$  of data taking. The  $t\bar{t}$  mass spectrum associated with such a case is shown in Figure 17.

#### 6.3.2 Measurement uncertainties

Uncertainties on the sensitivity arise from:

- the reconstruction efficiency for the  $Z'$  signal and  $t\bar{t}$  background. The main contribution arises from the expected error on the b-tag efficiency, which is set to  $\pm 5\%$ .
- the background contribution (Standard Model  $t\bar{t}$ ). The main contribution comes from the  $t\bar{t}$  cross section uncertainty  $^{+6.2}_{-4.7} \%$ .

Figure 17: Expected  $t\bar{t}$  invariant mass spectrum for the discovery threshold of a 700 GeV  $Z'$  resonance  $\sigma \times Br(Z' \rightarrow t\bar{t}) = 11.07$  pb with  $1 \text{ fb}^{-1}$  of data.

Table 22: Sources of uncertainties considered on the  $5\sigma$  discovery potential computation.

Source of uncertainty	Error (%)	Effect on the discovery potential (%)
Reconstruction efficiency	16.6	8.3
Background contribution	+6.2 -4.7	3.1
$t\bar{t}$ mass resolution	$\pm 1\sigma_{\text{resolution}}$	2 to 11
Luminosity	5	2.5
Jet energy scale	5	-

- the  $t\bar{t}$  mass resolution (Figure 15). The effect on the discovery potential increases with the resonance mass.
- the uncertainty on the integrated luminosity.

The  $5\sigma$  discovery potential is given as a function of the  $t\bar{t}$  resonance mass. The position of the resonance mass peak depends on the accuracy of the jet energy scale. This will be constrained by the W-boson and top quark events themselves.

All these quantities have been varied within expected errors. The impact on the sensitivity is reported in Table 22.

## 7 Summary and conclusions

The ATLAS sensitivity to the measurement of several top quark properties was reviewed in this paper for an expected luminosity of  $1 \text{ fb}^{-1}$  at the LHC. The precision of several measurements was estimated, using the full simulation of the ATLAS detector. For the tests of physics beyond the Standard Model associated with the production of top quarks, the 95% CL limit (in the absence of a signal) was presented. In Table 23 a summary of the expected sensitivity on these observables is shown, for a luminosity of  $1 \text{ fb}^{-1}$ . Several sources of systematic errors were considered using an approach common to all studies appearing in this note.

Table 23: Expected ATLAS sensitivity for the top quark properties, for a luminosity of  $1 \text{ fb}^{-1}$ . For the Standard Model measurements the sensitivity is given as the total error divided by the expected Standard Model value, for the searches the absolute value is presented.

Observables	Expected Precision
Top quark charge (2/3 versus -4/3)	$\geq 5\sigma$
Spin Correlations:	
$A$	50%
$A_D$	34%
W-boson Polarisation:	
$F_0$	5%
$F_L$	12%
$F_R$	0.03
Angular Asymmetries:	
$A_{\text{FB}}$	19%
$A_+$	11%
$A_-$	4%
Anomalous Couplings:	
$V_R$	0.15
$g_L$	0.07
$g_R$	0.15
Top quark FCNC decays (95% C.L.):	
$Br(t \rightarrow q\gamma)$	$10^{-3}$
$Br(t \rightarrow qZ)$	$10^{-3}$
$Br(t \rightarrow qg)$	$10^{-2}$
$t\bar{t}$ Resonances (discovery):	
$\sigma \times Br(m_{t\bar{t}}=700\text{GeV})$	$\geq 11 \text{ pb}$

The sensitivity of the ATLAS experiment to the top quark charge measurement was evaluated. The analysis shows that using the weighting technique, already with  $0.1 \text{ fb}^{-1}$  it is possible to distinguish with a  $5\sigma$  significance, between the b-jet charges associated with leptons of opposite charges, which allows to distinguish the Standard Model from an exotic scenario. For the semileptonic b-decay method the required luminosity is  $\simeq 1 \text{ fb}^{-1}$ . The top quark charge itself was reconstructed relying on a Monte Carlo calibration of the b-jet charge. Although the reconstruction of the numeric value of the top quark charge using the weighting technique seems possible with  $\simeq 1 \text{ fb}^{-1}$ , it will be necessary to check the performance of the method with real data e.g. di-jet  $b\bar{b}$  events, once available. A more realistic treatment of the background processes will be required for a full understanding of the top quark charge issues.

A study of the W-boson polarisation fractions ( $F_0$ ,  $F_L$  and  $F_R$ ) and  $t\bar{t}$  spin correlation parameters ( $A$  and  $A_D$ ) has been performed in the semileptonic  $t\bar{t}$  channel. Reconstructed angular distributions were used to set the ATLAS sensitivity to the measurement of the W-boson polarisations and top quark spin correlation parameters.

The W-boson polarisation ratios ( $\rho_R$  and  $\rho_L$ ) and the angular asymmetries ( $A_+$  and  $A_-$ ) dependence on the anomalous couplings ( $V_R$ ,  $g_L$  and  $g_R$ ) was used to find the sensitivity to the  $Wtb$  anomalous couplings (for the analyses with and without b-tag).

Top quark rare decays through FCNC processes ( $t \rightarrow qZ, q\gamma, qg$ ) were studied in this note using  $t\bar{t}$  events produced at the LHC. Expected limits on the branching ratios were set at 95% CL in the absence

of signal.

The discovery potential of the ATLAS experiment for narrow  $t\bar{t}$  resonances decaying in the semileptonic channel, was studied as a function of the resonance mass.

## ***B*-Physics**

# Introduction to $B$ -Physics

## 1 ATLAS $B$ -physics programme

The ATLAS  $B$ -physics programme covers many aspects of beauty flavour physics. First, by measuring production cross-sections of beauty and charm hadrons and of the heavy-flavour quarkonia,  $J/\psi$  and  $\Upsilon$ , ATLAS will provide sensitive tests of QCD predictions of production in proton-proton collisions at the LHC. Secondly, ATLAS will study the properties of the entire family of  $B$  mesons ( $B_d^0$ ,  $B^+$ ,  $B_s^0$ ,  $B_c$  and their charge-conjugate states) and  $B$  baryons, thereby broadening our knowledge of both the spectroscopic and dynamical aspects of  $B$ -physics. However, the main emphasis will be on precise measurements of weak  $B$  hadron decays. In the Standard Model, all flavour phenomena of weak hadronic decays are described in terms of quark masses and the four independent parameters in the Cabibbo-Kobayashi-Maskawa (CKM) matrix [1]. Enormous quantities of data collected in the past decade by the experiments BaBar, Belle, CDF and D0 allowed very precise measurements of flavour and CP-violating phenomena. Whilst the analysis of the remaining data of these experiments may still push the boundaries, no evidence of physics beyond the Standard Model, nor any evidence for CP violation other than that originating from the CKM mechanism, has yet been found. At the LHC, thanks to the large beauty production cross-section and the high luminosity of the machine, the sensitivity of  $B$  decay measurements is expected to substantially improve. Whilst direct detection of new particles in ATLAS will be the main avenue to establish the presence of new physics, indirect constraints from  $B$  decays will provide complementary information. In particular, precise measurements and computations in  $B$ -physics are expected to play a key role in constraining the unknown parameters of any new physics model emerging from direct searches at the LHC.

In ATLAS, the main  $B$ -physics measurements will be made with an instantaneous luminosity of around  $10^{33} \text{ cm}^{-2} \text{ s}^{-1}$ ; however, the  $B$ -physics potential begins during early data taking at low luminosity ( $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ ). With an integrated luminosity of  $10 \text{ pb}^{-1}$  ATLAS will already be able to register about  $1.3 \cdot 10^5$  events containing  $J/\psi \rightarrow \mu^+ \mu^-$  selected by the low luminosity trigger menu [2]. Recorded events will contain  $J/\psi \rightarrow \mu^+ \mu^-$  produced both directly in proton-proton interactions as well as indirectly from decays of  $B$  hadrons. With these statistics, beauty and quarkonia studies will play an important role in the early data-taking period.

In this document we present studies for several periods of beauty measurements in ATLAS. First, there will be a period of integrated luminosity of order of  $10 - 100 \text{ pb}^{-1}$  when  $B$ -physics and heavy-flavour quarkonia signatures will serve in helping to understand detector properties and the muon trigger, as well as measuring production cross-sections. The physics analyses in this period will deal with prompt  $J/\psi$  and  $\Upsilon$  events, along with inclusive  $B$  hadron decays to muon pairs via  $J/\psi$ . Further on, the exclusive decays of  $B^+ \rightarrow J/\psi K^+$ ,  $B_d^0 \rightarrow J/\psi K^{0*}$  and  $B_s^0 \rightarrow J/\psi \phi$  will be studied.

During the next period, from about  $200 \text{ pb}^{-1}$  to  $1 \text{ fb}^{-1}$ , we expect to collect the same or higher statistics as are currently available at the Tevatron. During this period we will start to improve upon current measurements of  $B$  hadron properties and set new decay rate limits or possibly give evidence for rates above Standard Model predictions for rare decays (e.g. in the channel  $B_s^0 \rightarrow \mu^+ \mu^-$ ).

In the most important period for ATLAS  $B$ -physics we expect to achieve about  $10 - 30 \text{ fb}^{-1}$  at an instantaneous luminosity of mostly around  $10^{33} \text{ cm}^{-2} \text{ s}^{-1}$ . It is expected that ATLAS can achieve this integrated luminosity in about three years. We are preparing to study a large variety of  $B$ -physics topics covering both the production and decay properties of  $B$  hadrons. In this document we give examples of performance studies for this period with polarization measurements of heavy-flavour quarkonia and of the baryon  $\Lambda_b$ , by the oscillation phenomena of the  $B_s^0 - \bar{B}_s^0$  system, and the rare

decay measurement  $B_s^0 \rightarrow \mu^+ \mu^-$ . We expect to achieve sensitivities allowing the confirmation of possible contributions of physics beyond the Standard Model.

## 2 Trigger

All  $B$ -physics studies reported in the current document include trigger reconstruction. The ATLAS trigger comprises three levels and the selection of  $B$ -physics events is initiated by a di-muon or a single-muon trigger at the first level trigger (L1). At  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  the lowest possible threshold of about  $p_T > 4 \text{ GeV}$  will be used, rising to 6 - 8 GeV at  $10^{33} \text{ cm}^{-2} \text{ s}^{-1}$  for at least one of the L1 muons. The muon is confirmed at the second trigger level (L2), first using muon-chamber information alone, and then combining muon and inner-detector (ID) information. The use of the more precise muon information available at L2 allows rejection of below-threshold muons that passed the L1 trigger. Combining information from the muon chambers and ID track segments gives rejection of muons from  $\pi$  and  $K$  decays.

Following the confirmation of the L1 muon(s), cuts on invariant mass and secondary vertex reconstruction of  $B$  decay products are used to select specific channels of interest. Channels such as  $B^+ \rightarrow J/\psi(\mu^+ \mu^-)K^+$  and  $B_s^0 \rightarrow \mu^+ \mu^-$  are triggered by requiring two muons fulfilling  $J/\psi$  or  $B_s^0$  mass cuts. At  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  a single muon is required at L1, with the second muon either originating from an additional L1 trigger or found at L2 in an enlarged Region of Interest (RoI) around the trigger muon. At luminosities above about  $10^{33} \text{ cm}^{-2} \text{ s}^{-1}$ , a L1 dimuon trigger is used, giving an acceptable rate while keeping a low  $p_T$  threshold for both of the two muons.

For hadronic final states such as  $B_s^0 \rightarrow D_s \pi$ , ID tracks are combined to reconstruct first the  $\phi \rightarrow K^+ K^-$ , then the  $D_s \rightarrow \phi \pi$ , and finally the  $B_s^0$ . Two different strategies are used for finding the tracks, depending on luminosity. Full reconstruction of the whole ID can be performed at  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ . At higher luminosities, reconstruction will be limited to regions of interest defined by the L1 calorimeter jets.

In all studies reported in the current document the trigger decision was used to accept or reject a given event. The trigger menu used to produce the datasets contained low- $p_T$  L1 muon thresholds of 4, 5 and 6 GeV. These were used to initiate selections at L2 of decays containing  $J/\psi \rightarrow \mu^+ \mu^-$ , like  $B^+ \rightarrow J/\psi(\mu^+ \mu^-)K^+$ , and  $B_s^0 \rightarrow \mu^+ \mu^-$ . The lowest thresholds for  $J/\psi$  or  $B_s^0$  required two 4 GeV muons. In addition there were selections for  $B_s^0 \rightarrow D_s \pi$  based either on full ID reconstruction or on a RoI-based reconstruction in L1 Jet RoIs with a 4 GeV threshold. More detailed information on the  $B$ -physics trigger is presented in three studies in this document. Specific questions on the L1 di-muon trigger performance for  $B$ -physics are addressed in Section 1 of this chapter. L2 triggering on muons and di-muons is presented in Section 2. Finally, triggers for  $B$  decays to purely hadronic final states have been studied in the last part of this chapter, Section 8.

If not stated otherwise, the trigger efficiencies in di-muon events were calculated with respect to Monte Carlo samples generated with cuts of  $p_T > 6 \text{ GeV}$  and  $p_T > 4 \text{ GeV}$  for the first and second muon respectively and with pseudorapidity cuts of  $|\eta| < 2.4$  on both muons.

## 3 Simulation of the events

Some 1 million  $B$  hadron events, along with around 400 000 prompt  $J/\psi$  and  $\Upsilon(1S)$  as well as  $c\bar{c}$  events, were produced using PYTHIA 6.4 [3]. The simulations were performed with the CTEQ6L set of parton distribution functions. For quarkonium production, the NRQCD matrix element parameters

in PYTHIA were tuned to fit Tevatron data [4]. In the production of non-resonant  $b\bar{b}$  and  $c\bar{c}$  flavour-creation, PYTHIA models describing flavour-excitation and gluon-splitting were included. The fragmentation of  $b$  quarks and  $c$  quarks to hadrons was simulated according to the Peterson fragmentation function with parameter 0.006 and 0.05 respectively. The choice of parameters was motivated by Tevatron measurements [5]. Kinematic selections on final state particles from  $B$  decays were applied so that most of the generated  $B$  events passed the trigger threshold at the reconstruction stage.

The total  $b\bar{b}$  or  $c\bar{c}$  cross-section is not well defined in PYTHIA when one includes processes other than those of the lowest order for  $b\bar{b}$  ( $c\bar{c}$ ) production, since PYTHIA takes the partons to be massless and therefore the cross-section diverges when the transverse momentum approaches zero. However, only part of the cross section is relevant for our studies - in the phase space of events passing  $B$  triggers.

Table 3 summarises the predicted single and di-muon cross-sections from charm, beauty and onia production expected at ATLAS from PYTHIA with cuts on the transverse momenta of the muons of 6 or 4 GeV (as appropriate) and pseudorapidity cuts on both muons of  $|\eta| < 2.4$ . The cuts reflect the trigger thresholds and were selected to allow most of the simulated events to be accepted by the trigger.

Process ( $\mu 6$ threshold)	Cross-section	Process ( $\mu 4$ threshold)	Cross-section
$bb \rightarrow \mu 6 X$	6.1 $\mu\text{b}$	$bb \rightarrow \mu 4 X$	19.3 $\mu\text{b}$
$cc \rightarrow \mu 6 X$	7.9 $\mu\text{b}$	$cc \rightarrow \mu 4 X$	26.3 $\mu\text{b}$
$bb \rightarrow \mu 6 \mu 4 X$	110.5 nb	$bb \rightarrow \mu 4 \mu 4 X$	212.0 nb
$cc \rightarrow \mu 6 \mu 4 X$	248.0 nb	$cc \rightarrow \mu 4 \mu 4 X$	386.0 nb
$pp \rightarrow J/\psi(\mu 6 \mu 4)X$	23.0 nb	$pp \rightarrow J/\psi(\mu 4 \mu 4)X$	28.0 nb
$pp \rightarrow \Upsilon(\mu 6 \mu 4)X$	4.6 nb	$pp \rightarrow \Upsilon(\mu 4 \mu 4)X$	43.0 nb
$bb \rightarrow J/\psi(\mu 6 \mu 4)X$	11.1 nb	$bb \rightarrow J/\psi(\mu 4 \mu 4)X$	12.5 nb

Table 1: Predicted PYTHIA cross-sections for various muon and di-muon sources. The numbers following each symbol  $\mu$  denote the  $p_T$  thresholds that were used in generating the events with PYTHIA.

After PYTHIA simulation, the events were passed through detector simulation (based on GEANT4 [6]) which first modelled the behavior of the particles as they passed through the detector, and simulated the response of the active detector components to the energy deposition by these particles. The layout of the detector used by the simulation code was published in Ref. [7]. The output of the simulation was then reconstructed as if it were real data. Following this, reconstructed muons and hadrons were analysed using the dedicated  $B$ -physics analysis software.

## 4 Organization of the $B$ -physics chapter

The following reports on  $B$ -physics present our best current understanding of the ATLAS  $B$ -physics programme. As the  $B$  trigger plays a role in all the studies presented here, the chapter starts with two reports, in Sections 1 and 2, dealing with L1 and L2 muon triggers respectively. There follow three physics studies typical for the early data period: physics of heavy-flavour quarkonia (Section 3), measurements of beauty cross-sections (Section 4) and early physics and performance measurements with decays of  $B_d^0$  and  $B_s^0$  mesons in Section 5. Finally there are Sections 6, 7 and 8, which give typical examples of ATLAS  $B$  measurements that can only be achieved during the more advanced data taking period; they are measurements of the polarization of the baryon  $\Lambda_b$ , the rare decay  $B_s^0 \rightarrow \mu^+ \mu^-$  and

finally the oscillation measurement of the  $B_s^0 - \overline{B}_s^0$  system.

# Performance Study of the Level-1 Di-Muon Trigger

## Abstract

An event with two muons in the final state is a distinctive signal and can be triggered efficiently with the use of the level-1 di-muon trigger. Nevertheless triggering is still an issue if these muon tracks are fairly soft and fake di-muon triggers originating from muons that traverse more than one region of the trigger chambers increase the trigger rate. It is important to provide an acceptable trigger rate, while keeping high trigger efficiency to study low- $p_T$   $B$ -physics such as rare  $B$  hadron decays or CP violation in the  $B$ -events, especially in a multi-purpose experiment like ATLAS. In this note, the level-1 di-muon trigger and its expected performance are described.

## 1 Introduction

ATLAS is a multi-purpose experiment and its main focus is the direct search for and study of physics beyond Standard Model. However the indirect search for new physics will also play an important role in revealing the (flavor) structure of a non-trivial Higgs sector, which cannot be obtained by direct searches.

The  $B_{s,d}^0 \rightarrow \mu^+ \mu^-$  rare decay is one of the interesting signatures which are sensitive to new physics at the TeV energy scale. The precise measurement of the forward-backward asymmetry [1] or branching ratio in the semi-muonic  $B$  decay  $B \rightarrow \mu^+ \mu^- X$  requires good understanding of the possible biases introduced by event selection. Also important are precise measurements of Standard Model parameters, including CP-violation in  $B$ -events, such as  $B_s^0 \rightarrow J/\psi \phi$  and  $B_d^0 \rightarrow J/\psi K_s^0$ . The key to the detection of these  $B$  signals in ATLAS is to achieve a high trigger efficiency for low- $p_T$  di-muon events, keeping an acceptable trigger rate. It is also essential to understand the acceptance and efficiency using  $pp \rightarrow J/\psi(\mu^+ \mu^-) X$  or  $pp \rightarrow \Upsilon(\mu^+ \mu^-) X$  [2].

First, the level-1 muon trigger is briefly explained in Section 2, then trigger simulation and MC samples used in this note are described in Section 3. The performance of the level-1 single- and di-muon trigger as well as the effect of an algorithm to resolve muons traversing more than one trigger chambers are described in Section 4. Finally, the performance and the impact of various level-1 muon trigger configurations on some example  $B$  signal events are discussed in Section 5.

## 2 Level-1 muon trigger

The ATLAS trigger system architecture is organised in three levels; level-1, level-2 and event filter. The level-2 and event filter triggers provide a software-based event selection after the level-1 trigger and events accepted by this trigger chain are finally reconstructed and analyzed offline.

The ATLAS level-1 muon trigger is based on dedicated, fast and finely segmented muon chambers (RPC and TGC) [3] and a trigger logic implemented in hardware. The muon trigger system provides acceptance in pseudo-rapidity up to  $|\eta| \sim 2.4$  and in the full azimuthal angle ( $\phi$ ) range. A muon track is triggered by the coincidence of two or three detector stations (consists of chamber doublet or triplet) within a certain road (coincidence window). The transverse momentum of a muon candidate is determined by its deviation from the trajectory of an infinite-momentum track (i.e. a straight line). A three station coincidence is required for any  $p_T$  threshold in the endcap and forward regions ( $|\eta| > 1.05$ ) to avoid high trigger rates caused by accidental coincidences due to background.<sup>1</sup> As a result, the acceptance at large  $|\eta|$  becomes small for low- $p_T$  muons, as shown in Section 4.

<sup>1</sup>The number of stations used for coincidence is programmable giving the possibility of lowering a  $p_T$  threshold at low luminosity if background conditions allow it.

The granularity of the level-1 muon trigger, the size of a Region of Interest (RoI), is  $\Delta\eta \times \Delta\phi = 0.1 \times 0.1$  in the barrel region ( $|\eta| < 1.05$ ) and  $\sim 0.03 \times 0.03$  in the endcap regions ( $1.05 < |\eta| < 2.4$ ). In short, if two muons leave tracks in the same RoI, they are counted as a single muon candidate by the trigger system. The level-1 muon trigger decisions from different regions are sent to the Muon Central Trigger Processor Interface (MuCTPI) which combines the information and calculates the multiplicity of muon candidates for each  $p_T$  threshold over the whole detector. In forming the multiplicities, care is taken to avoid double counting of single-muon tracks, reconstructed separately in adjacent trigger sectors, while retaining a high efficiency for genuine di-muons. The overlap handling is carried out using Lookup Tables (LUT) to give flexibility and programmability. The LUTs are generated based on Monte Carlo simulations of single-muon events, selecting the regions of the level-1 muon system that can be traversed by a single muon.

The overlap handling is mandatory to avoid unacceptably high trigger rates caused by doubly-counted single muons, so called *fake di-muon triggers*. Most of the overlaps are resolved by the MuCTPI, which takes the muon candidate with the higher  $p_T$  into account when calculating the muon multiplicity and finding overlapping muon candidates. The MuCTPI consists of independent 16 octant modules and overlap resolving is performed in each module. Therefore, overlapped regions connected to two different octant modules cannot be solved in MuCTPI and should be treated in each subdetector (RPC and TGC) by masking channels or flagging a overlap bit. The parameters used in the overlap handling, such as the combination of RoIs and masked channels are programmable. More details are described in Refs. [3, 4].

### 3 Monte Carlo samples and trigger configuration

Single-muon Monte Carlo samples with various, fixed  $p_T$  values are used for performance tests of the level-1 single muon trigger logic. Single-muon events are generated uniformly over the full azimuthal angle range and  $|\eta| < 2.7$  with a fixed  $p_T$  value. The detector response is simulated using Geant4 [4] with the ATLAS geometry in the Athena framework [5]. Trigger simulation is performed using the trigger configuration for luminosity of  $10^{31}$ - $10^{33}\text{cm}^{-2}\text{s}^{-1}$  running, with a set of  $p_T$  thresholds of 4, 5, 6, 11, 20 and 40 GeV. The production vertex is smeared with a Gaussian distribution with  $\sigma_x = \sigma_y = 15\text{ }\mu\text{m}$  and  $\sigma_z = 56\text{ mm}$ . The level-1 single- and di-muon trigger menu items are named as MUx (single-muon trigger) and 2MUx (di-muon trigger with the same threshold for both muons) respectively, where x represents the  $p_T$  threshold. The exceptions are MU0 and 2MU0, which correspond to completely opened coincidence windows. However, even in this case, the acceptance of the coincidence windows is limited by connectivity as well as by the dimension of the coincidence matrix ASICs [6].

The trigger efficiencies of various level-1 trigger configurations are also studied using *B*-physics Monte Carlo events. Event generation is done using PYTHIA [7]. Only interesting events associated with at least two muons with  $p_T > 6\text{ GeV}$  (the leading muon) and 4 GeV (the second muon) within  $|\eta| < 2.5$  are studied. The *B*-physics samples used in this note are  $B_s^0 \rightarrow \mu^+\mu^-\phi$  (47,650 events),  $B_s^0 \rightarrow \mu^+\mu^-$  (47,450 events) and  $B^+ \rightarrow J/\psi(\mu^+\mu^-)K^+$  (49,250 events). The last sample is chosen partly as a control sample. The opening angle of the two muons is smaller in this sample than in the other two samples.

In this note, only the level-1 muon trigger is simulated and events triggered by level-1 are studied.

### 4 Level-1 muon trigger efficiency in single-muon events

Detailed performance studies of the single muon trigger were performed in the barrel and endcap regions separately and the results are described in Ref. [8]. The single muon trigger efficiencies as a function of the transverse momentum of the simulated muon, over the whole muon trigger system are shown in

Figure 1. The single muon trigger efficiency is defined by:

$$\varepsilon(\text{MU}_x) = \frac{\text{\# of events triggered}}{\text{\# of single muon events with } |\eta| < 2.5} . \quad (1)$$

The range of pseudo-rapidity applied in the efficiency calculation is  $|\eta| < 2.5$  and not 2.4 as used in Ref. [8], since  $|\eta| < 2.5$  is applied for muons in the  $B$ -physics samples (Muons with  $|\eta| > 2.4$  can be triggered if their momentum is relatively low and the track is bent towards smaller  $|\eta|$ ). The efficiency,  $\varepsilon(\text{MU}_x)$ , includes all contributions from geometrical acceptance and coincidence window coverage. The trigger efficiency of MU5 and MU6 is lower than MU0 even for high  $p_T$  muon tracks. This is because all regions don't have full (100 %) acceptance except MU0 which accepts all muons within station coincidence windows. Figures 2 (a) and (b) show the trigger efficiency as a function of the  $|\eta|$  of the simulated

Figure 1: Trigger efficiency as a function of  $p_T$  with each low- $p_T$  threshold; MU0 (filled circles), MU5 (filled triangles) and MU6 (open squares) for muons with  $|\eta| < 2.5$  at the interaction point.

muon with  $p_T$  at threshold and with  $p_T=19$  GeV for MU0 and MU6 trigger selections, respectively. The efficiency at the plateau is predominantly determined by geometrical acceptance. Efficiency losses at  $|\eta| \sim 0, 0.4$  and  $0.7$  are caused by cracks and inactive material, like ribs, detector support structures and the elevator hole. Around the transition region between the barrel and the endcap,  $|\eta| \sim 1.05$ , some efficiency is lost because the station coincidence cannot be satisfied. A small efficiency gap at the boundary between the endcap and forward regions ( $|\eta| \sim 2$ ) is also due to the station coincidence, since the endcap and forward systems are treated separately. However, this effect is smaller than in the transition region between the barrel and the endcap. Poor MU0 efficiency at  $p_T = 4$  GeV is seen in the endcap region due to the requirement of three station coincidence, not two as required in the barrel. The trigger was originally designed for  $p_T > 6$  GeV as the lowest threshold, but can be applied below this threshold at very low luminosity.

Figures 3 (a) and (b) show the trigger efficiency as a function of  $\phi$  ( $\phi=0$  and  $\pm\pi$  denote directions perpendicular to the beam axis in the horizontal plane) of the simulated muon with  $p_T$  at threshold and with  $p_T=19$  GeV for MU0 and MU6 trigger selections, respectively. The efficiency loss can be clearly

Figure 2: The  $|\eta|$  dependency of the trigger efficiency for MU0 (a) and MU6 (b) trigger selections. Solid lines correspond to the simulated muons with  $p_T=19$  GeV, dotted lines are for muons with  $p_T$  at threshold (in the case of MU0 this threshold is set to 4 GeV).

seen around  $\phi \sim -1.2$  and  $-2$  at the magnet's feet, especially for high  $p_T$  muons. The geometrical structure is in general more visible in efficiency using higher  $p_T$  muons, as they produce straighter tracks.

Figure 3: The  $\phi$  dependency of the trigger efficiency for MU0 (a) and MU6 (b) trigger selections. Solid lines correspond to the simulated muons with  $p_T=19$  GeV, dotted lines are for muons with  $p_T$  at threshold (in the case of MU0 this threshold is set to 4 GeV).

## 5 Level-1 muon trigger performance in B-physics events

A detailed level-1 trigger simulation is mandatory to find effective trigger menus and thresholds for certain physics processes and to determine the trigger efficiency and rate as well as to study the trigger bias. In this section, di-muon and single-muon trigger efficiencies with different  $p_T$  thresholds and the dependency of di-muon trigger efficiencies as a function of the opening angle between simulated muons

are discussed using  $B$ -physics Monte Carlo samples.

### 5.1 Efficiency with various trigger configurations

The efficiency of the level-1 muon trigger for three different  $B$ -physics processes,  $B_s^0 \rightarrow \mu^+\mu^-$ ,  $B_s^0 \rightarrow \mu^+\mu^-\phi$  and  $B^+ \rightarrow J/\psi(\mu^+\mu^-)K^+$  is studied with various trigger configurations. The efficiencies of the single muon triggers (MU0 and MU6) and the di-muon triggers (2MU0 and 2MU6) are summarized in Table 1. The efficiency of the single muon trigger is high, about 95 %, since multiple muons have a higher probability to be triggered by a single muon trigger. The 2MU0 trigger gives better efficiency than 2MU6 by  $\sim 16$  % for di-muon events with  $p_T$  above 6 GeV (4 GeV) for the fastest (second fastest) muon. The efficiency loss due to the MuCTPI overlap handling is seen in all physics processes, although the relative efficiency loss is small,  $\sim 0.5$  %.

Trigger Menu / Process	Efficiency [%]		
	$B_s^0 \rightarrow \mu^+\mu^-$	$B^+ \rightarrow J/\psi(\mu^+\mu^-)K^+$	$B_s^0 \rightarrow \mu^+\mu^-\phi$
MU0	97.0 $\pm$ 0.1	96.8 $\pm$ 0.1	97.0 $\pm$ 0.1
MU6	93.0 $\pm$ 0.1	92.9 $\pm$ 0.1	93.1 $\pm$ 0.1
2MU0	67.9 $\pm$ 0.2	68.8 $\pm$ 0.2	69.0 $\pm$ 0.2
2MU6	51.6 $\pm$ 0.2	52.9 $\pm$ 0.2	53.2 $\pm$ 0.2
2MU0 (w/o MuCTPI overlap handling)	68.2 $\pm$ 0.2	69.1 $\pm$ 0.2	69.4 $\pm$ 0.2
2MU6 (w/o MuCTPI overlap handling)	52.0 $\pm$ 0.2	53.4 $\pm$ 0.2	53.7 $\pm$ 0.2

Table 1: The level-1 trigger efficiency of various configurations. The efficiency is calculated with respect to the number of generated events (not to the number of muons) of three different physics processes. The errors are statistical only.

### 5.2 Opening-angle dependency

In case of measuring some quantity as a function of a certain parameter, one must ensure that the trigger efficiency is independent of that parameter, or correct the measurement to avoid a bias from the trigger.

Figure 4 shows the 2MU0 and 2MU6 trigger efficiencies as a function of  $\Delta R (= \sqrt{\Delta\eta^2 + \Delta\phi^2})$  between the two leading muons in  $B_s^0 \rightarrow \mu^+\mu^-\phi$  events. The  $\eta$  and  $\phi$  are true parameters of muon flight direction at the production vertex. No offline selection is applied in order to see the bias from the level-1 trigger. The trigger efficiency clearly depends on the opening angle of the two leading muons. The efficiency is lower at large opening angles because in this case the  $B_s$  system is not boosted i.e. momenta of the muons are lower. Since overlap removal between the muon candidates doesn't play a role at large opening angles, this effect is purely due to kinematics. Figure 5 (a) shows the  $p_T$  distribution of the leading muons for three different  $\Delta R$  ranges:  $\Delta R < 0.1$ ,  $0.2 < \Delta R < 0.4$  and  $\Delta R > 0.5$ . The muons at large opening angles clearly have a softer  $p_T$  spectrum. The effect is even more clearly visible for higher threshold di-muon trigger items, as the probability of having muons at large  $\Delta R$  with transverse momenta high enough to trigger a high threshold di-muon trigger item is very small, but non-negligible at small opening angles.

The small efficiency loss at very small opening angles ( $\Delta R < 0.1$ ) is however due to the trigger system. In the case that the muons both leave hits in the same RoI, only one muon can be triggered by

Figure 4: (a) Trigger efficiency as a function of  $\Delta R$  in the semi-leptonic rare  $B$  decay  $B_s^0 \rightarrow \mu^+ \mu^- \phi$  using the 2MU0 (filled circles) and 2MU6 (open squares) with MuCTPI. (b) Effect of MuCTPI as a function of the opening angle,  $\epsilon(\text{without MuCTPI})/\epsilon(\text{with MuCTPI})$  for 2MU0 (filled circles) and 2MU6 (open squares).

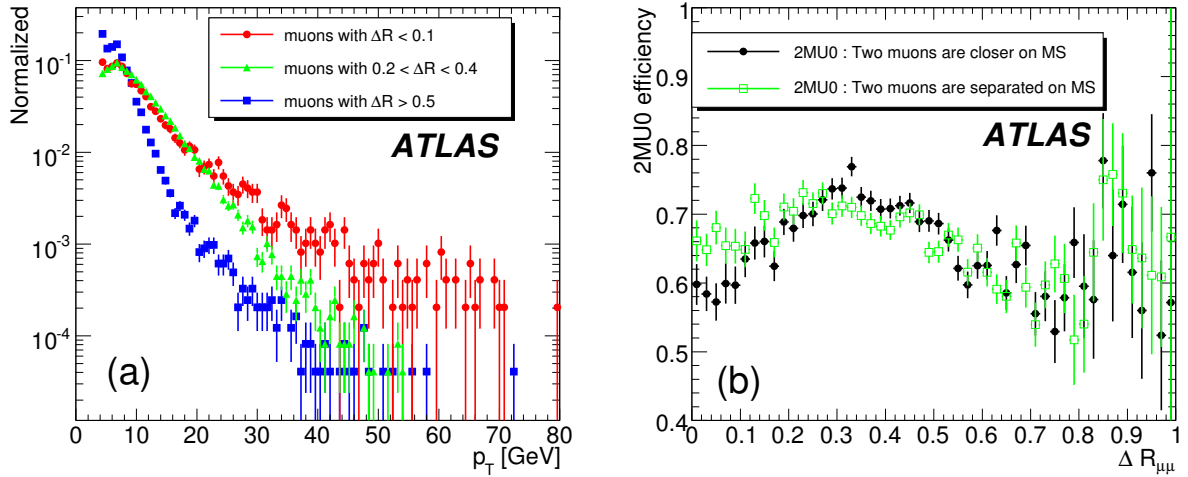

Figure 5: (a) The truth  $p_T$  distribution of the two leading muons is different opening angles range in  $B_s^0 \rightarrow \mu^+ \mu^- \phi$  events:  $\Delta R < 0.1$  (filled circles),  $0.2 < \Delta R < 0.4$  (filled triangles) and  $\Delta R > 0.5$  (filled squares). (b) The efficiency of 2MU0 as a function of opening angles for two cases: the  $\Delta R$  separation of the two muons is either larger (filled circles) or smaller (open circles) at the muon trigger system compared to that at the primary vertex.

the system. Figure 5(b) shows the 2MU0 efficiency as a function of the opening angle, but events are divided into two classes: In one case we select the muon pairs whose separation is expected to shrink when reaching the muon spectrometer (filled circles), while in the other case (open squares) we select the muon pairs whose separation is expected to grow.

Figure 6: (a) Scaled di-muon invariant mass-squared distribution in  $B_s^0 \rightarrow \mu^+\mu^-\phi$  events: no level-1 selection (open histogram), triggered by 2MU0 (hatched histogram) and by 2MU6 (cross hatched histogram). (b) Efficiencies of 2MU0 (filled circles) and 2MU6 (open squares) as a function of di-muon invariant mass-squared. The two lines show the relative efficiency with respect to the corresponding average value for 2MU0 (solid line) and 2MU6 (dotted line).

One example  $B$ -physics study is to look at the differential decay rate  $d\text{Br}(B \rightarrow \mu^+\mu^-\phi) / d\hat{s}$  or forward-backward asymmetry  $A_{FB}$  as a function of di-muon invariant mass to discriminate between Standard Model and new physics contributions. The  $\hat{s}$  is  $m_{\mu\mu}^2/m_B^2$  and the  $A_{FB}(\hat{s})$  is defined as

$$\left( \int_0^1 \frac{d\Gamma}{d\hat{s}\hat{z}} d\hat{z} - \int_{-1}^0 \frac{d\Gamma}{d\hat{s}\hat{z}} d\hat{z} \right) / \int_{-1}^1 \frac{d\Gamma}{d\hat{s}\hat{z}} d\hat{z}, \quad (2)$$

where  $\hat{z} = \cos \theta$  ( $\theta$  is the angle between the  $\mu^+$  and  $\phi$  in the  $\mu^+\mu^-$  rest frame) and  $d\Gamma/d\hat{z}$  is the differential event rate of  $B_s^0 \rightarrow \mu^+\mu^-\phi$ .

Figure 6 (a) shows the  $\mu^+\mu^-$  invariant mass distribution with and without level-1 triggers in  $B_s^0 \rightarrow \mu^+\mu^-\phi$  events. Trigger efficiency with 2MU0 and 2MU6 are shown as a function of  $\mu^+\mu^-$  invariant mass in Figure 6 (b). The relative trigger efficiency, normalized to the efficiency averaged over a whole  $m_{\mu\mu}^2/m_B^2$  range, is also shown to illustrate the trigger bias. The invariant mass dependency of the level-1 di-muon trigger efficiency is weak compared to the opening angle dependency and almost independent of the trigger threshold. A efficiency drop can be seen at small  $m_{\mu\mu}$ , which is also because the two muons are triggered as a single muon by the muon trigger system.

Similarly, the forward-backward asymmetry  $A_{FB}$  is shown as a function of  $\hat{s}$  in Figure 7(a). The difference ( $A_{FB}[2\text{MUx}] - A_{FB}[\text{no selection}]$ ) is also shown in Figure 7(b). It should be noted that significant differences between forward and backward samples in terms of momentum, pseudo-rapidity and  $\mu^+\mu^-$  opening angle distributions are observed. Nevertheless, as illustrated in Figure 7, the forward-backward asymmetry is more robust to the effects of level-1 di-muon triggering than di-muon mass distributions (see Figure 6).

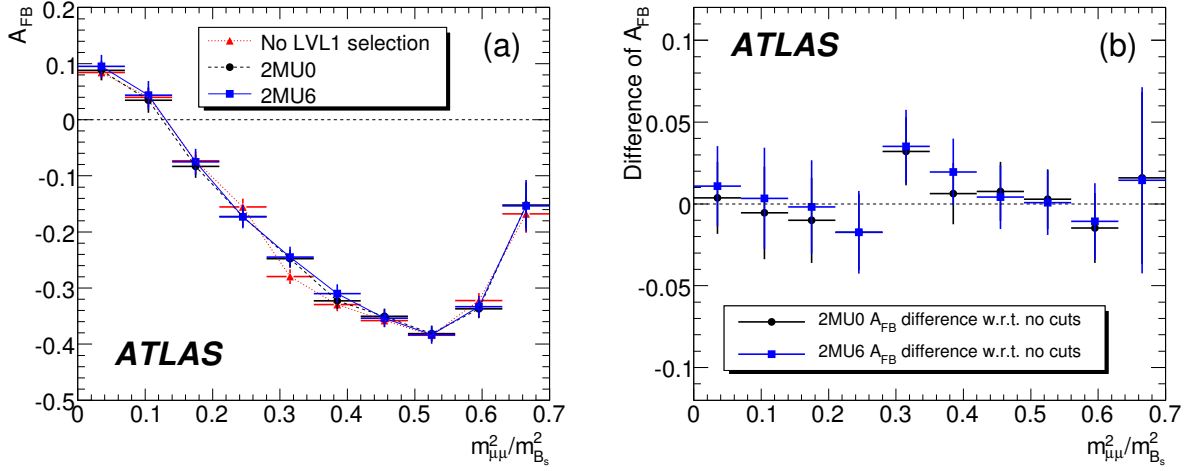

Figure 7: (a) Forward-Backward asymmetry in  $B_s^0 \rightarrow \mu^+\mu^-\phi$  events: no level-1 selection (filled triangles), triggered by 2MU0 (filled circles) and by 2MU6 (open squares). (b) deviation between  $A_{FB}$ 's with and without triggers ( $A_{FB}[2MUx] - A_{FB}[no\ selection]$ ): 2MU0 (filled circles) and 2MU6 (open squares).

## 6 Summary

The level-1 di-muon trigger is essential for selecting rare  $B$  decays that have low- $p_T$  muons in the final state. The rate for a single-muon trigger at the relevant thresholds would be unacceptably high. A detailed level-1 muon trigger simulation is implemented and used for the study of the trigger efficiency and its bias for  $B$ -physics events. The level-1 di-muon trigger efficiencies of 2MU0 and 2MU6 are high enough (about 70 % and 50 %, respectively) in the interesting  $B$ -physics events. The fake level-1 di-muon trigger rate is 2.3 kHz [8] while the genuine di-muon event rate is  $\sim 600$  Hz (muons with  $p_T > 4$  GeV from  $c\bar{c}$  and  $b\bar{b}$ ) at  $\mathcal{L} = 10^{33} \text{cm}^{-2}\text{s}^{-1}$ . The efficiency loss from the MuCTPI overlap handling is found to be negligible.

The trigger bias in regard to the opening angle and invariant mass of two muons was also studied. An opening angle dependence is clearly seen, of the order of  $\pm 10$  % and  $\pm 15$  % for 2MU0 and 2MU6, respectively. It is explained by the single-muon efficiency curves and muon kinematics in signal events. This dependency is stronger for higher  $p_T$  thresholds. No clear bias is seen due to the presence of the MuCTPI overlap handling. The trigger efficiency is rather flat over the invariant mass and less dependent on the trigger threshold since the invariant mass is not as strongly correlated to muon momenta as the opening angle is.

# Triggering on Low- $p_T$ Muons and Di-Muons for $B$ -Physics

## Abstract

Muon pairs from  $J/\psi$  decay are a clear signature of  $b$  hadrons. As a large fraction of  $b$  hadrons are produced at low- $p_T$ , a low rate, efficient di-muon trigger for low- $p_T$  muons and a good understanding of the trigger efficiency are essential. Di-muon final states will also play a key role in calibration, alignment and determination of the trigger efficiencies. The performance of the level-2 dimuon trigger algorithms is discussed, together with a method for reducing backgrounds from decays-in-flight. A strategy for calculating the single muon and di-muon trigger efficiencies at level-1 and level-2 using  $J/\psi$  from the data themselves is presented.

## 1 Introduction

$B$ -physics is one of the areas of the physics programme of the ATLAS experiment. It includes the study of production cross sections, searches for rare  $b$  decays and measurements of CP violation effects. These studies make use of the large  $b\bar{b}$  production cross section at the LHC where  $b\bar{b}$  pairs are abundant in the low transverse momentum ( $p_T$ ) region. On the other hand, one must extract signals from amongst the large QCD background, mostly composed of light quarks. For this purpose, one of the main channels for  $B$  physics study involves decay channels with one or more muons in the final state, especially the channel  $J/\psi \rightarrow \mu^+\mu^-$ .

The output rate of the first level trigger at a luminosity of  $10^{33}\text{cm}^{-2}\text{s}^{-1}$  is expected to contain 20 kHz of events where one muon passed the  $p_T$  threshold of 6 GeV. Early running is envisioned to include even lower  $p_T$  thresholds, down to the lowest threshold achievable in the hardware.

At the second level trigger this rate of events must be reduced to 1-2 kHz, of which 5-10% are available for channels of interest only to  $B$ -physics. Currently this goal is achieved for level-1 muon triggers by first confirming that a muon over the nominal threshold is reconstructed in the muon spectrometer (MS), and then confirming that there is a matching track in the inner detector (ID). This selection criterion removes many muons from  $K$  and  $\pi$  decays, but does not by itself produce the required rate reduction. To achieve the required rate  $p_T$  thresholds need to be raised and many interesting  $b$  events are likely to be filtered out. We therefore focus also on di-muon final states.

We developed an algorithm, TrigDiMuon, which achieves high efficiency at level-2 for the golden CP channels ( $J/\psi$ ), using the identification of relatively low- $p_T$  muons from  $J/\psi$  decay. TrigDiMuon searches for di-muon pairs from  $J/\psi$  or other resonant sources, when only one of the muons passed the level-1 or level-2 single muon selection. The use of TrigDiMuon can enhance  $J/\psi$  efficiency at low- $p_T$  compared to the trigger based on two muons found at level-1, with an acceptable increase in the fake rate.

In this note, we present the performance of the TrigDiMuon algorithm, that looks for a second low- $p_T$  muon partner to a single muon triggered at level-1. We compare it to the performance of an algorithm that requires a di-muon level-1 trigger. The comparison is based on a sample of  $J/\psi$  which decayed into muons with low- $p_T$ , such that the second muon of each decay may be below the level-1 threshold.

In addition to the foreseen specialised trigger strategies for di-muon signatures, it is important to optimize the rejection of muons from  $K$  and  $\pi$  decays for the standard single muon selection in order to have the lowest possible threshold on the inclusive single muon trigger. This is achieved

by extrapolating the muon track from the MS back to the interaction vertex and requiring a good match between this track and the associated track from the ID. Muons from light hadron decays do not match accurately the ID track, which in this case is the track produced by the parent hadron (or from a mixture of hits from the parent and the daughter muon) and not by the muon track. This note presents a method implemented at the level-2 trigger for rejecting muons from  $K$  and  $\pi$  decays. We summarize the rejection power of this method, show that the efficiency loss is minimal for direct muons and estimate the efficiency loss for low- $p_T$  muons from  $J/\psi$  decay.

Cross section measurements or searches for rare decays require a good understanding of the efficiency of the event selection. As we are interested in events with rather low- $p_T$ , the understanding of the trigger efficiency is crucial and we must have a strategy for measuring it from data with high precision. The tag-and-probe method for measuring the single muon trigger efficiency using  $J/\psi$  events is presented, and we demonstrate that the obtained trigger efficiency can be applied to calculate the di-muon trigger efficiency. A calibration trigger is proposed to collect an unbiased sample of single muons with an enhanced  $J/\psi$  fraction, and the expected performance of the trigger efficiency measurement in the early days of the data-taking is discussed.

Particles from additional collisions in the same bunch-crossing (pile-up) are not simulated in the samples used for this paper, and therefore this additional background is not taken into account in the analysis.

## 2 Simulated datasets used and production tools

Since the subject of this note is low- $p_T$  muons, we use simulated samples that were produced with especially low- $p_T$  cuts at the event generation level. Samples were generated using the PYTHIA event generator [1]. Except for the minimum bias events, a generator level filter was applied to pre-select efficiently the events in the sample. The di-muons sample passed a filter which required the existence of at least two muons with the appropriate  $p_T$  and  $\eta$  cuts. For the inclusive muon samples the filter required the existence of a single muon passing the corresponding selection. Events were processed with the full simulation of the ATLAS detector based on the GEANT package [2]. The level-1 simulation, High Level Trigger (HLT) selection and offline event reconstruction were performed.

The following di-muon samples were used:

- An 8000 event sample of the channel  $\Lambda_b \rightarrow J/\psi \Lambda$  with  $J/\psi \rightarrow \mu^+ \mu^-$ , where one of the muons is required at the event generation level to have  $p_T > 4$  GeV and the second muon is required to have  $p_T > 2.5$  GeV.
- Simulated samples of direct  $J/\psi$  production and  $b\bar{b} \rightarrow J/\psi$  production, with the generator level filter requiring the existence of at least two muons with  $p_T > 6$  GeV for the highest  $p_T$  muon and  $p_T > 4$  GeV for the second highest  $p_T$  muon. For both processes, 150000 events were generated.
- Two samples of inclusive muon from  $b$  decays were used. A 200000 event sample of  $b\bar{b} \rightarrow \mu X$  with a generator level filter requiring one muon with  $p_T > 4$  GeV, and a sample of 250000  $b\bar{b}$  events with at least one muon with  $p_T > 6$  GeV in the final state.
- Since this note deals specifically with methods of rejecting muons from  $K$  and  $\pi$  decays, a large sample of such decays was required. A minimum bias sample where pions and kaons were

forced to decay inside the inner tracker volume was produced for this purpose. The method developed for producing this “forced-decay” sample is described in detail below.

- Events containing a single muon each were used to study the effect on prompt muons of the method for rejecting muons from  $K$  and  $\pi$  decays. Some of the single muon samples were simulated with a perfectly aligned detector geometry, while some other samples were simulated with a misaligned detector description.

The trigger and reconstruction software used for some of the samples are of a later version than that used in other notes, because the level-2 and reconstruction software used here have improved significantly in recent version. The software modification will be explained where each package is described. Table 1 summarizes the simulated Monte Carlo samples used in this note.

	Samples	Generator level filter	Statistics
Signal samples	Direct $J/\psi \rightarrow \mu^+ \mu^-$	$p_T^{\mu_{1,2}} > 6,4 \text{ GeV}$	150 k
	$b\bar{b} \rightarrow J/\psi \rightarrow \mu^+ \mu^-$	$p_T^{\mu_{1,2}} > 6,4 \text{ GeV}$	150 k
	$\Lambda_b \rightarrow J/\psi \Lambda (J/\psi \rightarrow \mu^+ \mu^-)$	$p_T^{\mu_{1,2}} > 4,2.5 \text{ GeV}$	7.6 k
Background samples	$b\bar{b} \rightarrow \mu + X$	$p_T^\mu > 6 \text{ GeV}$	250 k
	$b\bar{b} \rightarrow \mu + X$	$p_T^\mu > 4 \text{ GeV}$	185 k
	Minimum bias (forced $K/\pi$ )		114 k
	Minimum bias (standard)		500 k

Table 1: Summary of MC samples.

## 2.1 Production tools and samples employed for $K$ and $\pi$ decays

Minimum bias events are the most copious source of pions and kaons. These particles are produced mainly with very low- $p_T$ , and typically the muons coming from their in flight decays do not escape the ATLAS hadronic calorimeter. On the other hand pions and kaons with high- $p_T$  have a low probability to decay before the calorimeter because of their high energy. As a consequence it is not efficient to use minimum bias events as a source of decays in flight to muons. Estimates made for this analysis indicated that the simulation of 5000 minimum bias events would be needed to provide one muon from  $K$  or  $\pi$  decay capable of passing the 6 GeV threshold of the ATLAS level-1 muon trigger.

To increase the statistics of events with charged pions and kaons decaying in flight, a special simulation tool is applied. Since we are interested in decays which happen inside the detector, the decays cannot be made on generator level but must happen in the GEANT simulation. The program to force the  $K/\pi$  to decay in the detector is an extension to GEANT which runs before the simulation itself.

In each event a list of all charged pions and kaons with  $p_T > 2 \text{ GeV}$  is compiled, and one of the particles in the list is randomly selected. Events with no charged pions or kaons with  $p_T > 2 \text{ GeV}$  are dropped at this stage, such that the events are not further simulated and nothing is written to output.

The point of decay is selected by first computing the trajectory length from the production vertex to where the particle would exit the ID (neglecting curvature in the magnetic field). The decay position is then determined by taking a random fraction of this maximum track length. Since particles assigned a late decay have a larger probability to be stopped through hadronic interactions, this procedure may introduce a weak bias towards shorter decay lengths.

For this study a minimum bias sample of 114 k events was simulated with forced decays. The transverse momentum cut of 2 GeV applied to the light hadrons reduces the cross section of the sample to  $(43.41 \pm 0.07)\%$  of the minimum bias cross section. In addition to this a minimum bias sample of 500 k events, simulated with the standard GEANT simulator, was also employed to provide a cross-check from a single source for both the muons from  $K/\pi$  decay and the prompt muons.

### 3 The muon trigger

The ATLAS trigger system [3] reduces the event rate from the 40 MHz beam crossing rate to  $\sim 200$  Hz for mass storage, keeping the events that are potentially the most interesting for physics. The first level trigger [4] selection is performed by custom hardware and identifies a detector region for which a trigger element was found. The second level trigger [5] is performed by dedicated software, making its decision based on data acquired from the Region of Interest (RoI) identified at level-1. Eventually, the event filter [5] uses the complete event data, and algorithms adapted from the offline reconstruction, to refine the selection of level-2 and further reduce the trigger rate by about a factor 10. An event must pass all trigger levels to be kept for analysis.

A detailed description of the ATLAS muon trigger and the estimated trigger rates are presented in [6]. Here we give a very brief summary of the principles of the level-1 and level-2 muon triggers.

#### 3.1 The level-1 muon trigger

The level-1 muon trigger is based on dedicated fast detectors: the Resistive Plate Chambers (RPC) in the barrel and the Thin Gap Chambers (TGC) in the end-caps [7]. The basic principle of the algorithm is to require a coincidence of hits in the different trigger stations within a predefined angular region, called a "road", from the interaction point through the detector. The width of the road is related to the bending of the muon in the magnetic field and thus to the  $p_T$  threshold to be applied.

The trigger in both the barrel and the end-cap regions is based on three trigger stations at different distances from the interaction point [4]. The low- $p_T$  triggers (4 to 10 GeV) are derived from a coincidence in two stations, while the high- $p_T$  triggers (over 10 GeV) require an additional coincidence with the third station. In the end-cap, there is an option to use all three stations also for the low- $p_T$  trigger. This option is the one used in the trigger performance studies in Reference [6].

The level-1 trigger provides for each muon candidate the region where it was found, called the region of interest (RoI). For the muon trigger, the size of the level-1 RoI is  $\Delta\eta \times \Delta\phi = 0.1 \times 0.1$  in the barrel and  $\Delta\eta \times \Delta\phi = 0.03 \times 0.03$  in the end-cap region, respectively.

#### 3.2 The level-2 single-muon trigger

The level-2 trigger is a software-based trigger and uses the information of the Region of Interest provided by the level-1 trigger. Level-2 algorithms only process data around the RoI, using the full granularity of the detector readout within the RoI.

The HLT trigger selection proceeds in "trigger chains". A chain consists of a series of reconstruction and decision (hypothesis) algorithms that process the data in a RoI identified by level-1. The role of the level-2 muon trigger is to confirm muon candidates flagged by the level-1 and to give more precise track parameters for the muon candidate.

The level-2 muon selection is performed in two stages. The first stage is performed by the muFast algorithm [8], which starts from a level-1 muon RoI and reconstructs the muon in the spectrometer, using the more precise Monitored Drift Tubes (MDT) to perform a new  $p_T$  estimate for the muon

candidate and creating a new trigger element. The hypothesis algorithm cuts on the estimated  $p_T$  and passes the validated trigger elements to the next algorithm.

Track finding in the inner detector is based on the region of the candidate found by muFast. The muFast candidate and ID tracks are passed to the next algorithm, muComb, which matches an ID track with the trigger element from the muon spectrometer and refines the  $p_T$  estimate [5].

### 3.2.1 muFast

For level-1 RoI's flagged by the RPC (barrel region) and the TGC (end-cap region), muFast performs global pattern recognition, a local segment fit in each muon station and a fast  $p_T$  estimation. The global pattern recognition is designed to select clusters in MDT tubes belonging to a muon track without using the drift time measurements. It is divided into two steps, firstly the pattern recognition in the trigger chambers seeded by the level-1 RoI, and the subsequent MDT pattern recognition seeded by the result of the previous step. In the MDT pattern recognition muon roads are opened in selected MDT chambers, and the locations of hit tubes are collected. A contiguity algorithm is applied on the selected hits to remove the background.

The track reconstruction approximates a muon track as a series of segments built separately in each MDT chamber. Segments are reconstructed using the drift time measurements and an approximate calibration to obtain hit radii from them. The fitted segments provide a precision measurement of the point where the fitted line crosses the middle of the MDT chamber, called the super-point.

The track bending is measured in a different way in the barrel and the end-cap. In the barrel, the sagitta is computed from the three super-points found in the three stations. In the end-cap, the track bending is measured by the angle  $\alpha$  between the track direction measured by the muon chambers in the middle and outer stations of the muon spectrometer, and the direction obtained by connecting the nominal interaction vertex with the mean hit position in the middle station.

The muon transverse momentum is estimated using an inverse linear relationship between the measured sagitta (in the barrel) or  $\alpha$  (in the end-cap) and  $p_T$ . The detector region is divided into bins in  $\eta$  and  $\phi$  and the parameters of this inverse linear function are estimated in each bin.

### 3.2.2 muComb

The muComb algorithm matches the muon track found by muFast to ID tracks reconstructed at level-2 ID-CSC. In reconstructing the level-2 ID tracks, only hits from the pixel and SCT detectors were used, for speed.

The matching between muFast and ID track segments proceeds as follows. First, a preselection of ID tracks is made based on the difference in  $\eta$  and  $\phi$  between muFast and ID track segments. In the barrel, this preselection also makes use of the difference in the  $Z$  of the extrapolated track segments at the radius of the barrel calorimeter. A weighted combined  $p_T$ , and a matching  $\chi^2$ , are calculated for each ID track passing the preselection in combination with the muon track information, and the ID track giving the lowest  $\chi^2$  is selected as the best match to the muFast track.

The version of the algorithm used in this study is improved with respect to that used in [6]. The resolution of muFast tracks assumed in combining with the ID tracks have been retuned, using the correct  $p_T$  resolutions for the different end-cap regions, and for the misaligned detector geometry. A specific tuning of the matching windows is used to improve the resolution for very low  $p_T$  muons. This algorithm will be referred to as “the baseline muComb selection” in Section 5, where a modified algorithm with better rejection for muons from  $K$  and  $\pi$  decays is also described, and the performance of the two algorithms is compared.

### 3.2.3 Level-2 muon hypotheses

The  $p_T$  cuts corresponding to each nominal threshold are set so that 90% of the muons at the nominal threshold would pass the selection. The actual cuts used depend on the resolution of the  $p_T$  estimation. Therefore the cuts are different for different regions of the detector as well as different between muFast and muComb. Thus for a nominal threshold of 6 GeV the muFast hypothesis cuts at estimated  $p_T$  values between 4.5 and 5.4 GeV in the different  $\eta$  regions, while the muComb hypothesis cuts at estimated  $p_T$  of 5.8 GeV in the barrel and end-cap and 5.6 GeV in the forward region. Since the  $p_T$  resolution of muComb is better than that of muFast, the cuts are closer to the nominal thresholds, and reject more muons with  $p_T$  below the threshold. A special case is the 4 GeV nominal threshold which is meant to accept lower  $p_T$  muons and the cuts are set at 3 GeV in the barrel and 2.5 GeV in the end-cap for both muFast and muComb.

### 3.3 The level-2 di-muon triggers

There are two approaches at level-2 for selecting di-muon events from a resonance such as  $J/\psi$  and  $\Upsilon$ . The first approach is to start from a di-muon trigger at level-1 which produces two muon regions of interest. In this approach, reconstruction of a muon is confirmed separately in each RoI as described above and the two muons are subsequently combined to form a resonance and to apply a mass cut. We will refer to this trigger as the “topological di-muon trigger”.

An alternative approach is to start with a level-1 single muon trigger and search for two muons in a wider  $\eta$  and  $\phi$  region. This approach starts from reconstructing tracks in the inner detector and extrapolating the track to the muon spectrometer to tag muon tracks. Since this method does not explicitly require the second muon at level-1, it has an advantage for reconstructing  $J/\psi$  at low- $p_T$ . This is implemented in the TrigDiMuon algorithm. The two approaches using either two or one muon RoI are illustrated in Figure 1.

Figure 1: A schematic picture of RoI based di-muon trigger, using two RoI's (left) and seeded by a single muon RoI (right).

### 3.3.1 The TrigDiMuon algorithm

TrigDiMuon is a level-2 trigger algorithm based on associations established between ID tracks and MS hits. Each time a pair of oppositely charged ID tracks, above a minimal invariant mass, is successfully associated with the MS hits, a muon pair object is created with the parameters of these ID tracks. Later, in the hypothesis step, an additional invariant mass selection can be applied, thus selecting interesting physics objects such as  $J/\psi$  or  $B$ .

The motivation for developing this algorithm comes from the fact that while di-muon final states exist in many interesting  $B$ -physics channels, the cross sections for di-muon final states are orders of magnitude smaller than those for single muons of the same  $p_T$ . An additional advantage is that resonant final states can also be used to calibrate trigger efficiencies as will be shown in Section 5.

First, the initial muon RoI is extended in order to search for a second muon, which was not triggered by level-1. The input muon may be from a region of interest identified at level-1, but the input rate to the algorithm can be reduced if, prior to the RoI extension, the level-1 RoI would be confirmed in the level-2 trigger by the muFast and (possibly also) the muComb algorithms. The performance of these options is studied in Section 4. The size of the extended RoI is based on the distribution of angular distance in  $\eta$  and  $\phi$  between two muons from  $J/\psi$  decay. Figure 2 shows the probability of including the second muon from  $J/\psi$  decays RoI as a function of the extended RoI size for different samples. The current default region size in TrigDiMuon is  $\Delta\eta \times \Delta\phi = 0.75 \times 0.75$ .

Figure 2: Probability of including the second muon from  $J/\psi$  decays RoI as a function of the extended RoI size for different samples. Open squares are from  $J/\psi$  decays where one muon has  $p_T > 6\text{ GeV}$  and the other  $p_T > 3\text{ GeV}$ . Full squares are from  $J/\psi$  decays where one muon has  $p_T > 4\text{ GeV}$  and the other  $p_T > 2.5\text{ GeV}$ .

The ID tracks in the search region are found using the trigger-tracking program IdScan or SiTrack [9], and are selected if they form a pair of oppositely charged tracks with invariant mass  $M > 2.8\text{ GeV}$ . Each selected track is extrapolated to the different stations of the MS using a formula parameterizing the expected track bending in the magnetic field. The bending parameterization is calculated separately for different regions of the muon spectrometer to account correctly for the inhomogeneous toroidal field in the end-cap region. Figure 3 shows the difference,  $\Delta\eta$ , between  $\eta$  measured in the inner detector and that measured in the middle station of the muon spectrometer. The lines indicate the choice of  $\eta$  regions for the parameterization. The parameterization was also subdivided in  $\phi$ .

The algorithm then searches for muon hits within a road around the extrapolated track. The road size also differs for different  $\eta$  regions. If a sufficient number of muon hits are found in the MS, the

Figure 3: The  $\eta$  direction of muons at the interaction point vs. the difference in  $\eta$  position between the inner detector and the middle station of the muon spectrometer, for muons with  $p_T = 6$  GeV. The lines indicate the choice of  $\eta$  regions for the parameterization.

track is identified as a muon. If both tracks from the pair are identified as muons, a muon pair object is created. The two tracks are fit to a common vertex, and the vertex  $\chi^2$  is calculated to allow a later selection of only the pairs with a good quality vertex.

#### 4 Performance of the level-2 di-muon triggers for $J/\psi$

In this Section the efficiency and fake rates resulting from the two approaches to selecting di-muons at level-2 will be presented and compared. For the TrigDiMuon algorithm we calculate the efficiency and fake rates in three different trigger chains.

In the first configuration, TrigDiMuon runs directly after the level-1 trigger based on the RoI produced by level-1. The performance of this trigger is compared to the efficiency and fake rate of the level-1 di-muon trigger.

The other two trigger chains confirm a single level-2 muon before calling TrigDiMuon. The purpose of these chains is not to reduce the fake di-muon trigger rate, but rather to reduce processing time by reducing the input rate to TrigDiMuon. Since TrigDiMuon starts from ID track reconstruction in an extended region around the muon region of interest, the tracking in the inner detector requires three times longer than if only reconstructing ID tracks in the narrow road used by muComb. Thus, this time consuming process can be avoided for candidates for which the level-1 trigger is not confirmed at level-2.

In the second chain TrigDiMuon runs after muFast. The input to TrigDiMuon in this case is a muon confirmed in the MS, with a cut on the  $p_T$  estimated at this stage. The efficiency of this trigger is compared with that of a topological di-muon trigger based on a level-1 di-muon with two oppositely charged muons confirmed in the MS at level-2.

In the third chain TrigDiMuon runs after muComb. The input to TrigDiMuon in this case is a muon confirmed in the MS and the ID, with a cut on the  $p_T$  estimated at this stage. The efficiency of this trigger is compared with that of the topological di-muon trigger with two oppositely charged level-2 combined muons, within the same invariant mass window. The invariant mass window can be

applied in this chain, and not the second chain, because only after muComb the momentum resolution is sufficient for a reasonable selection on invariant mass.

The efficiency and fake rates of these trigger sequences were studied for two different trigger thresholds, a 4 GeV threshold that is envisioned to run at initial luminosity, and a 6 GeV threshold that will be the lowest threshold for running at a luminosity of  $10^{33}\text{cm}^{-2}\text{s}^{-1}$ .

A selection requiring the two muons to be oppositely charged, and the pair to have invariant mass between 2.8 GeV and 3.4 GeV was applied to both TrigDiMuon and the topological di-muon trigger. For the topological algorithm the invariant mass selection was only applied after muComb. The fake rates were calculated as follows: the probability of each of the level-2 strategies to find a di-muon pair in events which contain only a single muon was estimated separately for the  $b$  events and the minimum-bias events. This probability was multiplied by rates which were estimated independently from [6], but are consistent with it. The fake probability in  $b$  events was taken to be representative of that in all events with prompt muons. For the topological di-muon trigger, the probability was calculated relative to the number of di-muon level-1 triggers, and multiplied by the level-1 fake di-muon trigger rate from [6].

#### 4.1 Efficiency relative to events accepted at level-1

Table 2 gives the efficiency, relative to level-1, for the two di-muon trigger algorithms for a trigger threshold of 4 GeV. Table 3 gives the efficiencies, relative to level-1, for a trigger threshold of 6 GeV. The efficiencies in these tables are calculated with respect to the  $J/\psi$  events accepted by the corresponding level-1 single muon trigger. In parenthesis we give the efficiency relative to  $J/\psi$  events at the starting point of the di-muon algorithm.

One can see that the TrigDiMuon efficiency is significantly higher than the topological di-muon trigger in all cases. As a matter of fact, the topological di-muon trigger, which applies  $p_T$  cuts on both muons, can have only a limited acceptance for  $J/\psi$  events passing a single muon trigger because the second muon is very frequently below the trigger threshold. To pass the topological di-muon trigger the second, lower  $p_T$  muon also has to pass the level-2 selections.

Because TrigDiMuon can reconstruct muons below the level-1 thresholds, the TrigDiMuon efficiency, shown in brackets, remains nearly the same with the different chains. However, the total efficiency is reduced when starting from the single muons accepted by muFast or muComb, because of the  $p_T$  cut imposed by those algorithms. In particular, in Table 3 muFast and muComb reject successively more of the muons below the nominal threshold and this explains the big drop from row to row for TrigDimuon and even bigger drop for the topological trigger.

The loss of efficiency in the single muon triggers is smaller for the 4 GeV threshold, because the level-2 cuts for the 4 GeV threshold are quite loose, as mentioned above. When calculating the 4 GeV trigger efficiency using only muons from  $J/\psi$  with generated  $p_T$  above the 4 GeV threshold, TrigDiMuon has an efficiency of 90% and the topological trigger has an efficiency of 64%.

As discussed earlier, in spite of some loss of efficiency, the trigger chains with TrigDiMuon running after a level-2 confirmed muon might be more suitable to an overall planning of the ATLAS trigger menu due to the reduced input rate they have to sustain.

#### 4.2 Fake rates

Table 4 gives the expected fake rates for TrigDiMuon with the different chains described above, for a trigger threshold of 4 GeV at a luminosity of  $10^{31}\text{cm}^{-2}\text{s}^{-1}$ . Table 5 gives the rates for a trigger threshold of 6 GeV at a luminosity of  $10^{33}\text{cm}^{-2}\text{s}^{-1}$ .

Chain starting from	TrigDiMuon (%)	Topological trigger (%)
level-1	73 (73)	51
muFast	71 (73)	43
muComb	70 (74)	33

Table 2: Efficiency, relative to level-1, of the two di-muon trigger algorithms for a trigger threshold of 4 GeV. In parenthesis is the efficiency calculated relative to  $J/\psi$  events that passed the single muon trigger that selects the input to TrigDiMuon. To estimate the efficiency we used a sample of  $\Lambda_b \rightarrow J/\psi \Lambda$ , where  $J/\psi \rightarrow \mu(p_T > 2.5 \text{ GeV})\mu(p_T > 4 \text{ GeV})$ .

Chain starting from	TrigDiMuon (%)	Topological trigger (%)
level-1	75 (75)	56
muFast	67 (77)	25
muComb	60 (78)	15

Table 3: Efficiency, relative to level-1, of the two di-muon trigger algorithms for a trigger threshold of 6 GeV. In parenthesis is the efficiency calculated relative to  $J/\psi$  events that passed the single muon trigger that selects the input to TrigDiMuon. To estimate the efficiency we used a sample of  $\Lambda_b \rightarrow J/\psi \Lambda$ , where  $J/\psi \rightarrow \mu(p_T > 2.5 \text{ GeV})\mu(p_T > 4 \text{ GeV})$ .

Source	Chain starting from	Input rate (Hz)	Fake acceptance (%)	Fake rate (Hz)
$b + c$	level-1	460	0.42	1.9
	muFast	380	0.42	1.6
	muComb	340	0.43	1.5
$K/\pi$	level-1	620	0.07	0.43
	muFast	270	0.11	0.29
	muComb	170	0.09	0.15
<b>Total</b>	level-1	1080	0.22	2.3
	muFast	650	0.29	1.9
	muComb	510	0.32	1.6

Table 4: Fake rate of the TrigDiMuon algorithm for muons from different sources and total fake rate using a trigger threshold of 4 GeV, at a luminosity of  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ . The  $b$  and  $c$  components were estimated from a sample of  $b\bar{b} \rightarrow \mu + X$  with  $p_T^\mu > 4 \text{ GeV}$  and the  $K/\pi$  component from the minimum bias sample with forced decays

Fake rates can be further reduced by reconstructing the  $J/\psi$  decay vertex from the two muon tracks. Selecting  $J/\psi$  with a good quality vertex fit will reduce fake rates from unrelated track combinations. Figure 4 shows the distribution of the vertex  $\chi^2$  for true  $J/\psi$  decays and for fake di-muon triggers. A cut of  $\chi^2 < 30$  reduces the fake rate by 20-30% and only reduces the trigger

Source	Chain starting from	Input rate (Hz)	Fake acceptance (%)	Fake rate (Hz)
$b + c$	level-1	21500	0.48	103
	muFast	12500	0.60	76
	muComb	10300	0.75	76
$K/\pi$	level-1	15800	0.22	34
	muFast	5000	0.30	15
	muComb	3500	0.41	14
<b>Total</b>	level-1	37400	0.37	137
	muFast	17500	0.51	91
	muComb	13700	0.66	90

Table 5: Fake rate of the TrigDiMuon algorithm for muons from different sources and total fake rate using a trigger threshold of 6 GeV, at a luminosity of  $10^{33}\text{cm}^{-2}\text{s}^{-1}$ . The  $b$  and  $c$  components were estimated from a sample of  $b\bar{b} \rightarrow \mu + X$  with  $p_T^\mu > 4$  GeV and the  $K/\pi$  component from the minimum bias sample with forced decays

efficiency by 1-2%. The vertex position can also be used to reject  $J/\psi$  produced at the primary interaction and accept only  $J/\psi$  from  $b$  hadron decays, but a study of this is outside the scope of this note.

Figure 4: Distribution of the vertex  $\chi^2$  for true  $J/\psi$  decays (shaded) and for fake di-muon triggers (open histogram).

Finally Table 6 compares the total rates and efficiencies of the two level-2 di-muon algorithms. When TrigDiMuon runs after muComb, the signal to background ratio is worse than when it runs after muFast. Using the input rates from Table 4 and 5, one can calculate that the time needed to reconstruct

the ID tracks is also the smallest when TrigDiMuon runs after muFast, reduced by 1/3 for the 4 GeV threshold and by 1/2 for the 6 GeV threshold with respect to running after L1.

It can be seen from this table that the fake rate for the topological di-muon trigger is small. The fake rate from the TrigDiMuon algorithm is much higher but these output rates from level-2 should be acceptable for the gain in efficiency, at the initial low luminosity.

Threshold (Luminosity)	Chain starting from	TrigDiMuon			Topological		
		Efficiency (%)	$J/\psi$ rate (Hz)	Total rate (Hz)	Efficiency (%)	$J/\psi$ rate (Hz)	Total rate (Hz)
<b>4 GeV</b> ( $10^{31}\text{cm}^{-2}\text{s}^{-1}$ )	level-1	71	1.17	3.1	51	0.8	24
	muFast	70	1.15	2.7	43	0.7	-
	muComb	69	1.14	2.4	33	0.5	0.6
<b>6 GeV</b> ( $10^{33}\text{cm}^{-2}\text{s}^{-1}$ )	level-1	74	43	151	56	32.5	357.5
	muFast	66	38	114	25	14.5	-
	muComb	59	34	109	15	8.7	9.3

Table 6: Total rate and efficiency relative to level-1 of the TrigDiMuon algorithm including the vertex cut  $\chi^2 < 30$ , and of the topological di-muon trigger. The efficiency is estimated from a sample of  $\Lambda_b \rightarrow J/\psi \Lambda$ , where  $J/\psi \rightarrow \mu(p_T > 2.5 \text{ GeV})\mu(p_T > 4 \text{ GeV})$ .

The  $b$ -physics trigger rate from TrigDiMuon requires further reduction for  $L = 10^{33}$ . This can be achieved by introducing an additional trigger with a cut on the  $J/\psi$  decay length. Then the trigger without decay length cut will be prescaled to an acceptable rate for calibration and alignment purposes, as for example in Section 6. An event filter algorithm will further reduce the rates for a luminosity of  $10^{33}\text{cm}^{-2}\text{s}^{-1}$ .

### 4.3 Efficiency relative to reconstructed events

Our goal is to maximize trigger efficiency at the level-2 trigger for the muons that can later be identified offline. The efficiencies for the two algorithms and thresholds were re-estimated with respect to the  $J/\psi$  events reconstructed with the muon identification program MuGirl [10], which is efficient for low- $p_T$  muons. The resulting efficiencies are given in Table 7 for a trigger thresholds of 4 GeV and 6 GeV respectively. Figure 5 shows the efficiency of TrigDiMuon relative to muons identified by MuGirl for the higher  $p_T$  muon (left) and the second muon (right).

Threshold (Luminosity)	Chain starting from	TrigDiMuon Efficiency (%)	Topological Trigger Efficiency (%)
<b>4 GeV</b> ( $10^{31}\text{cm}^{-2}\text{s}^{-1}$ )	level-1	84	58
	muComb	81	42
<b>6 GeV</b> ( $10^{33}\text{cm}^{-2}\text{s}^{-1}$ )	level-1	81	45
	muComb	66	17

Table 7: Efficiency of the TrigDiMuon and Topological di-muon algorithms for  $J/\psi$  reconstructed by MuGirl. To estimate the efficiency we used a sample of  $\Lambda_b \rightarrow J/\psi \Lambda$ , where  $J/\psi \rightarrow \mu(p_T > 2.5 \text{ GeV})\mu(p_T > 4 \text{ GeV})$ .

Figure 5: Efficiency of TrigDiMuon relative to muons identified by MuGirl for the higher  $p_T$  muon (left) and the second muon (right).

## 5 Rejection of muons from $K$ and $\pi$ decays

The lowest single muon  $p_T$  threshold in the original ATLAS HLT design [5] was chosen to be 6 GeV. This is because below this  $p_T$  value the rate of muons from  $K$  and  $\pi$  decays becomes higher than that from  $b$  and  $c$  decays. Nevertheless, during the low luminosity phase, it is desirable to collect muons with lower  $p_T$ , both for detector and trigger calibration and for initial physics studies. If thresholds are lowered,  $K$  and  $\pi$  decays become the dominant source of single muon triggers. These decay muons must be rejected as early as possible so as not to dominate the single muon trigger rate, thus ensuring we can achieve the physics and calibration studies with prompt muons.

### 5.1 Description of the method

The method we describe rejects  $K$  and  $\pi$  decays based not on their  $p_T$  but on the topology of the decay. The track position of a prompt muon, extrapolated from the MS to the interaction vertex, is a gaussian distributed around the ID track position. The corresponding distribution of a decay muon around the light hadron from which it decayed is broader because of the contribution of the decay kink in addition to the multiple scattering effect. Thus if the track seen in the inner detector is that of the  $K$  or  $\pi$ , this discrepancy with prompt muons can be used to reject some of the muons from light hadron decays.

With this method, we can reject the muons from  $K$  and  $\pi$  decays by using a matching window tuned for prompt muons, with the window width varying according to the track  $p_T$ . Due to time constraints, a precise propagation of tracks in the magnetic field can not be done at level-2, so instead the muon track from the MS is extrapolated back to the interaction vertex using a parameterization that is a function of measured  $\eta$ ,  $\phi$  and  $p_T$  (exploiting the linear relationship between the bending and  $1/p_T$ ). Multiple scattering effects can be parameterized in the same way to estimate the corresponding errors of the back extrapolation, which determine the window size.

Three main regions are identified for the field parameterization used to propagate the muon tracks, one in the barrel and two in the end-cap. To account for the relative inhomogeneity of the magnetic field inside each region, the parameters of the back extrapolation are computed as a function of  $\eta$ ,  $\phi$ , muon charge and spectrometer side ( $z$  or  $-z$ ). A different tuning is used for high and low- $p_T$  tracks, to take into account the fluctuations of the energy loss in the calorimeter which are important for the

propagation of the latter. In the end-cap, the innermost station of the MS does not provide a complete geometric coverage, thus for the muons with no hits in the innermost station, a seed from the middle station is used to extrapolate the track back. This is the most difficult case since an extrapolation through the toroids must be performed and the resulting precision is spoiled by a factor of two with respect to the other cases. Therefore the back extrapolation in the end-cap is treated separately for regions with inner station coverage and region without inner station coverage.

The strategy for the level-2 combined muon reconstruction described in [5] is to use only the pixel and the SCT data. With this setup, the decays in flight happening near or after the last SCT layer are reconstructed using mainly the hits of the decaying  $K$  or  $\pi$ . Some rejection of these events can be achieved by checking the  $\eta$  and  $\phi$  position of the extrapolated MS track relative to the ID track with a matching window whose size is based on the position spread coming out from the muon multiple scattering. Some of the decays between the pixel and the SCT can be rejected by applying a cut on the  $\chi^2$  of the Inner Detector fit.

The cuts studied, ordered in terms of increasing rejection are:

- A loose-window cut, using the muon track position from muFast, and the track position from the ID reconstruction. The window size was tuned to recover almost 100% of the multiple scattering for a muon  $p_T$  equal to the threshold value (4 GeV and 6 GeV);
- A tight-window cut, refining the muon back-extrapolation by exploiting the measurement of the interaction vertex from the ID reconstruction. The window size was tuned to  $2.7 \sigma$  of the multiple scattering spread for that muon  $p_T$ ; the combined  $p_T$  estimation is used to tune the window width;
- The normalized  $\chi^2$  of the ID track fit is required to be less than 3.2.

## 5.2 Performance of the method

### 5.2.1 Rejection results for $K$ and $\pi$ decays

The 6 GeV threshold is used as a benchmark to estimate the  $K$  and  $\pi$  rejection achieved by the various cuts. The forced-decay minimum bias sample has been used to study and tune the cuts to reject muons from  $K$  and  $\pi$  decays. The results shown in Table 8 are expressed in terms of trigger rate, computed using the cross section of these events.

Cut	$\pi/K$ rate (Hz)
Baseline muComb	$3470 \pm 380$
Loose window cut	$2920 \pm 430$ (-16%)
Tight window cut	$2800 \pm 440$ (-20%)
Tight window + $\chi^2$ cut	$2550 \pm 440$ (-26%)

Table 8: Expected rate with a 6 GeV single muon threshold from the muComb algorithm for the  $\pi$  and  $K$  decays. The rejection with respect to the baseline muComb algorithm is shown in parenthesis. These rates were estimated from the forced-decay minimum bias sample

Figure 6 shows the trigger efficiency for muons from  $K$  and  $\pi$  decays as a function of  $p_T$  for the baseline muComb selection, compared to the tight window selection described above.

Figure 6: Efficiency for muons from  $K$  and  $\pi$  decays as a function of  $p_T$  for the baseline muComb selection, compared to the optimized muComb selection described in Section 5.1 for the 4 GeV threshold (left) and the 6 GeV threshold (right).

Figure 7: Efficiency of the tight window match on single muons simulated with the aligned detector setup. The efficiency drop for the 6 GeV threshold is shown according to different  $\sigma$  cuts.

### 5.2.2 Efficiency loss for prompt muons

The efficiency loss for prompt muons due to the matching window cuts has been estimated with a single muon sample. Figure 7 shows the relative efficiency obtained for the aligned detector setup. The relative efficiency is seen to be almost constant in the  $p_T$  range of 4-40 GeV and its value for the cut at  $2.7\sigma$  is about 98%. The detector misalignment reduces the efficiency plateau to 95% as shown in Figure 8, but the relative efficiency can be recovered by 1% with a specific tuning of the back extrapolator.

The rate reduction for  $b$  decays is calculated reliably from the  $b \rightarrow \mu(4) + X$  sample. The results are shown in Table 9. A good agreement between  $b$  events and single muons is found for the efficiency

Figure 8: Efficiency of the tight window match at  $2.7 \sigma$  on single muons simulated with the misaligned detector setup. The relative efficiency is shown for the 6 GeV threshold.

loss due to the tight window match.

Cut	$b \rightarrow \mu(4) + X$ rate (Hz)
Baseline muComb	$4850 \pm 20$
Loose window cut	$4780 \pm 20$ (-1.5%)
Tight window cut	$4710 \pm 20$ (-3%)
Tight window + $\chi^2$ cut	$4560 \pm 20$ (-6%)

Table 9: Expected rate with a 6 GeV single muon threshold from the muComb algorithm for the  $b$  component. In parenthesis is the percentage rejection with respect to the baseline muComb.

### 5.2.3 Resulting muon trigger rates

A coherent description of the full trigger rate after the muComb algorithm is obtained using the standard minimum bias sample and is shown in Table 10 and in Table 11. All the cuts mentioned were applied. A very good agreement is found with both the forced sample for the  $K/\pi$  component, and the  $b \rightarrow \mu + X$  sample for the  $b$  component.

The optimized version of muComb improves the rejection of muons from decays in flight by about 30% at the 4 GeV threshold and of about 20% at the 6 GeV threshold with respect to the baseline muComb algorithm. The rejection of muons from  $b$  events is 20% at the 4 GeV threshold and 7% at the 6 GeV threshold. Thus while the total trigger rate is reduced the purity of the sample increases. Given the uncertainties on the estimation of the production cross section for  $K$  and  $\pi$  this optimization is crucial for the low- $p_T$  single muon trigger.

Sample	muFast rate (Hz)	muComb rate (Hz)	muComb + $\pi/K$ cuts rate (Hz)
$\pi/K$	$224 \pm 15$	$210 \pm 9$	$145 \pm 9$
$b$	$145 \pm 7$	$140 \pm 6$	$114 \pm 6$
$c$	$234 \pm 8$	$200 \pm 8$	$168 \pm 8$

Table 10: Expected output rate of muFast and muComb for a 4 GeV threshold at the  $10^{31}\text{cm}^{-2}\text{s}^{-1}$  Luminosity.

Sample	muFast rate (Hz)	muComb rate (Hz)	muComb + $\pi/K$ cuts rate (Hz)
$\pi/K$	$5050 \pm 760$	$3530 \pm 380$	$2860 \pm 410$
$b$	$5550 \pm 600$	$4900 \pm 400$	$4550 \pm 430$
$c$	$6900 \pm 700$	$5390 \pm 420$	$5050 \pm 450$

Table 11: Expected output rate of muFast and muComb for a 6 GeV threshold at the  $10^{33}\text{cm}^{-2}\text{s}^{-1}$  Luminosity.

Checking the effect of this method to reject muons from  $K$  and  $\pi$  decays on the two level-2 di-muon strategies showed that both efficiency and trigger rates are reduced. There is no significant gain in purity from this method for the di-muon selections, because the rejection is achieved by using the  $J/\psi$  reconstruction and mass cuts, and most of the fake rate comes from  $b$  and  $c$  decays.

## 6 Measuring trigger efficiency for low- $p_T$ muons from ATLAS data

### 6.1 Method description

Cross section measurements require a good understanding of the efficiency of the event selections. A precise understanding of the trigger efficiency is crucial and we must have a strategy for measuring it from data with high precision. We study the performance of measuring the trigger efficiency from data with the tag-and-probe method which uses di-muon final states for measuring the single muon trigger efficiency. In this method, a single triggered muon from a reconstructed di-muon decay of a specific particle identified by mass cuts provides the tag that allows us to probe the trigger efficiency of the second muon.

For  $B$  physics we are interested in events with rather low- $p_T$  muons, so the tag-and-probe method for measuring the single muon trigger efficiency using  $J/\psi$  events is presented. We demonstrate that the obtained trigger efficiency can be applied to calculate the di-muon trigger efficiency. This principle can also be applied to  $Z$  decays to calibrate the high- $p_T$  trigger efficiency [11].

#### 6.1.1 Measuring single muon efficiency

We use the tag-and-probe method to measure the muon trigger efficiency, using as the calibration sample events collected by a single muon trigger where the  $J/\psi$  is found in the offline reconstruction. In this sample, one of the muons forming the  $J/\psi$  is triggered, while the other one may or may not be triggered, thus providing an unbiased sample of muons to study the single muon trigger efficiency.

First, the triggered muon is matched to one of the reconstructed muons from an identified  $J/\psi$ . This muon is called the *tagged*-muon. Once the tagged-muon is identified, the other muon, the *probe*-

muon is used to check whether it is also triggered or not. A matching between the reconstructed muon and the one found at the trigger level is needed here too.

At the high level trigger, the position of the muon found at the trigger level is stored, and can be compared precisely to the reconstructed muon. However, at level-1 the position granularity is that of the RoI. Due to the limited precision of the location of the RoI, care must be taken when matching a muon RoI to the reconstructed muon. The bending of the muon tracks in the magnetic field and the fact that high- $p_T$  decay muons have small opening angles between them also introduces an ambiguity in the matching.

The single muon trigger efficiency,  $\varepsilon_{1\mu}$ , is calculated as the ratio between the number of probe muons which were triggered ( $N_{probe\&triggered}$ ) to the total number of probe muons ( $N_{probe}$ ),

$$\varepsilon_{1\mu} = \frac{N_{probe\&triggered}}{N_{probe}}. \quad (1)$$

The single muon efficiency can be obtained in detail as a function of kinematic variables ( $p_T$ ,  $\eta$ ,  $\phi$ ) of the muons using as fine a binning as the statistics allows. A fine binning is, in fact, necessary since the efficiency depends on these variables, especially at level-1 where there are sharp changes in the efficiency due to structural features such as the experiment's support structures. Because of this the overall efficiency depends on the distribution of the muons produced. We call the detailed *map* of efficiencies in each region of the phase space a trigger efficiency map.

Our primary goal is to demonstrate that it is possible to obtain the trigger efficiency map from data alone. The di-muon trigger efficiency can then be calculated from it, given the distribution of the parent particles and the decay angular distribution.

### 6.1.2 Calculating di-muon trigger efficiency

The di-muon trigger efficiency can be calculated using the obtained single muon efficiencies, taking into account the dependence on kinematic variables of the muons. For example, the efficiency of  $J/\psi$  particles are different depending on the kinematic distribution of the two decay muons. The  $J/\psi$  efficiency,  $\varepsilon^{J/\psi}$  can be calculated using the single muon trigger efficiency map as

$$\varepsilon_{J/\psi}(p_T^{J/\psi}, \eta^{J/\psi}, \phi^{J/\psi}) = \frac{1}{2\pi} \iint \varepsilon_{1\mu}(p_T^{\mu_1}, \eta^{\mu_1}, \phi^{\mu_1}) \varepsilon_{1\mu}(p_T^{\mu_2}, \eta^{\mu_2}, \phi^{\mu_2}) f(\cos \theta^*) d\cos \theta^* d\phi^*. \quad (2)$$

Here,  $f(\cos \theta^*)$  is the angular distribution of the decay muon from the  $J/\psi$  where  $\theta^*$  represents the decay angle of the muon in the  $J/\psi$  rest frame with the  $z$ -axis taken as the direction of the  $J/\psi$  in the laboratory frame. The variable  $\phi^*$  is the azimuthal angle of the decay muon in the  $J/\psi$  rest frame, normalized as  $\int f(\cos \theta^*) d\cos \theta^* = 1$ . Kinematic variables of the decay muons ( $p_T^{\mu_1}, p_T^{\mu_2}, \eta^{\mu_1}, \eta^{\mu_2}, \phi^{\mu_1}, \phi^{\mu_2}$ ) are functions of the  $J/\psi$  variables,  $\cos \theta^*$  and  $\phi^*$ . To get the overall efficiency of  $J/\psi$  events, the integration of  $J/\psi$  variables must be performed in the kinematic region of the cross-section definition.

Note that this formula is universal and can be applied to other resonances such as  $B_{s,d} \rightarrow \mu\mu X$  using the same single muon efficiency map. The  $\cos \theta^*$  distribution depends on the polarization state of the  $J/\psi$  which reflects the  $J/\psi$  production mechanism. For the unpolarized case, this distribution is flat. In certain analysis, the production mechanism of the parent particle could be of interest, so we cannot assume the distribution to be flat. In such cases, it is necessary to be able to calculate the efficiency as a function of  $\cos \theta^*$  as well. In these cases, Equation 2 would become,

$$\varepsilon_{J/\psi}(p_T^{J/\psi}, \eta^{J/\psi}, \phi^{J/\psi}, \cos \theta^*) = \frac{1}{2\pi} \int \varepsilon_{1\mu}(p_T^{\mu_1}, \eta^{\mu_1}, \phi^{\mu_1}) \varepsilon_{1\mu}(p_T^{\mu_2}, \eta^{\mu_2}, \phi^{\mu_2}) d\phi^* \quad (3)$$

without the  $\cos \theta^*$  integration. Equation 3 is simply expressing the efficiency of events where  $J/\psi$  is produced with a fixed momentum and the decay angle is also fixed, so the decay muon momenta are also fixed. Some variables could be integrated out, but the important thing is that the efficiency with respect to  $\cos \theta^*$  can also be obtained from the single muon efficiency map,  $\varepsilon_{1\mu}(p_T^\mu, \eta^\mu, \phi^\mu)$ .

## 6.2 Performance studies

In order to emulate the efficiency measurement from data, we use  $J/\psi$  events with two muons in the offline reconstruction passing the single muon threshold of 6 GeV and a di-muon invariant mass between 2.88 GeV and 3.3 GeV.

### 6.2.1 Matching of muons at trigger and reconstruction

The first step of the tag-and-probe method is to find out which of the two offline muons was triggered. This is done by finding the best match using  $\Delta R = \sqrt{\Delta\eta^2 + \Delta\phi^2}$ , where  $\Delta\eta$  and  $\Delta\phi$  are the difference of  $\eta$  and  $\phi$  between the offline muon and the triggered muon. For the matching with level-2 muons, track parameters at the perigee are used. On the other hand, for level-1, the position of the triggered muon is taken as the center of the RoI. In this case, the matching must be done carefully as the opening angle of the two muons from the  $J/\psi$  is small and the bending, of the rather low- $p_T$  muons, in the magnetic field is non-negligible. The offline muon tracks are extrapolated to the plane of the RPC or TGC chamber which defines the RoI.

Figure 9 shows the  $\Delta R$  distribution between the level-1 RoI and offline track with and without using the extrapolation. The improvement obtained by the extrapolation is significant and as a result a good matching is established by requiring  $\Delta R < 0.15$ . To further reduce the possibility of having a wrong match, in this study we only use events where the opening angle between the two muons is  $\Delta R > 0.4$ .

Figure 10 shows the  $\Delta R$  distribution between the level-2 muon and the offline track. The resolution of  $\Delta R$  becomes an order of magnitude better than at level-1 since the level-2 muon tracks use the measurements from the ID. The condition  $\Delta R < 0.005$  is used for the matching between the offline track and the level-2 track.

Figure 9: The distribution of  $\Delta R$  between the level-1 RoI and the offline muon track, (a) using the offline track parameters at the perigee and (b) by extrapolating the offline track to the RoI position. The dashed line shows the value where the cut was applied for the matching.

Figure 10: The distribution of  $\Delta R$  between the level-2 muon and the offline muon track. The dashed line shows the value where the cut was applied for the matching.

### 6.2.2 Level-1 efficiency

Using the method described in Section 6.1 and the matching criteria, we obtain the single muon efficiency as a function of the  $p_T$  of the muon. Figure 11 shows the single muon efficiency as a function of  $p_T$  by evaluating how often the probe-muon was triggered. The points are fitted with the function

$$\varepsilon(p_T) = \frac{A}{1 + \exp(-a \times (p_T - b))}. \quad (4)$$

Also shown in Figure 11 is the efficiency measured directly in the single muon Monte Carlo sample which provides an unbiased value of the efficiency. The agreement of the efficiencies obtained by the two methods is around 5% in the turn-on region ( $4 \text{ GeV} < p_T < 8 \text{ GeV}$ ) and becomes smaller as the  $p_T$  increases, becoming within a few percent at  $p_T > 10 \text{ GeV}$ .

To calculate the di-muon trigger efficiency using Equation 2, the efficiency curve must be measured in each  $\eta$  and  $\phi$  region. For this, we divided the detector into  $10 \times 10$  regions for the barrel ( $-1.05 < \eta < 1.05$ ). For the end-cap region ( $1.05 < |\eta| < 2.4$ ), we assumed that there is a complete symmetry between octants and divided one octant into  $8 \times 6$  regions. Efficiency curves as a function of  $p_T$  are obtained in each of the regions. Figure 12 shows the three fit parameters,  $A$ ,  $a$  and  $b$  in Equation 4 as a function of  $\eta$  and  $\phi$ . The figure shows that the efficiency curve behaves differently for different regions but in a smooth way, except for a small region around  $\eta = 0.725$  and  $\phi = -1.6$ . In this region the efficiency is very low due to the MS layout and as a result the fit is unreliable. These results are used to calculate the di-muon efficiency.

Distributions of offline  $J/\psi$  variables,  $p_T^{J/\psi}$ ,  $\eta^{J/\psi}$  and  $\cos \theta^*$  are shown in Figure 13 after applying the selection criteria of muons ( $p_T^\mu > 6 \text{ GeV}$  and  $|\eta^\mu| < 2.4$ ). The open histograms are for all  $J/\psi$  in the MC sample and the filled histograms are for events where the level-1 di-muon trigger, requiring at least two muons with  $p_T > 6 \text{ GeV}$ , has fired. The generator level filter with the  $p_T$  cut for the highest (second highest)  $p_T$  muon of  $p_T > 6(4) \text{ GeV}$  was applied for the MC sample.

The  $\cos \theta^*$  distribution reflects the polarization state of the  $J/\psi$  and is flat for the non-polarized case. Since the  $\cos \theta^*$  distribution is an interesting quantity to measure in its own right, we do not make any assumptions about this distribution but instead try to measure the efficiency as a function

Figure 11: The overall efficiency of the level-1 single muon trigger with respect to the offline selection obtained by the tag-and-probe method (filled circles) and the efficiency estimated from a single muon Monte Carlo sample (open circles). The curve is a fit to the efficiency obtained by the tag-and-probe method from Equation 4.

of  $\cos \theta^*$ . Although the generated  $\cos \theta^*$  distributions were flat, reconstructed distributions will be biased by the  $p_T^\mu$  cuts applied at the generator level. At  $|\cos \theta^*| = 1$ , one of the decay muons flies in the opposite direction to the  $J/\psi$  and has low transverse momentum, therefore these events are more likely to be rejected by the  $p_T$  cut for the highest (second highest)  $p_T$  muon of  $p_T > 6(4)$  GeV requirement.

Figure 14 shows the di-muon trigger efficiencies calculated in two methods. The open circles are obtained by checking the decision of the level-1 di-muon trigger for each event. The efficiencies calculated using the parameterization in Figure 12 are shown by the filled circles. They are calculated by assigning an efficiency for each event according to the kinematics of the two muons in the final state using Equation 3. The same technique may be used once data are collected by the experiment. The effect of the systematic uncertainty of the method has been estimated by changing the procedure to obtain the trigger efficiency map, namely by using  $16 \times 16$  bins in  $\eta$ - $\phi$  in the barrel and  $15 \times 10$  in the endcap. In addition, the fitting function has been changed by adding a linear function  $c(p_T - d)$  to the original function for  $p_T > d$ . This was done to better describe a drop of efficiency for higher  $p_T$ .  $c$  and  $d$  are additional fit parameters. Both statistical and systematic errors are a few % in most of the region, but the systematic uncertainty increases where the change of efficiency is rapid. In Figure 14, the statistical and systematic errors are added in quadrature.

Results of the two methods agree within a few % in most regions. Efficiency losses at  $\eta^{J/\psi}$  around -1, 0 and +1 are due to the layout of the muon trigger chambers. These plots confirm that the requirement of  $p_T^\mu > 6$  GeV on two muons introduces an effective cut of  $p_T > 12$  GeV for the  $J/\psi$  and the efficiency with respect to  $\cos \theta^*$  is flat across the region between  $-0.8 < \cos \theta^* < 0.8$ . The overall efficiencies calculated in the kinematic region of  $p_T^{J/\psi} > 12$  GeV and  $|\eta^{J/\psi}| < 2$  are 76.1% and 77.0% using the trigger decision and the trigger efficiency map, respectively, which is in agreement within the statistical and systematic errors. The size of the systematic errors may be improved by creating the efficiency map with finer granularity, which requires more statistics.

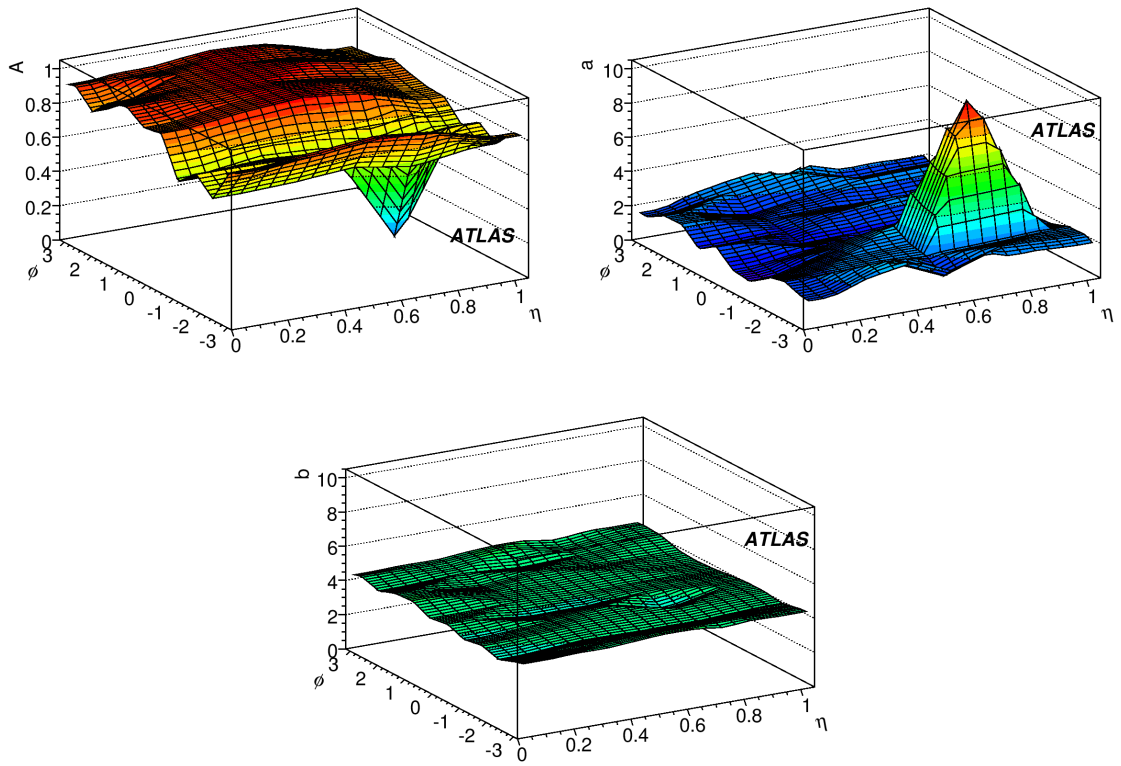

Figure 12: Fit parameters ( $A$ ,  $a$  and  $b$  in Equation 4) of the efficiency curve in different  $\eta$  and  $\phi$  regions.

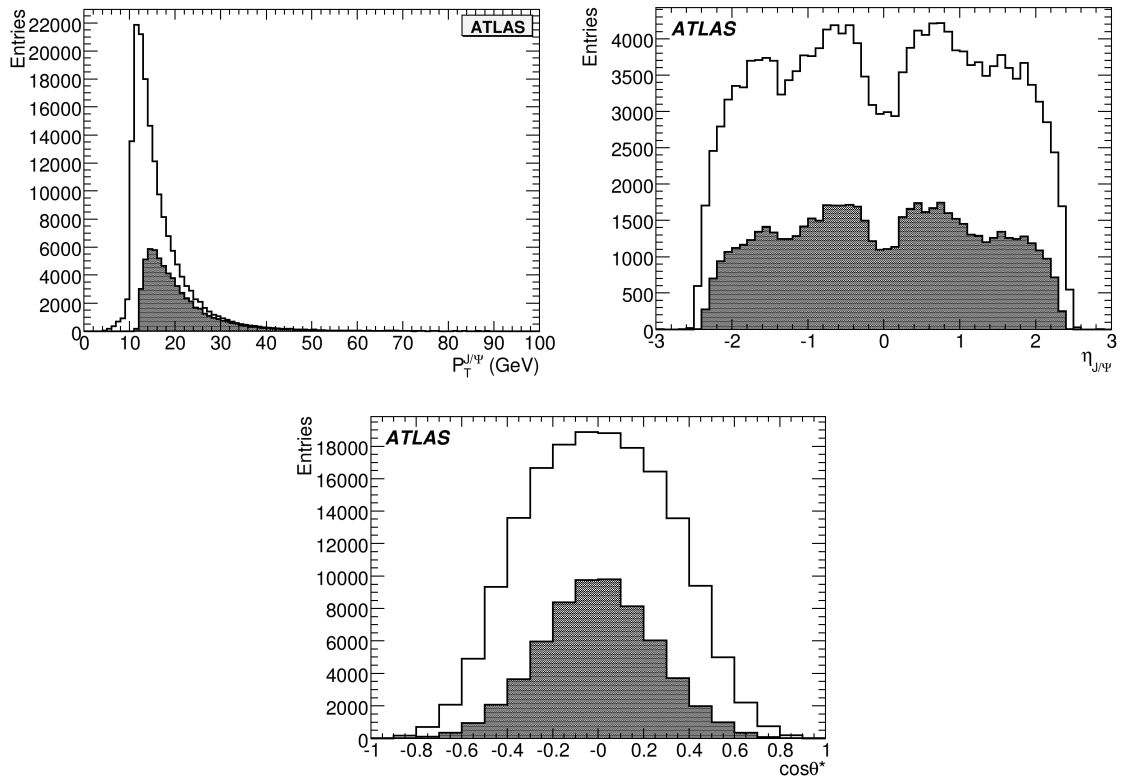

Figure 13: Distributions of  $J/\psi$  variables,  $p_T$ ,  $\eta$  and  $\cos\theta^*$ . The open histograms are for all reconstructed  $J/\psi$  s with the generator level cut of  $p_T^{\mu_1} > 6$  GeV and  $p_T^{\mu_2} > 4$  GeV. Filled histograms are distributions of events passing the level-1 di-muon trigger.

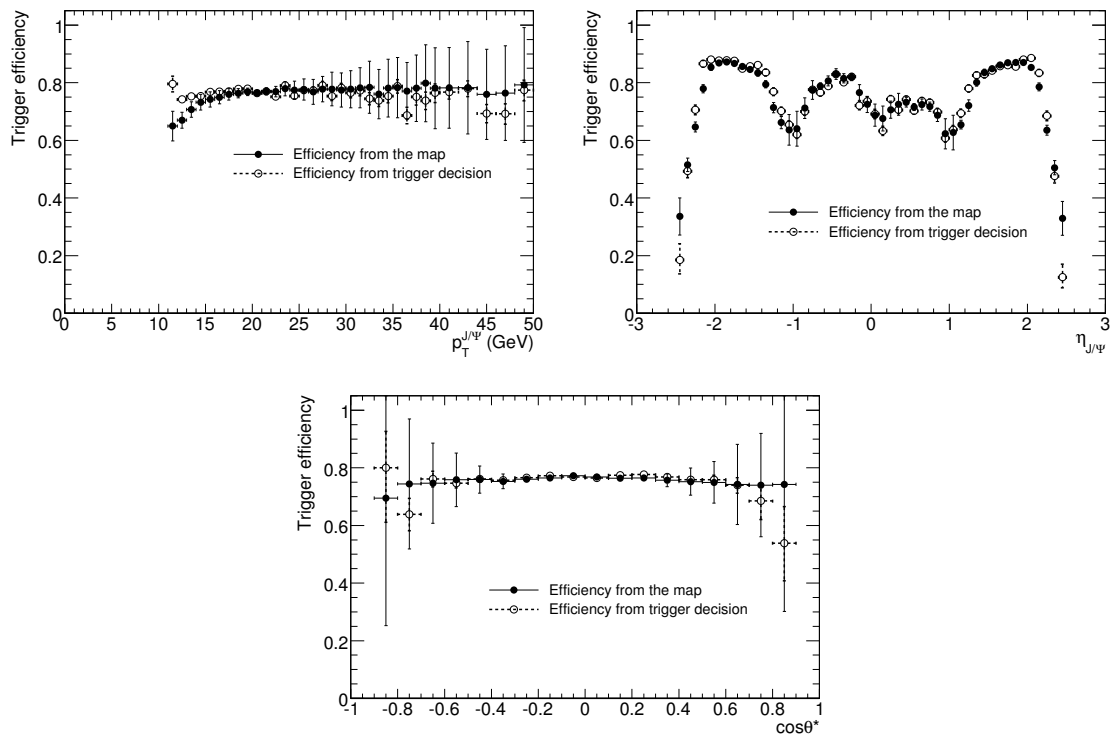

Figure 14: Di-muon trigger efficiency with  $p_T^\mu > 6$  GeV. Open circles are the result obtained from decision of the level-1 di-muon trigger and filled circles are the efficiency obtained using the parameterization shown in Figure 12.

### 6.2.3 Level-2 efficiency

The single muon level-2 efficiency can be defined in two ways: level-2 efficiency with respect to offline reconstruction ( $L2/rec$ ) and level-2 efficiency with respect to level-1 ( $L2/L1$ ). The  $L2/rec$  efficiency is obtained in the same way as the efficiency with respect to level-1. The only difference is that the probe muon must have both level-1 and level-2 trigger objects associated to be considered as triggered.

For the calculation of the  $L2/L1$  efficiency the set of probe muons is restricted to only those that have an associated level-1 RoI. This way the efficiency with respect to level-1 is obtained. Overall efficiencies as a function of  $p_T$  are shown in Figure 15. The points were fitted with the functional form of Equation 4. Efficiency curves calculated using all offline muons matched to generated muons are plotted in the same figure to check that the selection of probe muons is unbiased. It is clear that there is a good agreement between the measured efficiency and the direct Monte Carlo efficiency.

Figure 15: The overall efficiency of the level-2 single muon trigger, (a) with respect to offline reconstruction, (b) with respect to level-1.

To calculate level-2 di-muon efficiency the *trigger efficiency map* was created in the same way as for level-1. The  $\eta$ - $\phi$  plane was divided into regions as described in Section 6.2.2 and in each region an efficiency curve was constructed and fitted with Equation 4. This was done for  $L2/rec$  as well as for  $L2/L1$  efficiencies.

Using the trigger efficiency map for the  $L2/rec$  efficiency, we can calculate the level-2 trigger efficiency. To check that the map was created correctly, the single-muon efficiency curves were constructed using level-2 muons associated to the offline muons with the  $\Delta R$  matching criteria explained in Section 6.2.2. To get an agreement between the two methods one must use the same data sample. In Figure 16, open triangles represent a straightforward calculation of the efficiency using matched trigger objects while the solid circles are the efficiencies calculated using the map. To each offline muon from the sample the probability that it would be triggered was assigned using the map. In each  $p_T$  bin the efficiency was calculated as an average of these probabilities. Systematic uncertainties were estimated in the same way as the level-1 efficiency by changing the procedure to calculate the trigger efficiency map. The same method was used for other two variables  $\eta$  and  $\phi$ . The two methods give an agreement within 6% in most regions while the difference gets as large as 15% at some regions ( $\phi \simeq -1, -2$ ) where the efficiency is low and therefore the precision of the fit to create the trigger efficiency map was poor. Also, since the average efficiency is calculated in each bin of the map this causes discrepancies in the regions where efficiency changes rapidly.

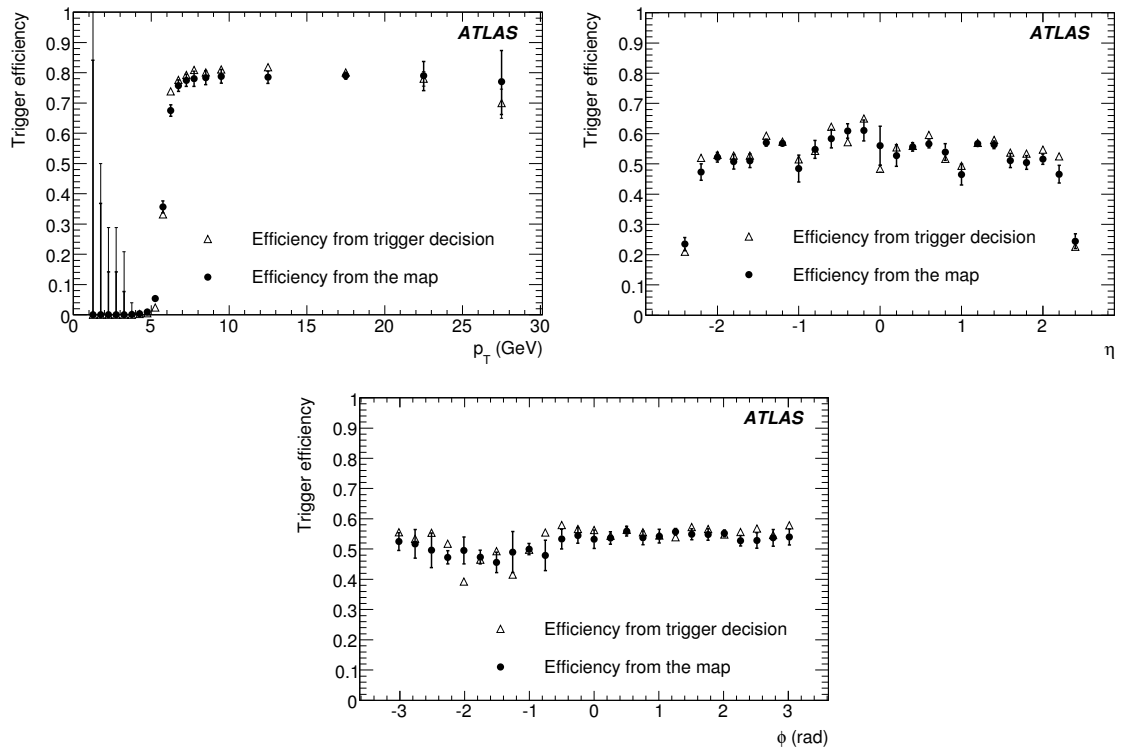

Figure 16: The overall *L2/rec* single-muon trigger efficiency as a function of  $p_T$ ,  $\eta$  and  $\phi$ . Efficiency is calculated using the *trigger efficiency map* (black circles) and it is compared to the one calculated using matched level-1 and level-2 trigger objects (open triangles).

The efficiency of the level-2 di-muon trigger for  $J/\psi$  was calculated in the same way as for level-1. Again two methods were used: firstly direct calculation using the trigger decision for the di-muon trigger and secondly using the efficiency map. Since a simple di-muon trigger without any cut on invariant mass was used, all the muons in the sample must be used in calculation of the efficiency (not just those from  $J/\psi$ ). To each offline muon in the event the probability  $\varepsilon_i$  that it would be triggered was assigned. The probability that the whole event will be triggered by the di-muon trigger is then

$$\varepsilon^{2\mu} = 1 - \prod_i (1 - \varepsilon_i) - \sum_i \varepsilon_i \prod_{j \neq i} (1 - \varepsilon_j) \quad (5)$$

where the products and sums run over all decay muons used in the measurement.

The di-muon efficiency is calculated in the same way as the single-muon efficiency, as an average of probabilities  $\varepsilon^{2\mu}$  in each bin of a given variable. In our case it is either the  $p_T$ ,  $\eta$ ,  $\phi$  or the  $\cos \theta^*$  of the  $J/\psi$  reconstructed in the event. Figure 17 shows a comparison of the  $J/\psi$  efficiency curves. Like the single muon efficiency results, the agreement between the two methods is within 6% in most regions except for some regions where the available statistics was low. The overall  $J/\psi$  efficiency ( $L2/rec$ ) in the kinematic region,  $p_T^{J/\psi} > 15$  GeV,  $|\eta^{J/\psi}| < 2$  with the cuts on the muons ( $p_T^\mu > 6$  GeV,  $|\eta^\mu| < 2.4$ ) is 69.2% and 69.4% using the trigger decision and the trigger efficiency map, respectively. We have a good agreement on the overall efficiency integrated in the above phase space.

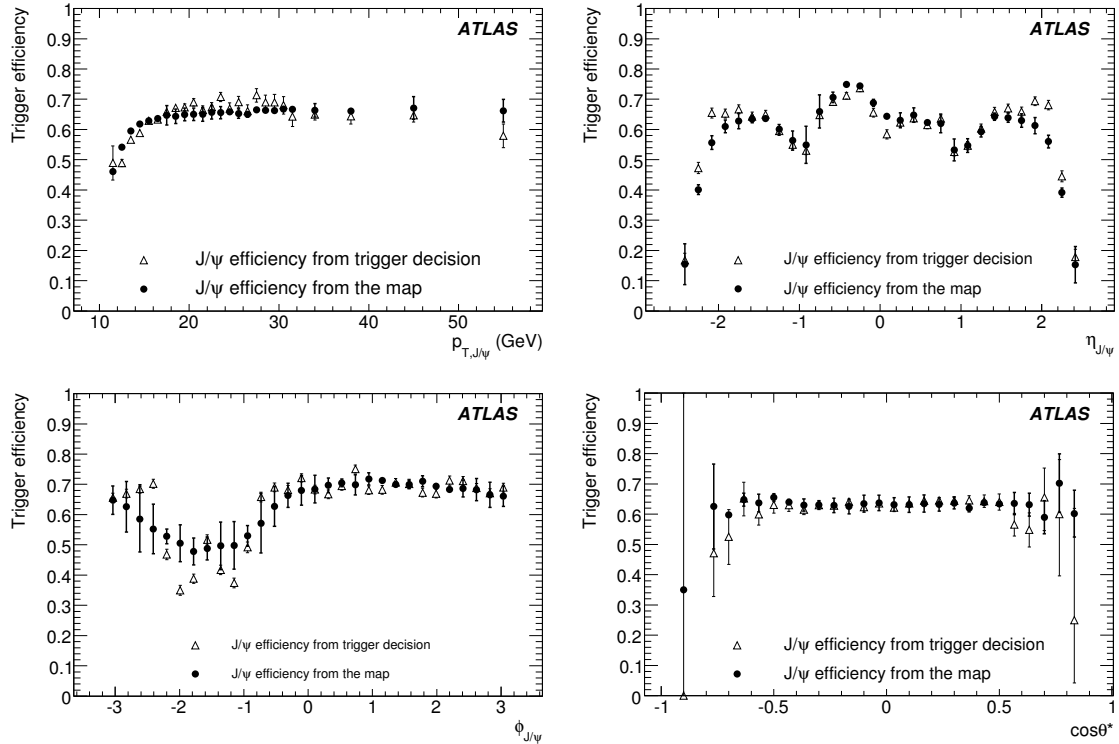

Figure 17: The overall di-muon  $J/\psi$  trigger efficiency as a function of  $p_T$ ,  $\eta$ ,  $\phi$  and  $\cos \theta^*$ . Efficiencies from the trigger decision bit (open triangles) and the ones calculated from the trigger efficiency map (black circles) are shown.

In Figure 18 the efficiency as a function of the distance,  $\Delta R$ , in the  $\eta$ - $\phi$  plane between the two

$J/\psi$  muons is shown.

Figure 18: The overall di-muon  $J/\psi$  trigger efficiency as a function of  $\Delta R$ . Efficiencies from the trigger decision bit (open triangles) and the ones calculated from the trigger efficiency map (black circles) are shown.

### 6.3 Requirements on the trigger menu

In order to use the method developed here for real data, we need a large sample of  $J/\psi$  events with at least one muon unbiased by the trigger selection. The following selection criteria at each trigger level will satisfy this requirement:

**Level-1** Single muon trigger above a certain threshold;

**Level-2**  $J/\psi$  reconstruction within one RoI using the TrigDiMuon algorithm to enhance  $J/\psi$  events;

**Event Filter (EF)** No further selection is imposed so as to avoid biasing the sample;

In this Section, we give some estimates of the statistics of the  $J/\psi$  sample using this trigger selection and show the precision on the trigger efficiency with a certain luminosity. Taking into account the limit on the EF output rate of 200 Hz it is plausible to use a few Hz of the bandwidth for this calibration trigger. The parameters to optimize are the prescale factor, to reduce the rate when it is too high, and the threshold value.

The level-1 single muon trigger rate has been studied in detail taking into account contributions from different sources. At low- $p_T$ , the main contribution is from  $K/\pi$  in-flight decay and muons from  $b$  and  $c$  quarks. The rejection of these non- $J/\psi$  events by the topological di-muon trigger at level-2 has been studied using a generated sample of  $b\bar{b} \rightarrow \mu + X$ , where the efficiency of non- $J/\psi$  events to be selected was found to be 0.8%. This factor is used to estimate the rate reduction by the level-2 selection.

Table 12 shows the expected rate of the level-1 single muon trigger and the contribution of the  $J/\psi \rightarrow \mu^+\mu^-$  to the rate assuming a luminosity of  $10^{31} \text{ cm}^{-2}\text{s}^{-1}$ . The rate of  $J/\psi$  events is the sum of  $J/\psi$  direct production and from  $b\bar{b}$  production. If we could allocate a bandwidth of 1 Hz to this trigger chain with 6 GeV level-1 threshold, we must apply a prescale factor of 3 to reduce the rate down to around 1 Hz. Given the fraction of  $J/\psi \rightarrow \mu^+\mu^-$  events among this rate is 6%, we get a rate of 0.06 Hz for collecting the calibration sample.

	rate (Hz)	$J/\psi$ fraction
level-1	380 (0.21)	0.05%
level-2	3 (0.19)	6%

Table 12: The rates after level-1 and level-2 using the proposed calibration trigger for a luminosity of  $10^{31} \text{ cm}^{-2}\text{s}^{-1}$  with the threshold of  $p_T > 6 \text{ GeV}$ . The contribution of  $J/\psi \rightarrow \mu^+\mu^-$  process to the rate is also shown in parentheses.

With one year of data, we expect to collect about 300 k  $J/\psi$  events according to this triggering strategy, which is comparable to the statistics used in this study (150 k direct  $J/\psi$  and 150 k  $b\bar{b} \rightarrow J/\psi$ ). Therefore, we expect a similar performance (for  $\simeq 1 \text{ Hz}$  calibration trigger rate) to that shown in Section 6.2 after the first year of data-taking. The number of events may increase if we allocate more than 1 Hz for the calibration trigger.

## 7 Conclusions

In this note we presented methods to efficiently select  $J/\psi$  events at the second level trigger, reject muons from  $K$  and  $\pi$  decays and measure the trigger efficiencies from the ATLAS data.

TrigDiMuon is a second-level trigger algorithm that selects efficiently at level-2 events which include  $J/\psi$  or other di-muon states, starting from a single level-1 muon trigger. The efficiency of TrigDiMuon for events accepted by level-1 and the level-2 single muon trigger is between 73% for the 4 GeV trigger threshold and 60% for the 6 GeV threshold. This may be compared with the topological di-muon trigger efficiencies of 33% for the 4 GeV threshold and 15% for the 6 GeV threshold. The fake trigger rates of TrigDiMuon are estimated to be 2 Hz for a trigger threshold of 4 GeV at a luminosity of  $10^{31} \text{ cm}^{-2}\text{s}^{-1}$ , and 90 Hz for a trigger threshold of 6 GeV at a luminosity of  $10^{33} \text{ cm}^{-2}\text{s}^{-1}$ . For the  $B$ -physics trigger at  $L = 10^{33} \text{ cm}^{-2}\text{s}^{-1}$  the rate will have to be further reduced by means of a decay length cut on the  $J/\psi$  decay vertex.

Extrapolating the muon track from MS back to the interaction vertex improves the single muon trigger selection at the level-2 stage and allows increased rejection of muons from  $K$  and  $\pi$  decays without a significant loss of efficiency for  $b$  events. The back extrapolator provides a further reduction factor of about 20% at the trigger threshold of 4 GeV and of about 10% at the trigger threshold of 6 GeV with respect to the output trigger rate of the baseline muComb selection. Despite this good performance, its use for triggering on low  $p_T$  di-muon objects is not recommended, since the background to TrigDiMuon is dominated by muons from  $b$  and  $c$  rather than by muon from  $K$  and  $\pi$  decays. However, because the rate of muons from  $K$  and  $\pi$  decays may be even higher than in our simulation, it is important to have it available for the single muon triggers.

The  $J/\psi$  trigger efficiency can be measured from ATLAS data using the tag-and-probe method. As the efficiency of the single muon trigger depends on the  $\eta$  and  $\phi$  regions, it is necessary to measure the efficiency as a function of these variables. With 300k  $J/\psi$  events, it is possible to measure the efficiency at level-1 and level-2 with better than 5 % precision for each region. The uncertainty comes mainly from the lack of statistics to measure the efficiencies for each region of  $\eta$  and  $\phi$  and will improve as more  $J/\psi$  events become available. To collect an unbiased  $J/\psi$  sample which can be used for the trigger efficiency measurement, we plan to use a level-1 single muon trigger with a  $J/\psi$  reconstruction using the inner detector at level-2. With this trigger we can collect around 300k events for an integrated luminosity of  $100 \text{ pb}^{-1}$  while keeping the rate of this calibration trigger around 1 Hz.

With the methods provided it is possible to collect a large number of  $J/\psi$  events at luminosities of around  $10^{31}\text{cm}^{-2}\text{s}^{-1}$ , without an overly high rate from  $K$  and  $\pi$  decays. Furthermore, these low- $p_T$   $J/\psi$  events can also be used to calibrate trigger efficiencies from the actual ATLAS data, and provide the trigger efficiencies for analyses that use low- $p_T$  muons.

# Heavy Quarkonium Physics with Early Data

## Abstract

Results are reported on an analysis on simulated data samples for production of heavy quarkonium states  $J/\psi \rightarrow \mu\mu$  and  $\Upsilon \rightarrow \mu\mu$ , corresponding to an integrated luminosity of  $10 \text{ pb}^{-1}$ . It is shown that the  $p_T$  dependence of the cross-section for both  $J/\psi$  and  $\Upsilon$  should be measured reasonably well in a wide range of transverse momenta,  $p_T \simeq 10 - 50 \text{ GeV}$ . The precision of  $J/\psi$  polarisation measurement is expected to reach  $0.02 - 0.06$ , while the projected error on  $\Upsilon$  polarisation is around  $0.2$ . Observation of radiative decays of  $\chi_c$  states, and the feasibility of observing  $\chi_b \rightarrow J/\psi J/\psi$  decays are also discussed.

## 1 Introduction and theoretical motivation

The number of  $J/\psi \rightarrow \mu^+\mu^-$  and  $\Upsilon \rightarrow \mu^+\mu^-$  decays produced at the LHC is expected to be quite large. Their importance for ATLAS is threefold: first, being narrow resonances, they can be used as tools for alignment and calibration of the trigger, tracking and muon systems. Secondly, understanding the details of the prompt onia production is a challenging task and a good testbed for various QCD calculations, spanning both perturbative and non-perturbative regimes. Last, but not the least, heavy quarkonium states are among the decay products of heavier states, serving as good signatures for many processes of interest, some of which are quite rare. These processes have prompt quarkonia as a background and, as such, a good description of the underlying quarkonium production process is crucial to the success of these studies.

This note mainly concentrates on the capabilities of the ATLAS detector to study various aspects of prompt quarkonium production at the LHC. The methods of separating promptly produced  $J/\psi$  and  $\Upsilon$  mesons from various backgrounds are discussed, and strategies for various measurements are outlined.

### 1.1 Theory overview

Quarkonium production was originally described in a model where the quark pair was assumed to be produced endowed with the quantum numbers of the quarkonium state that it eventually evolved into [1]. This approach, subsequently labelled as the Colour Singlet Model (CSM), enjoyed some success before CDF measured an excess of direct  $J/\psi$  production [2], more than an order of magnitude greater than predicted (see Figure 1(a)).

The Colour Octet Model (COM) [5] was proposed as a solution to this quarkonium deficit. COM suggests that the heavy quark pairs produced in the hard process do not necessarily need to be produced with the quantum numbers of physical quarkonium, but could evolve into a particular quarkonium state through radiation of soft gluons later on, during hadronisation. This approach isolates the perturbative hard process from the non-perturbative long-distance matrix elements, which are considered as free parameters of the theory. However, their universality means that their values can be extracted independently from a number of different processes, such as deep inelastic scattering, hadro- and photoproduction.

Hence the good description of the Tevatron data by the Colour Octet Model shown in Figure 1(a) is, at least in part, due to the fact that the values of some parameters were determined from the same data. Tests of other COM predictions have not been so successful: Figure 1(b) shows the polarisation coefficient in  $\Upsilon \rightarrow \mu\mu$  decay as a function of its transverse momentum, where the COM prediction disagrees with the data.

A model based on  $k_T$  factorisation in QCD showers [6] claims to be able to describe both the lack of transverse polarisation in  $J/\psi$  decays [4, 7] and the high cross-section of  $J/\psi$  production. Another

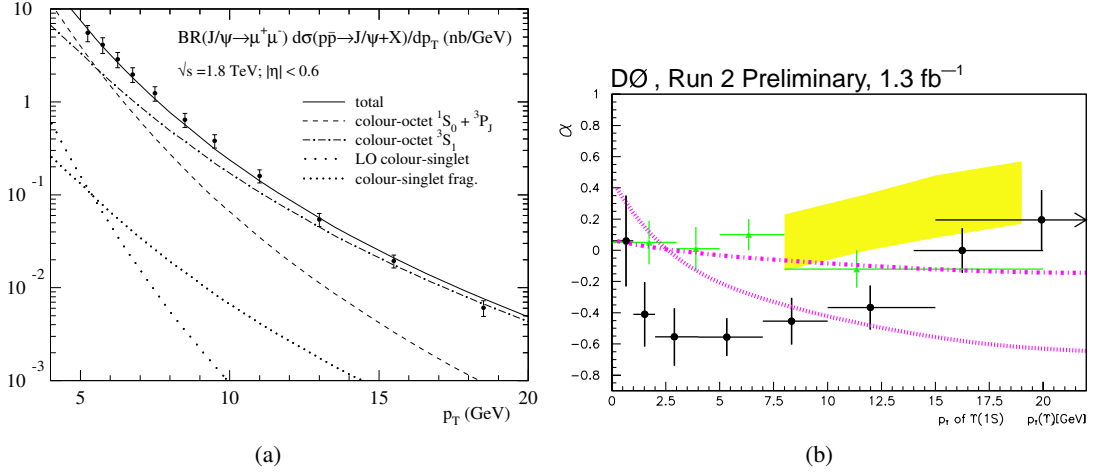

Figure 1: (a) Differential cross-section of  $J/\psi$  production at CDF, with predictions from CSM and COM mechanisms (from [3]). (b)  $\Upsilon$  polarisation measured as a function of  $p_T$  at DØ (black dots) and CDF (green triangles), compared to the limits of the  $k_T$  factorisation model (dashed and dotted curves [6]) and COM predictions [5], depicted by a shadowed band (from [4]).

model [8] argues that the deficit in the cross-section as predicted by CSM can be largely explained by the production of a quarkonium state in association with an additional heavy quark, and also predicts lower levels of polarisation.

In the following, we show that ATLAS is capable of detailed checks of the predictions of various models by measuring not only  $p_T$  and  $\eta$  distributions of onium states in a wide range of these variables, but also the degree of polarisation and the production of  $C$ -even states. In the absence of a comprehensive Monte Carlo generator capable of simulating all aspects of all theoretical models, we used the PYTHIA 6.403 generator [9] incorporating the Colour Octet Mechanism, with model parameters fixed through a combination of theoretical and experimental constraints [10]. Inevitably, this simulation is unable to reproduce adequately some features of the data, notably the polarisation angle distributions and hadronic accompaniment of the quarkonium states. However, the simulated samples allowed us to study the acceptance and efficiency of ATLAS to detect all required particles and measure their parameters, across the whole range of the accessible phase space.

## 1.2 Classification of production mechanisms in the simulation

In the following, we will use a simple classification of the quarkonium production mechanisms based on the model implemented in the PYTHIA generator.

A sample diagram describing the leading colour-singlet subprocess  $g + g \rightarrow J/\psi + g$  is shown in Figure 2(a). In the accessible range of transverse momenta of  $J/\psi$  its contribution is expected to be small. The dominant contribution at the lower  $p_T$  comes from the subprocess shown in Figure 2(b), where both singlet and octet  $c\bar{c}$  states with various quantum numbers contribute to  $J/\psi$  production, through  $\chi_{cJ} \rightarrow J/\psi + \gamma$  decays and/or soft gluon emission.

At high  $p_T$ , the gluon fragmentation subprocess shown in Figure 2(c) becomes increasingly dominant. According to COM, this is unlikely to produce anything other than  $^3S_1$  quarkonium states. Hence, the fraction of  $J/\psi$  mesons produced from  $\chi_{cJ}$  decays should decrease with increasing  $p_T$ . The production mechanisms for the radially excited  $\psi'(3686)$  meson follows the same pattern, except for the absence of respective  $\chi'_{cJ}$  contributions, thus one should expect different  $p_T$  distributions for  $J/\psi$  and

Figure 2: Some example diagrams for the singlet and octet  $J/\psi$  production mechanisms implemented in PYTHIA.

$\psi'$ .

The overall picture is expected to be similar for bottomonium production, except the number of radial excitations below the open beauty threshold is now three, and many more radiative transitions are possible between the various  $n^3P_J$  and  $n^3S_1$  state. However, compared to  $J/\psi$ , the accessible range of  $p_T$  for  $\Upsilon$  is significantly extended towards smaller transverse momenta. This opens up the range of  $p_T$  dominated by the colour singlet contribution, which may make it directly observable for  $\Upsilon$ .

### 1.3 $\chi_b \rightarrow J/\psi J/\psi$ decay

Despite much higher production cross-sections,  $C$ -even states of quarkonia are far more difficult to observe than their vector counterparts. The usual way of studying  $\chi_{c,b}$  (and  $\eta_{c,b}$ ) states has been so far through radiative decays of or into respective vector states. However, in the high energy hadronic collision environment, observation of the photon in  $\chi_b \rightarrow \Upsilon + \gamma$  may be problematic (see Section 5.1).

We have performed a feasibility study to assess the capability of ATLAS to observe  $\chi_b \rightarrow J/\psi J/\psi \rightarrow \mu^+ \mu^- \mu^+ \mu^-$  decay with the standard di-muon trigger. The results are presented in Section 5.2. The observation and measurement of these final states will give a valuable insight into the heavy quark bound state dynamics from several separate viewpoints.

## 2 Trigger considerations

Details of the triggers to be used in ATLAS  $B$  physics programme can be found in [11]. This section discusses the trigger signatures relevant for quarkonium production at ATLAS, the implications they have on the measured cross-section, and the expected effects they have on our ability to make various physics measurements.

Two specific types of di-muon triggers dedicated to quarkonium are: the topological di-muon triggers, which require two level-1 regions of interest (RoIs) corresponding to two muon candidates with  $p_T$  thresholds of 6 and 4 GeV, and di-muon triggers that only require a single level-1 RoI above a threshold of 4 GeV and searches for the second muon of opposite charge in a wide RoI at level-2. They are discussed in Section 2.1. An additional trigger scenario is based on a single muon trigger with a higher  $p_T$  threshold of 10 GeV, discussed in Section 2.2.

### 2.1 Di-muon triggers

Being able to determine the trigger efficiency of measured  $J/\psi$  and  $\Upsilon$  is crucial to correctly infer the production cross-section of quarkonium at the LHC. Indeed, using  $J/\psi$  and  $\Upsilon$  (as well as the  $Z$  boson) to construct a trigger efficiency map is a necessary step in order to perform cross-section measurements in ATLAS.

Studies are being conducted in ATLAS into developing a calibration method to obtain the low- $p_T$  single muon trigger efficiency, and henceforth the di-muon trigger efficiency of events using real data by virtue of the so-called tag-and-probe method (see Ref. [11] for details). In the absence of data, we have performed our own studies of trigger efficiencies, based on Monte Carlo simulation.

If not stated otherwise, the quoted trigger efficiencies have been calculated with respect to the Monte Carlo samples, generated with the cuts  $p_T(\mu_1) > 6$  GeV,  $p_T(\mu_2) > 4$  GeV, where  $\mu_1$  ( $\mu_2$ ) is the muon with the largest (second largest) transverse momentum in the event.

The level-1 trigger is a hardware trigger that uses coarse calorimeter and muon spectrometer information to identify interesting signatures to pass to the level-2 and Event Filter stage. Figure 3 shows the various individual level-1 trigger efficiencies as a function of the  $p_T$  of the di-muon system. The total trigger efficiency at level-1, running over direct  $J/\psi$  events, is 87%.

Figure 3: Efficiency of various level-1 triggers for prompt  $J/\psi$  events versus  $p_T$  of the di-muon system. Only the triggers with efficiencies greater than 2% in some region of  $p_T$  are displayed. The relevant triggers are the single muon  $p_T$  threshold triggers labelled L1\_MUXX (where XX indicates the  $p_T$  threshold in GeV) and the di-muon trigger L1\_2MU06. Each  $p_T$  range of these triggers is exclusive. The efficiency curve labelled LVL1\_Muon is the sum of all level-1 single muon efficiencies (excluding the di-muon trigger L1\_2MU06).

The level-2 trigger is software-based and is designed to reduce the output rate of the data, passed to it from level-1, by two orders of magnitude. Within regions of interest defined by the level-1 trigger, full granularity of the detector is accessible. The efficiency of the level-2 triggers for prompt  $J/\psi$  events is plotted in Figure 4 as a function of di-muon  $p_T$ . The total level-2 trigger efficiency in the reconstructed prompt  $J/\psi$  events (relative to level-1) is 97%. The di-muon trigger scenario  $\mu_6\mu_4$ , considered in the majority of this note, uses all the above trigger signatures.

### 2.1.1 Effect of di-muon trigger cuts on quarkonium rates

Figures 5(a) and 5(b) illustrate the distribution of cross-sections across the values of the  $p_T$  of the harder and softer muon from the quarkonium decay without any muon cuts applied at generator level. The lines

Figure 4: Efficiency of various level-2 triggers for prompt  $J/\psi$  events versus  $p_T$  of the di-muon system. Only the triggers with efficiencies greater than 2% in some region of  $p_T$  are displayed. The level-2 trigger signatures of interest include single muon  $p_T$  threshold triggers L2\_MUXX and ‘TrigDiMuon’ triggers L2\_BJpsimuXmuY which are specialised for searching for  $J/\psi$  [11]. The efficiency curve labelled LVL2.Pass in (b) is the sum of all level-2 efficiencies.

overlaid on the plots represent various nominal muon  $p_T$  thresholds: (6 GeV, 4 GeV) and (4 GeV, 4 GeV), as well as the nominal thresholds (10 GeV, 0.5 GeV) corresponding to the single muon trigger  $\mu_{10}$  (see below).

For  $J/\psi$  the bulk of the cross-section lies near the (4 GeV, 1 GeV) region, far from the low- $p_T$  muon trigger thresholds proposed for ATLAS, and we see only a small increase in accessible cross-section by lowering the cut on the harder muon from 6 GeV to 4 GeV (although this reduction in the effective  $J/\psi$   $p_T$  threshold is useful from a physics standpoint). The situation for  $\Upsilon$  is significantly different however, as the relatively large mass of the  $\Upsilon$  shifts the bulk of the production to the region near muon  $p_T$  thresholds of (5 GeV, 4 GeV). This means that by lowering the di-muon trigger cuts from (6 GeV, 4 GeV), which sits just above the highest density area of  $\Upsilon$  production, to (4 GeV, 4 GeV), a much higher fraction of the produced  $\Upsilon$  can be recorded, leading to a predicted order-of-magnitude increase in the accessible cross-section. The predicted cross-sections for the processes  $pp \rightarrow J/\psi(\mu^+\mu^-)X$  and  $pp \rightarrow \Upsilon(\mu^+\mu^-)X$  (before incorporating trigger and reconstruction efficiencies) for a number of trigger scenarios are presented in Table 1. Although no higher  $\psi$  and  $\Upsilon$  states have been simulated for this analysis, their expected cross-sections are also shown in Table 1, as estimated using Tevatron results on their relative yields [12]. Numbers include feed-down from  $\chi$  states and higher radial excitations to lower ones. Due to the expected ATLAS mass resolution for the  $\Upsilon$  states, however, it is unlikely that the higher state resonances will be separable. These predictions have been obtained by extrapolating the Colour Octet Model, tuned to describe the Tevatron results, to the LHC energy. Although every care has been taken to ensure stability of this extrapolation, inevitably there is an uncertainty in the overall scale of the predicted cross-sections (linked to the uncertainties in the parton distribution functions at small  $x$ ), which we estimate at the level of  $\pm 50\%$ .

Figure 5: Densities of  $J/\psi \rightarrow \mu\mu$  (a) and  $\Upsilon \rightarrow \mu\mu$  (b) production cross-section as a function of the two muon transverse momenta. No cut was placed on the generated sample. The overlaid lines represent the nominal thresholds of observed events with various trigger cuts applied:  $\mu 6\mu 4$  (solid line),  $\mu 4\mu 4$  (dashed line) and  $\mu 10$ +track (dash-dotted line).

It is likely that the cross-section accessible by ATLAS will be higher than the values quoted in Table 1, as during early running the low  $p_T$  muon trigger will run with an open coincidence window in  $\eta$  at level-1 and no requirement of an additional level-2 di-muon trigger. This trigger item has a turn-on threshold at around 4 GeV, giving the (4 GeV, 4 GeV) trigger scenario described above, but in practice there is a non-zero trigger efficiency below 4 GeV, which, combined with the large rate of low  $p_T$  onia, may add a significant extra contribution to the overall observed cross-section. Even including this contribution, the overall rate of signal events from all quarkonium states is likely to remain below the rate of 1 Hz at a luminosity of  $10^{31} \text{ cm}^{-2}\text{s}^{-1}$ , which is a small fraction of the available trigger bandwidth.

Quarkonium	Cross-section, nb			
	$\mu 4\mu 4$	$\mu 6\mu 4$	$\mu 10$	$\mu 6\mu 4 \cap \mu 10$
$J/\psi$	28	23	23	5
$\psi'$	1.0	0.8	0.8	0.2
$\Upsilon(1S)$	48	5.2	2.8	0.8
$\Upsilon(2S)$	16	1.7	0.9	0.3
$\Upsilon(3S)$	9.0	1.0	0.6	0.2

Table 1: Predicted cross-sections for various prompt vector quarkonium state production and decay into muons, with di-muon trigger thresholds  $\mu 4\mu 4$  and  $\mu 6\mu 4$  and the single muon trigger threshold  $\mu 10$  (before trigger and reconstruction efficiencies). The last column shows the overlap between the di-muon and single muon samples.

### 2.1.2 Effect of trigger cuts on analysis of octet states

As discussed above, the quarkonium cross-section is composed of three main classes of processes: direct colour singlet production, colour octet production and singlet/octet production of  $\chi$  states. Figure 6 illustrates the contributions of these three classes to the overall production rate for  $\Upsilon$ , once the  $p_T$  trigger cuts of 6 and 4 GeV are applied to the muons. Lower  $p_T$  trigger cuts will strongly enhance the  $\Upsilon$  rate and

Figure 6: Expected  $p_T$ -distribution for  $\Upsilon$  production, with contributions from direct colour singlet, singlet  $\chi$  production and octet production overlaid.

allow for analysis of colour singlet production, which is expected to dominate for  $\Upsilon$  with  $p_T < 10$  GeV. Lower trigger cuts available during early running, such as the  $\mu 4 \mu 4$  trigger described above, will allow the opportunity to extend the low- $p_T$  region down to  $p_T \simeq 0$  in the case of  $\Upsilon$  and help separate octet and singlet contributions.

### 2.1.3 Acceptance of $\cos \theta^*$ with di-muon triggers

An important consideration for calculating the di-muon trigger efficiencies of  $J/\psi$  and  $\Upsilon$  is the angular distribution of the decay angle  $\theta^*$ , the angle between the direction of the positive muon (by convention) from quarkonium decay in the quarkonium rest frame and the flight direction of the quarkonium itself in the laboratory frame (Figure 7).

Figure 7: Graphical representation of the  $\theta^*$  angle used in the spin alignment analysis. The angle is defined by the direction of the positive muon in the quarkonium decay frame and the quarkonium momentum direction in the laboratory frame.

The distribution in  $\cos \theta^*$  may depend on the relative contributions of the various production mechanisms, and is as of yet not fully understood. Crucially, Monte Carlo studies have shown that different production mechanisms (and thus different angular distributions) can have significantly different trigger

acceptances, and without the measurement of the spin-alignment of quarkonium it will be difficult to be sure that the full trigger efficiency has been calculated correctly.

It is clear that  $\cos \theta^* \simeq 0$  corresponds to events with both muons having roughly equal transverse momenta, while in order to have  $\cos \theta^*$  close to  $\pm 1$  one muon's  $p_T$  needs to be very high while the other's  $p_T$  is very low. In the case of a di-muon trigger, both muons from the  $J/\psi$  and  $\Upsilon$  decays must have relatively large transverse momenta. Whilst this condition allows both muons to be identified, it also severely restricts acceptance in the polarisation angle  $\cos \theta^*$ , meaning that for a given  $p_T$  of  $J/\psi$  or  $\Upsilon$  a significant fraction of the total cross-section is lost.

Examples of the polarisation angle distributions for the  $\mu 6\mu 4$  trigger are shown by solid lines in Figure 8. Here, the samples for both  $J/\psi$  and  $\Upsilon$  were generated with zero polarisation, so with full acceptance the corresponding distribution in  $\cos \theta^*$  should be flat, spanning from  $-1$  to  $+1$ . Clearly,

Figure 8: Reconstructed polarisation angle distribution for  $\mu 6\mu 4$  di-muon triggers (solid line) and a  $\mu 10$  single muon trigger (dashed line), for  $J/\psi$  (a) and  $\Upsilon$  (b). The distributions are normalised to unit area. The generated angular distribution is flat in both cases.

narrow acceptance in  $|\cos \theta^*|$  would make polarisation measurements difficult.

## 2.2 Single muon trigger

Another possibility for quarkonium reconstruction is to trigger on a single identified muon. The non-prescaled level-1 single muon trigger L1\_MU10 with a 10 GeV  $p_T$  threshold is expected to produce manageable event rates at low luminosities [11]. Once this muon triggers the event, offline analysis can reconstruct the quarkonium by combining the identified muon with an oppositely-charged track in the event. In Figure 5 this trigger corresponds to the dash-dotted lines, with the predicted cross-sections also shown in Table 1. With this trigger (referred to as  $\mu 10$  in the following) one removes the need for the other muon to have a large  $p_T$ , i.e. one has a fast muon, which triggered the event, and one track, whose transverse momentum is only limited by the track reconstruction capabilities of ATLAS, with the threshold around 0.5 GeV.

Thus, the onium events with a single muon trigger typically have much higher values of  $|\cos \theta^*|$ , as illustrated by the dotted lines in Figure 8, complementing the di-muon trigger sample. So, the single- and di-muon samples may be used together to provide excellent coverage across almost the entire range of  $\cos \theta^*$  in the same  $p_T$  range of onia.

It's worth noting that the di-muon and single muon samples have comparable cross-sections and similar  $p_T$  dependence. They are not entirely independent: at high transverse momenta the two samples

have significant event overlap (see Table 1 for more details), which could be useful for independent calibration of muon trigger and reconstruction efficiencies.

### 3 Reconstruction and background suppression

#### 3.1 Quarkonium reconstruction with two muon candidates

In each event which passes the di-muon trigger, all reconstructed muon candidates are combined into oppositely charged pairs, and each of these pairs is analysed in turn. The invariant mass is calculated and, if the mass is above 1 GeV, the two tracks are refitted to a common vertex. If a good vertex fit is achieved, the pair is accepted for further analysis. If the invariant mass of the refitted tracks is within 300 MeV of the nominal mass in the case of  $J/\psi$ , or 1 GeV in the case of  $\Upsilon$ , the pair is considered as a quarkonium candidate. The values quoted by the Particle Data Group [13], 3097 MeV and 9460 MeV for  $J/\psi$  and  $\Upsilon$  respectively, are used throughout this paper, and the widths of the mass windows are chosen to be about six times the expected average mass resolution (see Table 2).

For those pairs for which the vertex fit is successful (more than 99% for both  $J/\psi$  and  $\Upsilon$ ), the invariant mass is recalculated. The invariant mass resolution depends on the pseudorapidities of the two muon tracks. To illustrate this effect, all accepted onia candidates are divided into three classes depending on  $\eta$  of the muons, and Gaussian fits are performed to determine the resolutions and mass shifts. The results are presented in Table 2. It is found that the mass resolution is the highest when both tracks are

Quarkonium	$M_{\text{rec}} - M_{\text{PDG}}$ , MeV	Resolution $\sigma$ , MeV			
		Average	Barrel	Mixed	Endcap
$J/\psi$	$+4 \pm 1$	53	42	54	75
$\Upsilon$	$+15 \pm 1$	161	129	170	225

Table 2: Mass shifts and resolutions for di-muon invariant mass distributions after the vertex fit, for  $J/\psi$  and  $\Upsilon$  candidates.

reconstructed in the barrel area,  $|\eta| < 1.05$ , degrades somewhat if both tracks are reconstructed in the endcap regions,  $|\eta| > 1.05$ , and is close to its average value for the mixed  $\eta$  events, with one muon in the barrel and the other in the endcap. It should be noted that no significant non-gaussian tails are observed in either of these mass distributions, and the fit quality is good. Also shown in the table are the shifts of the mean reconstructed invariant mass from the respective nominal values. The observed mass shifts are due to a problem with simulation of material effects in the endcap, which has since been understood and corrected.

The reconstructed muon pairs that remain after vertexing cuts are considered to be good quarkonium candidates, and further analysis is done using these pairs only. The transverse momentum distributions of these candidates are shown in Figure 9.

As can be seen from the Figure 9(a), prompt  $J/\psi$  are mainly selected with  $p_T$  above around 10 GeV, due to the di-muon trigger cuts applied to the events. The decay kinematics of  $\Upsilon$  is somewhat different due to its larger mass, thus allowing  $\Upsilon$  to be selected with  $p_T$  as low as 4 GeV. Even at these, relatively low, statistics one expects to see significant numbers of both types of quarkonia at large  $p_T$ , which will allow statistically significant high- $p_T$  analyses beyond the reach of the Tevatron.

Figure 10(a) presents the  $J/\psi$  acceptance as a function of the  $J/\psi$  transverse momentum, relative to the Monte Carlo generated dataset, which requires the two muons to be within  $|\eta| < 2.5$  and have transverse momenta greater than 6 and 4 GeV, respectively. Geometric acceptance of the detector and

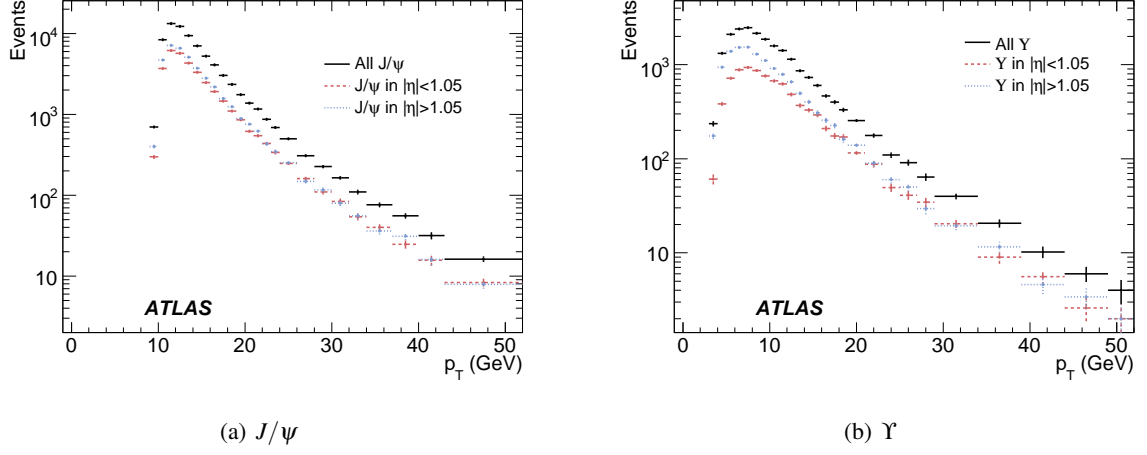

Figure 9: Transverse momentum distribution of triggered reconstructed quarkonium candidates, also shown separately for quarkonia found in the barrel and endcap regions of the detector. Statistics shown in the figures correspond to integrated luminosities of about  $6 \text{ pb}^{-1}$  and  $10 \text{ pb}^{-1}$  for  $J/\psi$  and  $\Upsilon$ , respectively.

Figure 10: Acceptance of reconstructed prompt  $J/\psi$  as a function of  $J/\psi$  transverse momentum and pseudorapidity (relative to the MC generated dataset with  $\mu 6\mu 4$  cuts).

reconstruction efficiency losses due to vertexing, as well as trigger efficiencies have been taken into account. When  $J/\psi$  are produced with a transverse momentum above 10 GeV, we see a sharp rise in the acceptance as  $J/\psi$  above this threshold are able to satisfy the muon trigger requirements within a certain kinematic configuration.

The structure in the plot of the  $\eta$ -dependence of  $J/\psi$  reconstruction efficiency, shown in Figure 10(b), highlights the configuration necessary in order for muons from the  $J/\psi$  to be able to pass the di-muon trigger, described below. The distribution of reconstructed quarkonium candidates with the angular separation of the two muons, described by the variable  $\Delta R = \sqrt{\Delta\phi^2 + \Delta\eta^2}$ , is shown in Figure 11. On average, muons from reconstructed  $J/\psi$  ( $\mu 6\mu 4$ ) candidates are separated by  $\Delta R \simeq 0.47$ , and are restricted from being detected with separations larger than around 0.7.

Figure 11: Distribution of  $\Delta R$  separation of the two muons from  $J/\psi$  and  $\Upsilon$  candidates with di-muon  $\mu 6\mu 4$  generator-level cuts (left) and single muon  $\mu 10$  cuts (right) applied.

In comparison, the higher mass of  $\Upsilon$  requires the muons in the  $\mu 6\mu 4$  case to have a much larger opening angle, with a broad distribution in  $\Delta R$  peaking at around 1.8 and spanning up to 2.6. One can see that for the single  $\mu 10$  case in Figure 11(b) the distributions are much broader, and generally with smaller separation in  $\Delta R$ , reflecting the lower  $p_T$  constraint on the second muon.

The small separation of muons in  $\Delta R$  for the  $J/\psi$  ( $\mu 6\mu 4$ ) case has consequences for the  $J/\psi$  reconstruction efficiency as a function of pseudorapidity, shown in Figure 10(b). Significant dips in efficiency are seen near  $\eta \pm 1.2$  and  $\eta = 0$ , due to the muon spectrometer layout [14]. As the muons from  $J/\psi$  are on average separated by only  $\Delta R = 0.47$ , they are subject to similar material and detector effects, and so these effects are carried over into the  $J/\psi$  reconstruction with very little smearing. Hence, this distribution has a similar shape to the individual muon reconstruction efficiency distribution in ATLAS.

Figure 12: Acceptance of reconstructed prompt  $\Upsilon$  as a function of transverse momentum and pseudorapidity of the quarkonium state (relative to the Monte Carlo generated dataset with  $\mu 6\mu 4$  cuts).

This contrasts with the  $\Upsilon$  reconstruction efficiency dependence on pseudorapidity, shown in Fig-

ure 12(b), which is much smoother than in  $J/\psi$  case: the two muons have large angular separation and the detector layout effects are smeared over a broader range of  $\eta$  values. Figure 12(a) shows the variation of acceptance with the  $\Upsilon$  transverse momentum, and reflects the fact that with the  $\mu 6\mu 4$  trigger  $\Upsilon$  can be reconstructed with a lower  $p_T$  threshold. In the absence of a dedicated topological trigger for  $\Upsilon$ , trigger efficiency at low  $p_T$  suffers due to the differing decay kinematics between  $J/\psi$  and  $\Upsilon$  as only specialised  $J/\psi$  triggers exist in reconstruction software used in this analysis. At larger  $p_T$  both acceptances reach a plateau at around 80–85%.

### 3.2 Offline monitoring using quarkonium

The di-muon decays of  $J/\psi$  and  $\Upsilon$  will be used in both online and offline monitoring at ATLAS. Mass shifts for the reconstructed quarkonium states, plotted versus a number of different variables, have been proposed to monitor detector alignment, material effects, magnetic field scale and its stability, as well as to provide checks of muon reconstruction algorithm performance. The CDF collaboration extensively and successfully used this method, although it took many years at the Tevatron to collect sufficient statistics to allow for the disentanglement of various detector effects [15].

The expected rate of quarkonium production at ATLAS is such that we can expect to be able to perform meaningful monitoring and corrections online. There are many examples of where monitoring of quarkonium mass shifts can be useful in data-taking. Mass shifts in quarkonia as a function of transverse momentum can reveal problems with energy loss corrections and the muon momentum scale. As a function of pseudorapidity this can be a good probe of over- or under-correction of material effects in the simulated detector geometry and of magnetic field uniformity.  $J/\psi$  mass shifts in Monte Carlo simulations have already helped to improve muon reconstruction algorithms in ATLAS.

An example of a reconstructed  $J/\psi$  mass shift measurement at ATLAS with the statistics corresponding to  $6 \text{ pb}^{-1}$  is presented in Figure 13. This is the dependence of  $\Delta M$  on the difference in curvatures

Figure 13:  $J/\psi$  mass shift plotted versus the difference of curvature between the positive and negative muons. Statistics corresponds to the integrated luminosity of about  $6 \text{ pb}^{-1}$ .

of positive and negative muons, which allows for checks of a potentially important effect seen at CDF: horizontal misalignments in some detector elements may result in a constant curvature offset that can lead to significant charge-dependent tracking effects. A misalignment may be such that a negative track has a higher assigned curvature (and hence lower momentum) than is truly the case, whilst a positive track would be affected in the opposite way. The sample shown in the figure is simulated with ideal geometry and does not show any significant effects of this kind.

For detector alignment and data monitoring purposes, quarkonium provides a low  $p_T$  point for calibration, complementary to the  $Z$  boson sample, and allows for the possibility to identify any systematic variations that may develop at higher  $p_T$ .

In order to be able to analyse mass shifts due to two-variable correlations and disentangle various detector effects, significant statistics of  $J/\psi$  and  $\Upsilon$  di-muon decays have to be accumulated. A dedicated study is being performed in ATLAS to optimise the strategy of real time and offline monitoring using this method, but these results lie beyond the scope of this note.

### 3.3 Background suppression in di-muon case

The expected sources of background for prompt quarkonium with a di-muon  $\mu 6\mu 4$  trigger are:

- indirect  $J/\psi$  production from  $b\bar{b}$  events;
- continuum of muon pairs from  $b\bar{b}$  events;
- continuum of muon pairs from charm decays;
- di-muon production via the Drell-Yan process;
- decays in flight of  $\pi^\pm$  and  $K^\pm$  mesons.

The most important background contributions are expected to come from the decays  $b \rightarrow J/\psi + X$ , and the continuum of di-muons from  $b\bar{b}$  events. Both of these have been simulated and analysed. The estimated total contribution from charm decays is higher than that from  $b\bar{b}$  events. However, this background has not been simulated, as it is not expected to cause problems for prompt quarkonium reconstruction because the transverse momentum spectrum of the muons falls very steeply and the probability of producing a di-muon with an invariant mass within the range of interest is well below the level expected from  $b\bar{b}$  events. Only a small fraction of the Drell-Yan pairs survive the di-muon trigger cuts of  $\mu 6\mu 4$  in the  $J/\psi - \Upsilon$  mass range, which makes this background essentially negligible, as estimated from generator-level simulation. Muons from decays in flight also have a steeply falling muon momentum spectrum, and in addition require random coincidences with muons from other sources in the quarkonium invariant mass range. This is estimated to be at the level of a few percent of the signal rate, spread over a continuum of invariant masses.

All background di-muon sources mentioned above, apart from Drell-Yan pairs, contain muons which originate from secondary vertices, which makes it possible to suppress these backgrounds by removing such di-muons whenever a secondary vertex has been resolved, based on the pseudo-proper time measurement. The pseudo-proper time is defined as

$$\text{Pseudo-proper time} = \frac{L_{xy} \cdot M_{J/\psi}}{p_T(J/\psi) \cdot c}, \quad (1)$$

where  $M_{J/\psi}$  and  $p_T(J/\psi)$  represent the mass and the transverse momentum of the  $J/\psi$  candidate,  $c$  is the speed of light in vacuum, and  $L_{xy}$  is the measured radial displacement of the two-track vertex from the beamline. Once the two muons forming a  $J/\psi$  candidate are reconstructed, the pseudo-proper time is used to distinguish between the prompt  $J/\psi$ , which have a pseudo-proper time of zero, and  $J/\psi$  coming from  $B$ -hadron decays and hence having an exponentially decaying pseudo-proper time distribution, due to the non-zero lifetime of the parent  $B$ -hadrons.

The dependence of the resolution in radial decay length  $L_{xy}$  on di-muon pseudorapidity  $\eta$  is shown in Figure 14, while the variation of the expected resolution in the pseudo-proper time with di-muon  $p_T$  is shown in Table 3. An improvement in the resolution is seen with increasing  $p_T$  of the  $J/\psi$  and

Figure 14: Radial position resolution of secondary vertex for  $J/\psi$  decays as a function of the  $J/\psi$  pseudorapidity.

$J/\psi$ transverse momentum (GeV)	9 – 12	12 – 13	13 – 15	15 – 17	17 – 21	> 21
Pseudo-proper time resolution (ps)	0.107	0.103	0.100	0.093	0.087	0.068

Table 3: Pseudo-proper time resolution of direct  $J/\psi$  events as a function of  $J/\psi$   $p_T$ .

decreasing  $|\eta|$ . Here a perfect detector alignment is assumed, with the resulting average resolution estimated at around 0.1 ps.

Figure 15(a) illustrates the pseudo-proper time distribution for both the prompt and indirect  $J/\psi$  samples. By making a cut on the pseudo-proper time, one can efficiently separate most of the indirect  $J/\psi$  from a prompt  $J/\psi$  sample (or vice-versa). The efficiency and purity of the pseudo-proper time cuts for prompt  $J/\psi$  are presented in Figure 15(b). A pseudo-proper time cut of less than 0.2 ps allows to retain prompt  $J/\psi$  with the efficiency of 93% and the purity of 92%. Note that the distribution shown in Figure 15(a) is, in a sense, self-calibrating: the part to the left of the maximum can be used to determine the resolution  $\sigma$ , and an appropriate cut of  $2\sigma$  can be applied to remove the ‘tail’ of secondary  $J/\psi$  candidates on the right hand side.

The background levels of beauty and Drell-Yan production under the  $\Upsilon$  peak are similar to those for the  $J/\psi$ , except that here one does not have to contend with sources of non-prompt quarkonia from  $B$ -decays. However, the  $bb \rightarrow \mu 6\mu 4$  background continuum under the  $\Upsilon$  is more problematic: higher invariant masses around the  $\Upsilon$  mean that the two triggered muons will necessarily come from two separate decays, meaning that the pseudo-proper time cut is far less effective.

Fortunately, flags associated to individual reconstructed muon tracks provide further vertexing information, which could be used for suppressing of the  $bb \rightarrow \mu 6\mu 4$  continuum background. Reconstructed tracks are assigned to either come from the primary vertex, a secondary vertex, or are left undetermined. By requiring that both of the muons combined to make a  $J/\psi$  or a  $\Upsilon$  candidate are determined to have come from the primary vertex, background from the  $bb \rightarrow \mu 6\mu 4$  continuum can be reduced by a factor of three or more, whilst reducing the number of signal events by around 5% in both cases.

Figure 16 illustrates the quarkonium signal and main background invariant mass distributions in the mass range 2 – 12 GeV, for those events which satisfy the  $\mu 6\mu 4$  trigger requirements, with reconstruction efficiencies and background suppression cuts taken into account. Peaks from the  $J/\psi$  and  $\Upsilon(1S)$  clearly dominate the background. As no higher  $\psi$  and  $\Upsilon$  states were simulated for this analysis, their peaks are

Figure 15: (a) Pseudo-proper time distribution for reconstructed prompt  $J/\psi$  (dark shading) and the sum of prompt and indirect  $J/\psi$  candidates (lighter shading). (b) Efficiency (solid line) and purity (dotted line) for prompt  $J/\psi$  candidates as a function of the pseudo-proper time cut. Statistics correspond to the integrated luminosity of  $6 \text{ pb}^{-1}$ .

not shown. The dotted line indicates the level of the background continuum before the vertexing cuts.

In conclusion, we find that the level of the backgrounds considered for both  $J/\psi$  and  $\Upsilon$  do not represent any serious problem for reconstruction and analysis of direct quarkonia with the di-muon  $\mu 6 \mu 4$  trigger.

### 3.4 Reconstruction and background suppression with a single muon candidate

By using the  $\mu 10$  trigger, one selects events with at least one identified muon candidate with  $p_T$  above 10 GeV. In this part of the analysis, each reconstructed single muon candidate is combined with oppositely-charged tracks reconstructed in the same event. For both  $J/\psi$  and  $\Upsilon$  reconstruction, we insist that any other reconstructed track to be combined with the identified trigger muon has an opposite electric charge and is within a cone of  $\Delta R = 3.0$  around the muon direction, so as to retain over 99% (91%) of the signal events in the  $J/\psi$  ( $\Upsilon$ ) case. As in the di-muon analysis, we require that both the identified muon and the track are flagged as having come from the primary vertex. In addition, we impose a cut on the transverse impact parameter  $d_0$ ,  $|d_0| < 0.04 \text{ mm}$  on the muon and  $|d_0| < 0.10 \text{ mm}$  on the track, in order to further suppress the number of background pairs from  $B$ -decays.

The invariant mass distribution for the remaining pairings of a muon and a track is shown in Figure 17(a) for  $J/\psi$  with  $p_T$  larger than 9 GeV and in Figure 17(b) for  $J/\psi$  with  $p_T$  larger than 17 GeV. The distributions are fitted using a single gaussian for the signal and a straight line for the background. Clear  $J/\psi$  peaks can be seen, with statistically insignificant mass shifts and the resolution close to that in the di-muon sample. It's worth noting that the signal-to-background ratio around the  $J/\psi$  peak improves slightly with increasing transverse momentum of  $J/\psi$ . At higher  $p_T$  the  $\cos \theta^*$  acceptance also becomes broader, which should help independent polarisation measurements.

For  $\Upsilon$  the situation is less favourable, due to the combination of a lower signal cross-section and a higher background. Although the  $\Upsilon$  peak can be seen above the smooth background, its statistical significance is rather low. Hence, with this statistics, the use of the single muon sample for  $\Upsilon$  cannot be justified, and in the following we will only rely on the di-muon sample.

In conclusion, we expect that the single muon trigger with a 10 GeV threshold can be successfully

Figure 16: The cumulative plot of the invariant mass of di-muons from various sources, reconstructed with a  $\mu 6\mu 4$  trigger, with the requirement that both muons are identified as coming from the primary vertex and with a pseudo-proper time cut of 0.2 ps. The dotted line shows the cumulative distribution without vertex and pseudo-proper time cuts.

used to select prompt  $J/\psi$  events. The expected background here, although much larger than in di-muon case, is well under control. For  $\Upsilon$  however, the single muon sample is only likely to be useful at significantly higher statistics and higher transverse momenta.

### 3.5 Summary of cuts and efficiencies

Table 4 summarises the efficiencies of all the selection and background suppression cuts described above, for both the di-muon and single muon trigger samples. Not all cuts are applicable to all samples; those which are not are labelled accordingly. Numbers in *italics* are estimates in cases where no adequate fully simulated sample was available. The efficiencies for  $\mu 6\mu 4$  samples are calculated relative to the Monte Carlo sample with generator-level cuts on the two highest muon transverse momenta of 6 and 4 GeV. For the  $\mu 10$  samples, the generator-level cut of 10 GeV was applied to the  $p_T$  of the highest- $p_T$  muon. Expected yields  $N_S$  of quarkonia for  $10 \text{ pb}^{-1}$  are given at the bottom of the table, along with background yields  $N_B$  within the invariant mass window of  $\pm 300 \text{ MeV}$  for  $J/\psi$  and  $\pm 1 \text{ GeV}$  for  $\Upsilon$ , and the signal-to-background ratios at respective  $J/\psi$  and  $\Upsilon$  peaks for each sample.

For higher, excited quarkonium states with vector quantum numbers the efficiencies are expected to be similar, but not necessarily identical. The biggest differences are expected for  $\psi'$ , where the production mechanisms as well as decay kinematics are significantly different.

## 4 Polarisation and cross-section measurement

The Colour Octet Model predicts that prompt quarkonia produced in  $pp$  collisions are transversely polarised, with the degree of polarisation increasing as a function of the transverse momentum. Other production models predict different  $p_T$  dependencies of the polarisation and so this quantity serves as an important measurement for discrimination of these models (see Figure 1(b)).

Quarkonium polarisation can be assessed by measuring the angular distribution of the muons produced in the decay. The relevant decay angle  $\theta^*$  is defined in Figure 7. The spin alignment of the parent

Figure 17: Prompt quarkonium signal and  $bb \rightarrow \mu X$  background events selected with the  $\mu 10$  trigger, in the mass range around  $J/\psi$  with (a)  $p_T$  above 9 GeV, and (b)  $p_T$  above 17 GeV, corresponding to  $10 \text{ pb}^{-1}$  of data. The background from  $B$  decays is shown in light grey. Cuts described in the text have been applied. The distributions were fitted using the sum of a linear background and a gaussian peak centered at  $M = 3097 \text{ MeV} + \Delta M$  with resolution  $\sigma$ .

vector quarkonium state can be determined by measuring the polarisation parameter  $\alpha$  in the distribution

$$\frac{dN}{d\cos\theta^*} = C \frac{3}{2\alpha + 6} (1 + \alpha \cos^2\theta^*). \quad (2)$$

The choice of parameters in Equation 2 is such that the distribution is normalised to  $C$ . The parameter  $\alpha$ , defined as  $\alpha = (\sigma_T - 2\sigma_L)/(\sigma_T + 2\sigma_L)$ , is equal to  $+1$  for transversely polarised production (helicity  $= \pm 1$ ). For a longitudinal polarisation (helicity  $= 0$ ),  $\alpha$  is equal to  $-1$ . Unpolarised production consists of equal fractions of helicity states  $+1$ ,  $0$  and  $-1$ , and corresponds to  $\alpha = 0$ .

The difficulty of quarkonium polarisation measurements is evidenced by the discrepancies between DØ and CDF results shown in Figure 1(b). The problem can be traced to the limited acceptance at high  $|\cos\theta^*|$ , and hence difficulties in separating acceptance corrections from spin alignment effects (see, e.g., [7]).

Note that the feed-down from  $\chi$  state and  $b$ -hadron decays may lead to a different spin alignment and hence to a possible effective depolarisation which is hard to estimate. In addition, due to the limited statistics, the polarisation measurements at the Tevatron cannot reach the region of high  $p_T$ , where theoretical uncertainties are expected to be smaller.

At ATLAS we aim to measure the polarisation of prompt vector quarkonium states, in the transverse momentum range up to  $\sim 50$  GeV and beyond, with extended coverage in  $\cos\theta^*$  which will allow for improved understanding of efficiency measurements and thus reduced systematics. The promptly produced  $J/\psi$  mesons and those that originated from  $B$ -hadron decays can be separated using the displaced decay vertices, as explained above. With a high production rate of quarkonia at LHC, it will be possible to achieve a higher degree of purity of prompt  $J/\psi$  in the analysed sample and reduce the depolarising effect from  $B$ -decays, whilst retaining high statistics.

As explained in Section 2.1.3, with the di-muon trigger signature such as  $\mu 6 \mu 4$ , the acceptance at large values of  $|\cos\theta^*|$  (where the difference between various polarisation states is the biggest)

	Quarkonium Trigger type	$J/\psi$ $\mu 6\mu 4$	$J/\psi$ $\mu 10$	$\Upsilon$ $\mu 6\mu 4$	$\Upsilon$ $\mu 10$
	MC cross-section	23 nb	23 nb	5.2 nb	2.8 nb

Table 4: Predicted and observed cross-sections for prompt vector quarkonia, and efficiencies of various selection and background suppression cuts described in Section 3.

is strongly reduced, especially at low transverse momenta of quarkonium. The kinematic acceptance  $\mathcal{A}(p_T, \cos \theta^*)$  of the  $\mu 6\mu 4$  cuts applied at generator level, with respect to the full generator-level sample with no cuts on muon transverse momenta, is shown by the solid lines in Figure 18 for various  $p_T$  slices of  $J/\psi$ . The acceptance is seen to be quite low at  $J/\psi$   $p_T$  below 12 GeV, but in higher  $p_T$  slices there is an area in the middle of  $\cos \theta^*$  range with essentially 100% acceptance, which becomes broader with increasing  $p_T$  of the  $J/\psi$ , but does not go beyond  $|\cos \theta^*| \simeq 0.5$ .

The acceptance for the single muon trigger sample, shown with the dashed lines in Figure 18, is different: here the areas of 100% acceptance are at high  $|\cos \theta^*|$ , and the dip in the middle gradually fills up with increasing  $p_T$ . This sample essentially has a full acceptance at  $p_T > 20$  GeV, apart from the drop at  $|\cos \theta^*| > 0.95$  due to the cut of 0.5 GeV on the  $p_T$  of the track of the second muon.

The plots in Figure 18 were obtained using a dedicated generator-level Monte Carlo sample. The error bars shown in the figure reflect both statistical errors and the uncertainties due to possible dependence on  $\eta$  coverage.

The simulated ‘raw’ measured distributions  $dN^{\text{raw}}/d\cos \theta^*$ , for the same slices of  $J/\psi$  transverse momenta, are shown in Figure 19. Again, solid and dashed lines represent the events selected by the di-muon  $\mu 6\mu 4$  and the single muon  $\mu 10$  triggers, respectively. The sample was generated with zero polarisation. The raw numbers of measured events in the  $\mu 10$  sample were obtained by fitting the invariant mass distributions with a gaussian peak and a linear background, for each bin of  $\cos \theta^*$  in each  $p_T$  slice. With the estimated signal-to-background ratios shown in Figure 17(a), this causes an increase in the statistical errors, typically by a factor of 2.

The corrected distributions  $dN^{\text{cor}}/d\cos \theta^*$  are calculated according to the following formula:

$$\frac{dN^{\text{cor}}}{d\cos \theta^*} = \frac{1}{\mathcal{A}(p_T, \cos \theta^*) \cdot \varepsilon_1 \cdot \varepsilon_2} \cdot \frac{dN^{\text{raw}}}{d\cos \theta^*} \quad (3)$$

Figure 18: Generator-level kinematic acceptances of the  $\mu 6\mu 4$  (solid lines) and  $\mu 10\mu 0.5$  (dashed lines) cuts, calculated with respect to the sample with no muon  $p_T$  cuts, in slices of  $J/\psi$  transverse momentum: left to right, top to bottom 9 – 12 GeV, 12 – 13 GeV, 13 – 15 GeV, 15 – 17 GeV, 17 – 21 GeV, above 21 GeV.

Here  $\varepsilon_1$  stands for the trigger and reconstruction efficiency, while  $\varepsilon_2$  denotes the efficiency of background suppression cuts for each sample, as defined in Table 4. Their values have been averaged over the accessible phase space within the relevant  $p_T$  slice. Studies have shown that while  $\varepsilon_1$  depend on  $p_T$  (cf. Figure 10(a)),  $\varepsilon_2$  remain essentially constant over the phase space of interest. The efficiencies  $\varepsilon_1$  and  $\varepsilon_2$  for both samples are listed in Table 5, while the acceptances  $\mathcal{A}(p_T, \cos \theta^*)$  are shown in Figure 18.

$p_T$ , GeV	9 – 12	12 – 13	13 – 15	15 – 17	17 – 21	> 21
$\varepsilon_1(\mu 6\mu 4)$ , %	$67 \pm 1$	$75 \pm 1$	$77 \pm 1$	$78 \pm 1$	$79 \pm 1$	$80 \pm 1$
$\varepsilon_2(\mu 6\mu 4)$ , %	$90 \pm 1$	$90 \pm 1$	$90 \pm 1$	$90 \pm 1$	$90 \pm 1$	$90 \pm 1$
$\varepsilon_1(\mu 10)$ , %	$86 \pm 1$	$89 \pm 1$	$90 \pm 1$	$90 \pm 1$	$90 \pm 1$	$90 \pm 1$
$\varepsilon_2(\mu 10)$ , %	$76 \pm 1$	$76 \pm 1$	$76 \pm 1$	$76 \pm 1$	$76 \pm 1$	$76 \pm 1$

Table 5: Efficiencies for the  $\mu 6\mu 4$  and  $\mu 10$  samples, averaged over each of the six  $p_T$  slices.

At high  $p_T$  the two samples increasingly overlap, thus allowing for a cross-check of acceptance and efficiency corrections. However, for measurement purposes the  $\mu 6\mu 4$  samples are used whenever possible, complemented by  $\mu 10$  samples at high  $\cos \theta^*$ . In order to achieve this, the distributions shown in Figure 19 were appropriately masked and combined. The combined distributions  $dN^{\text{cor}}/d\cos \theta^*$ , corrected according to Equation 3, are shown in Figure 20. The errors shown in the plots include the statistical errors on the raw data, as well as the uncertainties on the acceptance and efficiencies. These  $\cos \theta^*$  distributions are fitted using the Equation 2, with  $\alpha$  and  $C$  as free parameters for each  $p_T$  slice. The fit

Figure 19: Measured distributions for  $\mu 6\mu 4$ - (solid lines) and  $\mu 10$ - (dashed lines) triggered events, in the same  $p_T$  slices of the  $J/\psi$  candidate as in Figure 18. The simulated data sample is unpolarised. Statistics correspond to  $10 \text{ pb}^{-1}$ .

results are presented in Table 6, with constant  $C$  rescaled to the measured cross-section  $\sigma$ , corresponding to the integrated luminosity of  $10 \text{ pb}^{-1}$ .

To further check our ability to measure the spin alignment of  $J/\psi$ , the raw distributions shown in Figure 19 were reweighted to emulate transversely polarised ( $\alpha_{\text{gen}} = +1$ ) and longitudinally polarised ( $\alpha_{\text{gen}} = -1$ )  $J/\psi$  samples, and the analysis described above was repeated. The results are shown in Figure 21 and in the middle two sections of Table 6.

A similar analysis can be done for measuring the polarisation and cross-section of  $\Upsilon$ , but at the integrated luminosity of  $10 \text{ pb}^{-1}$  these measurements are expected to be far less precise than in  $J/\psi$  case. The main reasons are lower  $\Upsilon$  cross-sections at high transverse momenta, and higher backgrounds for the  $\mu 10$  sample. The latter reason, as explained in Section 3.4, means that with these statistics the  $\mu 10$  sample is essentially unusable, and the limited acceptance of the  $\mu 6\mu 4$  sample at high  $|\cos \theta^*|$  makes a precise measurement difficult.

The corrected  $|\cos \theta^*|$  distributions for unpolarised  $\Upsilon$  from the  $\mu 6\mu 4$  sample are shown in Figure 22. The results of the fit using Equation 2, with normalisation matched to the integrated luminosity of  $10 \text{ pb}^{-1}$ , are shown in the last section of Table 6. With the integrated luminosity increased by an order of magnitude, the  $\mu 10$  sample should become useful and the estimated errors on  $\Upsilon$  polarisation measurement could be reduced by a factor of 5.

The errors shown in Figures 20 — 22 and Table 6 include the statistical uncertainties on the measured numbers of events as well as various systematic errors stemming from the uncertainties on acceptances and efficiencies described above.

The overall uncertainty on the integrated luminosity needs to be added to all measured cross-sections, and is expected to be rather large during the initial LHC runs. This uncertainty will not, however, affect the relative magnitudes of the cross-sections measured in separate  $p_T$  slices, or the measured values of

Figure 20: Combined and corrected distributions in  $J/\psi$  polarisation angle  $\cos \theta^*$ , for the same  $p_T$  slices as in Figure 18. The data sample is unpolarised ( $\alpha_{\text{gen}} = 0$ ). The lines show the results of the fit using Equation 2, where the fitted values of  $\alpha$  are given in Table 6. Statistics correspond to  $10 \text{ pb}^{-1}$ .

Table 6:  $J/\psi$  and  $\Upsilon$  polarisation and cross-sections measured in slices of  $p_T$ , for  $10 \text{ pb}^{-1}$ .

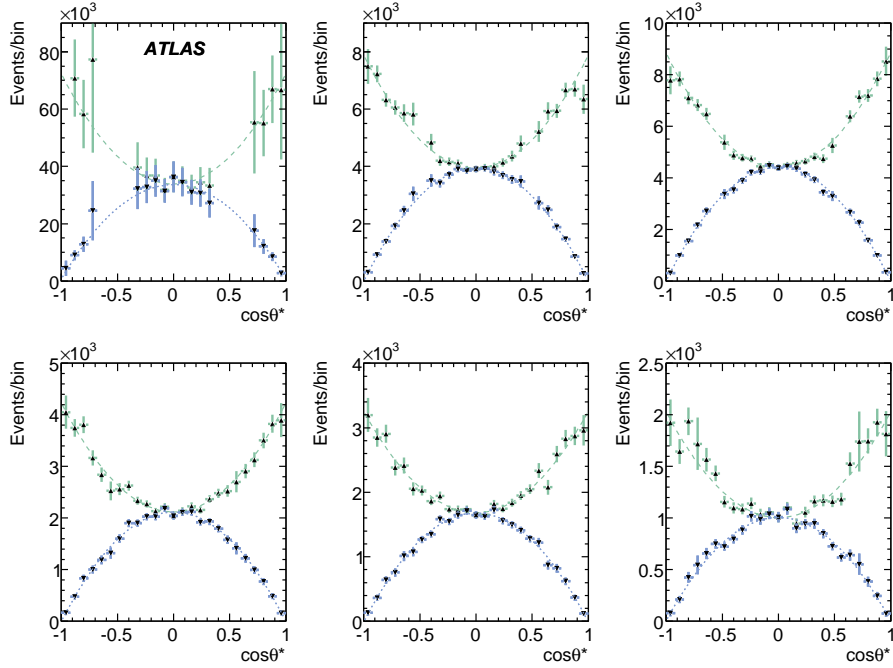

Figure 21: Combined and corrected distributions in polarisation angle  $\cos \theta^*$ , for longitudinally ( $\alpha_{\text{gen}} = -1$ , dotted lines) and transversely ( $\alpha_{\text{gen}} = 1$ , dashed lines) polarised  $J/\psi$  mesons, in the same  $p_T$  slices as in Figure 18. The lines show the results of the fit using Equation 2, where the fitted values of  $\alpha$  are given in Table 6. Statistics correspond to  $10 \text{ pb}^{-1}$ .

the polarisation coefficient  $\alpha$ . Additional systematic effects have also been studied, such as the influence of finite resolution in  $p_T$  and  $\cos \theta^*$ , changes in binning, details of the functions used for fitting the invariant mass distributions, and variations of cuts used for background suppression. Their respective uncertainties on the measured values of  $\alpha$  and  $\sigma$  have been found not to exceed a small fraction of the quoted errors, and have thus been deemed negligible.

In conclusion, with the integrated luminosity of  $10 \text{ pb}^{-1}$  it should be possible to measure the polarisation of  $J/\psi$  with the precision of order  $0.02 - 0.06$ , depending on the level of polarisation itself, in a wide range of transverse momenta,  $p_T \simeq 10 - 20 \text{ GeV}$  and beyond. In case of  $\Upsilon$ , the expected precision is somewhat lower, of order  $0.20$ . In both cases, however, the  $p_T$  dependence of the cross-section should be measured reasonably well.

## 5 Analysis of $\chi$ production

Quarkonium states with even C parity, such as  $\eta_{c,b}$  and  $\chi_{c,b}$ , have a strong coupling to the colour-singlet two-gluon state, and hence a significantly higher production cross-section than vector quarkonia. Their dominant production mechanism for the phase space area accessible in ATLAS is via the subprocess shown in Figure 2(b) in Section 1. Their detection, however, is rather more difficult due to the absence of purely leptonic decays.

About 30 to 40% of  $J/\psi$  and  $\Upsilon$  are expected to come from decays  $\chi_c \rightarrow J/\psi \gamma$  and  $\chi_b \rightarrow \Upsilon \gamma$ . Unfortunately, the energies of the radiated photons tend to be quite small. The ability of ATLAS to detect these photons and resolve various  $\chi$  states is analysed in Section 5.1. Another possibility of observing  $\chi_b$  and possibly  $\eta_b$  states is considered in Section 5.2, where the reconstruction of these states is attempted

Figure 22: Corrected distributions in polarisation angle  $\cos \theta^*$ , for unpolarised  $\Upsilon$  mesons, in the same slices of  $\Upsilon$  transverse momentum as in Figure 18. Only  $\mu 6 \mu 4$  sample has been used. Statistics correspond to  $10 \text{ pb}^{-1}$ .

through their decay into a pair of  $J/\psi$ , both of which subsequently decay into  $\mu^+ \mu^-$ .

### 5.1 Radiative decays of $\chi_c, \chi_b$ states

Reconstructing  $\chi_c$  candidates requires associating a reconstructed  $J/\psi$  with the photon emitted from the  $\chi_c$  decay. The transverse momentum distribution for all identified photon candidates in events with a prompt  $J/\psi$ , as measured by the ATLAS electromagnetic calorimeter, is shown in Figure 23(a) (light grey histogram).

For  $\chi_c$  reconstruction, each selected quarkonium candidate is combined with every reconstructed and identified photon candidate in the event, and the invariant mass of the  $\mu\mu\gamma$  system is calculated. No explicit cut is applied to the  $p_T$  of the photon. The  $\mu\mu\gamma$  system is considered to be a  $\chi$  candidate, if the difference  $\Delta M$  between the invariant masses of the  $\mu\mu\gamma$  and  $\mu\mu$  systems lies between 200 and 700 MeV, and the cosine of the opening angle  $\alpha$  between the  $J/\psi$  and  $\gamma$  momenta is larger than 0.97. The last requirement comes from the observation that for the correct  $\mu\mu\gamma$  combinations, the angle  $\alpha$  is usually very small (see reconstructed distribution in Figure 23(b)). By analysing Monte Carlo information, it was found that all photons from generated  $\chi$  decays were found in the peak near  $\cos \alpha = +1$ , with the long tail in the reconstructed distribution representing the combinatorial background. The transverse energy distribution for those photon candidates which satisfy the above requirements is presented in Figure 23(a) by the dark histogram. With these cuts, the combinatorial background is strongly reduced.

Figure 24 shows the distribution in  $\Delta M$  for the selected  $\chi_c$  decay candidates. The expected mean positions of the peaks corresponding to  $\chi_0, \chi_1$  and  $\chi_2$  signals (318, 412 and 460 MeV, respectively) are indicated by arrows. The grey histogram shows the contribution from the background process of  $J/\psi$  production from  $B$ -hadron decays, some of which survive the pseudo-proper time cut.

Figure 23: (a) Transverse momentum distribution of photons reconstructed in prompt  $J/\psi$  events. (b) Distribution of  $\cos \alpha$  for each reconstructed  $\gamma$  in an event. On both plots, the light grey (dark grey) histograms show the distributions before (after) the cut on the opening angle  $\alpha$  between the photon and the  $J/\psi$  momentum direction. All photons from  $\chi \rightarrow J/\psi \gamma$  decays have  $\cos \alpha > 0.97$ , while the vast majority of background combinations fall outside the range shown in plot (b). The sample corresponds to the integrated luminosity of  $6 \text{ pb}^{-1}$ .

The solid line in Figure 24 is the result of a simultaneous fit to the measured distribution, with the three peak positions fixed at their expected values, and the common resolution function  $\sigma(\Delta M)$ . The resolution in  $\sigma(\Delta M)$  is expected to increase with increasing  $\Delta M$ , and was empirically parameterised as  $\sigma(\Delta M) = a \cdot \Delta M + b$ . The dashed lines show the shapes of individual peaks and of the background continuum. The fit parameters are the heights of the three gaussian peaks  $h_0, h_1, h_2$ , the constants  $a$  and  $b$ , and the three parameters describing the smooth polynomial background. The systematic studies include the variation of the background parameterisation and the introduction of a mass shift common for the three resonances. The true amplitudes of the peaks (15, 123 and 87, respectively) are reproduced reasonably well:

$$\begin{aligned} h_0 &= 15 \pm 3(\text{stat.}) \pm 10(\text{syst.}), \\ h_1 &= 101 \pm 4(\text{stat.}) \pm 12(\text{syst.}), \\ h_2 &= 103 \pm 4(\text{stat.}) \pm 9(\text{syst.}), \end{aligned} \tag{4}$$

with a strong negative correlation between the last two. The resolution is found to increase from about 35 MeV at  $\chi_0$  to about 48 MeV at  $\chi_2$ , while the overall reconstruction efficiency of  $\chi_c$  states is estimated to be about 4%. It may be possible to significantly improve the resolution by using photon conversions, but this is unlikely to yield a big increase in efficiency.

The procedure of reconstructing  $\chi_b$  decays into  $\Upsilon + \gamma$  is the same as in the charmonium case, except the di-muon pair is required to be an  $\Upsilon$  candidate. However, the higher di-muon mass and hence smaller expected boost makes the photon much softer and hence more difficult to detect. With the available simulated statistics (50 000 events corresponding to  $10 \text{ pb}^{-1}$ ), only 20  $\chi_b$  candidates have been found in the appropriate mass window, which gives an efficiency estimate of 0.03%. In order to reliably observe  $\chi_b \rightarrow \Upsilon + \gamma$  decays, an integrated luminosity of at least  $1 \text{ fb}^{-1}$  will be needed.

Figure 24: Difference in invariant masses of  $\mu\mu\gamma$  and  $\mu\mu$  systems in prompt  $J/\psi$  events (light grey) with  $bb \rightarrow \mu 6\mu 4X$  background surviving cuts (dark grey). The arrows represent the true signal peak positions, and the lines show the results of the fit described in the text. Event yields correspond to an integrated luminosity of  $10 \text{ pb}^{-1}$ .

## 5.2 Analysis of $\chi_b \rightarrow J/\psi J/\psi$

Another possibility for measuring  $\chi_b$  production is through the decay  $\chi_b \rightarrow J/\psi J/\psi \rightarrow \mu\mu\mu\mu$ . The use of this decay for  $\chi_b$  detection was proposed in [16], while in [17] the corresponding branching fraction was calculated to be  $Br(\chi_{b0} \rightarrow J/\psi J/\psi) = 2 \times 10^{-4}$ .

The predicted total inclusive cross-section of  $\chi_{b0}$  production at LHC is estimated at around  $1.5 \mu\text{b}$  [17], yielding the following theoretical estimate (without any momentum cuts on muons):

$$\sigma(pp \rightarrow \chi_{b0} + X) Br(\chi_{b0} \rightarrow J/\psi J/\psi) = 330 \text{ pb} \quad (5)$$

We use this cross-section in our study. It should, however, be considered as a lower bound, with higher order QCD corrections expected to increase it significantly, especially within the COM approach. This cross-section also does not include other  $C$ -even states ( $\eta_b, \chi_{b2}$  and radial excitations), meaning that the overall combined cross-section of resonant  $J/\psi J/\psi$  production in the  $\Upsilon$  mass region can be at least an order of magnitude higher.

The PYTHIA Monte Carlo generator, used to simulate this process, was modified to include this particular decay. Events for this study are triggered with a di-muon trigger  $\mu 6\mu 4$ , as for the  $J/\psi$  and  $\Upsilon$  di-muon analysis. Out of 50 000 generated  $\chi_b \rightarrow J/\psi(\mu\mu)J/\psi(\mu\mu)$  events 815, or 1.6%, passed the  $\mu 6\mu 4$  trigger cuts. Taking into account di-muon branching fractions of the two  $J/\psi$  mesons, this corresponds to the cross-section  $\sigma = 20 \text{ fb}$  after trigger.

The two triggered muons have the highest  $p_T$  of the four. The two remaining muons, in many cases, have transverse momenta too low to be identified as muons (i.e. below 2.5 GeV), and sometimes too low to be even reconstructed (below 0.5 GeV).

Two classes of events, remaining after the trigger cuts, have been considered to be useful:

- a) events where the two trigger muons came from the same  $J/\psi$ . Then, the third muon has to be identified by the muon system, while the fourth must at least be reconstructed as a track (124 events);

- b) events where each trigger muon came from a different  $J/\psi$ . The remaining two muons may or may not be identified, but their tracks still need to be reconstructed (330 events).

Thus, taking the trigger, muon identification and track reconstruction efficiencies into account, one expects about 50% of triggered  $\chi_b \rightarrow J/\psi(\mu\mu)J/\psi(\mu\mu)$  decays to be observed, which amounts to 0.8% of the generated sample, corresponding to the cross-section of 10 fb. Hence, the observed statistics is expected to be around 100 events for the integrated luminosity  $10 \text{ fb}^{-1}$ .

Once the two  $J/\psi$  candidates in the event have been reconstructed, a simultaneous fit of the four muon tracks to the common vertex is performed, with  $J/\psi$  mass constraints applied to the respective di-muon invariant masses. The resulting distribution is presented in Figure 25(a). The resolution on the  $\chi_b$

Figure 25: (a) Reconstructed  $\chi_b$  invariant mass, with  $J/\psi$  mass constraints applied on the respective di-muon pair masses. (b) Higher di-muon invariant mass plotted versus the lower di-muon invariant mass in  $\chi_b \rightarrow J/\psi(\mu\mu)J/\psi(\mu\mu)$  events.

mass is estimated to be as good as 40 MeV. Similar resolution should be expected for the reconstructed invariant mass in the decays of other  $\chi_{bJ}$  states, while the resolution for  $\eta_b \rightarrow J/\psi(\mu\mu)J/\psi(\mu\mu)$  should be slightly better.

With two pairs of muons in each signal event, there are two possible pairings of oppositely charged muons. The plot of the invariant mass of one di-muon pair versus the invariant mass of the other is shown in Figure 25(b), using generator-level information. All correct pairings, and none of the incorrect pairings of di-muons fall within the circle of radius 200 MeV (about 3-4  $\sigma$ ) from the point with coordinates  $M_{J/\psi}, M_{J/\psi}$ . The incorrect pairings are scattered over the whole area, so by selecting the pairings from the circle defined above, the combinatorial background can be strongly reduced.

The main expected sources of background to  $\chi_b \rightarrow J/\psi(\mu\mu)J/\psi(\mu\mu)$  decays are the processes of bottom quark production,  $pp \rightarrow b\bar{b}X$ , with each  $b$  either decaying into  $J/\psi + X$ , or into a muon with additional charged tracks. These backgrounds have been analysed with the same Monte Carlo samples used in our study of backgrounds for single  $J/\psi$  and  $\Upsilon$  production. Within the available statistics, very few background events have survived the signal selection cuts described above, and the background suppression cuts on pseudo-proper time on secondary vertices. Extrapolating these results to the integrated luminosity of  $10 \text{ fb}^{-1}$  shows that the statistically significant  $\chi_b \rightarrow J/\psi(\mu\mu)J/\psi(\mu\mu)$  signal peak (or peaks) should be visible on top of the combinatorial continuum, with the expected signal-to-background ratio of 10-20% or above.

In short, so far we have seen no major obstacles in an attempt to search for narrow resonances in the  $J/\psi(\mu\mu)J/\psi(\mu\mu)$  invariant mass distributions. However, dedicated high statistics Monte Carlo samples are needed to draw more reliable conclusions.

## 6 Physics reach with early data

During the initial run of the LHC, the integrated luminosity of  $1 \text{ pb}^{-1}$  with the  $\mu 6\mu 4$  trigger would mean about 15 000  $J/\psi \rightarrow \mu\mu$  and 2 500  $\Upsilon \rightarrow \mu\mu$  recorded events. If the  $\mu 4\mu 4$  trigger is used, these numbers would increase up to 17 000 and 20 000 respectively, with these additional events mainly concentrated at the lower end of the quarkonium transverse momenta.

Additional, largely independent statistics will be provided by the  $\mu 10$  trigger: 16 000  $J/\psi$  and 2 000  $\Upsilon$  with transverse momenta above about 10 GeV, with distributions similar to those from the  $\mu 6\mu 4$  samples. Quite separate from these, another 7 000 of  $J/\psi \rightarrow \mu\mu$  events are expected from  $b$ -decay events. All these events should be perfectly usable for detector alignment, acceptance and trigger efficiency studies, as well as for understanding tracking and muon system performances.

At the integrated luminosity of about  $10 \text{ pb}^{-1}$  recorded numbers of  $J/\psi \rightarrow \mu\mu$  and  $\Upsilon \rightarrow \mu\mu$  will be roughly equal to the statistics used in this note. With these statistics, the  $p_T$  dependence of the cross-section for both  $J/\psi$  and  $\Upsilon$  should be measured reasonably well, in a wide range of transverse momenta,  $p_T \simeq 10 - 50 \text{ GeV}$ . The precision of  $J/\psi$  polarisation measurement can reach  $0.02 - 0.06$  (depending on the level of polarisation itself), while the expected error on  $\Upsilon$  polarisation is unlikely to be better than about 0.2. At this stage, first attempts may be made to understand the performance of the electromagnetic calorimetry at low photon energies, and to try and reconstruct  $\chi_c$  states from their radiative decays.

With an integrated luminosity of  $100 \text{ pb}^{-1}$ , the transverse momentum spectra are expected to reach about 100 GeV and possibly beyond, for both  $J/\psi$  and  $\Upsilon$ . With several million  $J/\psi \rightarrow \mu\mu$  and more than 500 000 of  $\Upsilon \rightarrow \mu\mu$  decays, and a good understanding of the detector, high precision polarisation measurements, at the level of few percent, should become possible for both  $J/\psi$  and  $\Upsilon$ .  $\chi_b \rightarrow \Upsilon\gamma$  decays could become observable, while other measurements mentioned above will become increasingly precise.

Further increase of the integrated luminosity should make it possible to observe the resonant production of  $J/\psi$  meson pairs in the mass range of the  $\Upsilon$  system. During the future high luminosity running, the need to keep event rates manageable will mean an increase of thresholds of relevant single- and di-muon triggers, and the prescaling of lower threshold triggers. The higher luminosity will further expand the range of reachable transverse momenta and allow further tests of the production mechanisms, as well as make  $\chi_b$  reconstruction easier.

# Production Cross-Section Measurements and Study of the Properties of the Exclusive $B^+ \rightarrow J/\psi K^+$ Channel

## Abstract

In the initial phase of the LHC operation at low luminosity several Standard Model physics analyses will be performed in order to validate the ATLAS detector and trigger system. The  $B^+ \rightarrow J/\psi K^+$  channel can be observed with the first ATLAS data at LHC and can be used for detector performance studies. This channel will provide a reference in the search for rare  $B$  decays. It will also be used to estimate the systematic uncertainties and efficiencies of flavor tagging algorithms, needed for  $CP$  violation measurements. The prospects to measure the  $B^+$  mass, its total and differential production cross sections and lifetime with the first ATLAS data, are described in this note.

## 1 Introduction

The expected large hadronic cross-section for  $b$ -quark production and the high luminosity at the LHC leads to copious  $b$ -quark production, with the presence of a  $b\bar{b}$  pair in about one percent of the collisions. Quantitatively, the expected inclusive production cross-section for  $pp \rightarrow b\bar{b} + X$  at LHC is estimated to be  $\sigma_{b\bar{b}} \approx 500 \mu\text{b}$  leading to more than  $10^5$   $b\bar{b}$  pairs per second at the LHC design luminosity of  $\mathcal{L} \approx 10^{33} \text{ cm}^{-2}\text{s}^{-1}$ . However, the extrapolation of the  $b\bar{b}$  cross-section measurement from the Tevatron energy of 1.8–1.96 TeV [1, 2] to the LHC energy of 14 TeV suffers from large uncertainties. The theoretical predictions are based on NLO QCD calculations with uncertainties smaller than 20 % [3] in the kinematical region of the LHC, originating mainly from scale uncertainties [4], as well as uncertainties due to the parton density functions and the  $b$ -fragmentation.

A precise measurement of the  $b\bar{b}$  inclusive cross-section at the LHC can be used to constrain these theoretical uncertainties. In addition, the large production rate allows for exclusive cross-section measurements shortly after the LHC start up, which have different systematic uncertainties and model dependencies (fragmentation models) from the inclusive ones. Furthermore, the  $b\bar{b}$  represents the largest physics background for many processes, therefore its measurement is a prerequisite to any discovery.

In this note the exclusive channel  $B^+ \rightarrow J/\psi K^+$  is studied extensively and the procedure to measure the differential and total cross-sections with the first  $10 \text{ pb}^{-1}$  is presented, with event selection based on the identification of the  $J/\psi$  decay to two muons.

The exclusive  $B^+ \rightarrow J/\psi K^+$  decay can be measured during the initial luminosity phase of the LHC, because of the clear event topology and rather large branching ratio. It can serve as a reference channel for rare  $B$  decay searches, whose total and differential cross-sections will be measured relative to its cross-section, thus allowing the cancelation of common systematic uncertainties. Furthermore, it can be used to estimate the systematic uncertainties and efficiencies of flavour tagging algorithms, which are needed for  $CP$  violation measurements. Finally, the relatively large statistics for this decay allow for initial detector performance studies. In particular, the precise measurement of the well-known mass and lifetime [5] can be used for inner detector calibration and alignment studies.

In Section 2 of the note the Monte Carlo data sets used for this study are described. In Section 3 the  $J/\psi$  selection procedure is presented. The  $B^+ \rightarrow J/\psi K^+$  mass, cross-section and lifetime measurements can be found in Section 4. The expected statistics during the early LHC luminosity phase are discussed in Section 5 together with estimates of the systematic uncertainties.

All the following studies have been done for luminosity of  $\mathcal{L} = 10^{32} \text{ cm}^{-2}\text{s}^{-1}$ . However, since pile-up does not play any role at this luminosity, it is straightforward to rescale the results of these studies to  $\mathcal{L} = 10^{31} \text{ cm}^2\text{s}^{-1}$ , in case this will be the luminosity at startup.

## 2 Monte Carlo Samples

All Monte Carlo (MC) data sets used for the studies presented in this note have been produced using PYTHIA-6.4 [6] without overlaying pileup events.

Process	$N_{\text{gen}}$	$\mathcal{L}$ [pb <sup>-1</sup> ]	$N_{\text{gen}}(B^+ \rightarrow J/\psi K^+)$
$b\bar{b} \rightarrow J/\psi(\mu 6\mu 4) + X$	145 500	13.2	7 072

Table 1: Monte Carlo data set used for the  $B^+$  study. The  $N_{\text{gen}}(B^+ \rightarrow J/\psi K^+)$  events are the ones contained in the whole generated sample.

At the generator level, the ATLAS specific PYTHIA implementation for  $B$ -physics which provides an interface to PYTHIA-6 [7] was used. The study of the  $B^+ \rightarrow J/\psi K^+$  channel is done using the inclusive production cross-section of  $\sigma(b\bar{b} \rightarrow J/\psi(\mu 6\mu 4)X)$ , where the numbers in the bracket denote the cuts applied on the muons from the  $J/\psi$  decay in order for the generated event to be accepted (one muon with  $p_T > 6$  GeV and the other with  $p_T > 4$  GeV). The cross-section at the generation level, after implementing these cuts to the muons from the  $J/\psi$  decay is 11.1 nb. The total number of generated events and the number of the  $B^+ \rightarrow J/\psi K^+$  decays found in the sample are given in Table 1. All efficiencies presented in this note, are calculated relative to the generated number of events.

## 3 $J/\psi$ Identification Procedure

A reliable identification of the  $J/\psi$  meson in the decay channel  $J/\psi \rightarrow \mu^+ \mu^-$ , as well as the reconstruction of the primary and secondary vertices, are the prerequisites for the  $B^+ \rightarrow J/\psi K^+$  cross-section measurement. For the selection of the  $B^+$  candidates a further requirement of a positively charged track ( $K^+$ ) originating from the  $J/\psi$  secondary vertex is imposed.

The distance  $\vec{x}$  between the  $pp$  interaction vertex and the secondary vertex of the  $B$ -decay in the transverse plane is used for the  $J/\psi$  identification. In the ATLAS Inner Detector TDR [8], the determination of the position of the primary vertex on an event-by-event basis was demonstrated, and for the  $B^+ \rightarrow J/\psi K^+$  decay, a vertex resolution of  $\sigma_x = 29 \mu\text{m}$  and  $\sigma_y = 27 \mu\text{m}$  was estimated. For up-to-date information on the average primary vertex resolution with the staged ATLAS detector see [9].

The vector  $\vec{x} = \vec{x}_{\text{prim}} - \vec{x}_B$  from the primary vertex  $\vec{x}_{\text{prim}}$  to the secondary  $B$ -decay vertex  $\vec{x}_B$  in the plane normal to the incoming proton beam [10] is used to define the transverse decay length  $L_{xy}$ , which is actually the projection of  $\vec{x}$  onto the direction of the transverse momentum of the  $B$  meson:

$$L_{xy} = \frac{\vec{x} \cdot \vec{p}_T}{|p_T|}. \quad (1)$$

The transverse decay length  $L_{xy}$  is a signed variable, which is negative if the particle appears to decay before the secondary vertex of its production and positive otherwise. For a zero lifetime sample, a Gaussian distribution peaked at  $L_{xy} = 0$  is expected. For exclusive decays, the proper decay length is given by:

$$\lambda = L_{xy} \cdot \frac{m_B}{p_T^B}. \quad (2)$$

For the uncertainty of the transverse decay length  $L_{xy}$ , only the contribution arising from the uncertainties on the primary and secondary vertex coordinates are taken into account:

$$\sigma_{L_{xy}}^2 = \frac{1}{(p_T^B)^2} \cdot \left( \sigma_x^2 (p_x^B)^2 + 2\sigma_{xy}^2 p_x^B p_y^B + \sigma_y^2 (p_y^B)^2 + \sigma_{x1}^2 (p_x^B)^2 + \sigma_{y1}^2 (p_y^B)^2 \right), \quad (3)$$

where  $\sigma_x$ ,  $\sigma_{xy}$ , and  $\sigma_y$  are the covariance matrix elements of the secondary vertex fit,  $\sigma_{x1}$  is the resolution of the primary vertex in  $x$ ,  $\sigma_{y1}$  is the resolution of the primary vertex in  $y$ ,  $p_T^B$  is the transverse momentum of the  $B^+$  meson and finally  $p_x$  and  $p_y$  are the  $x$  and  $y$  components of  $B^+$  momentum.

Since the  $J/\psi$  reconstruction relies on its decay into two muons:  $J/\psi \rightarrow \mu^+\mu^-$ , the first step in the event selection procedure is the identification of the decay muons, which in general have low  $p_T$ .

If a muon track reconstructed by the muon spectrometer has an inner detector track associated to it, it is considered to be a muon and is used to form the  $J/\psi$  candidate. An inner detector track may also be declared a muon candidate and used in the  $J/\psi$  mass reconstruction, if it has hits or track segments in the innermost stations of the muon spectrometer. In either case the  $J/\psi$  mass is calculated using the momentum of the muon candidate provided by the inner detector, in order to exploit the better momentum resolution of the inner detector in this  $p_T$  region. The main  $J/\psi$  selection cuts are as follows:

- All possible di-muons with  $p_{T,1} \geq 3.0$  GeV and  $p_{T,2} \geq 6.0$  GeV are formed;
- The tracks of each muon pair are then fitted to a common vertex;
- From the vertices found, only the ones with  $\chi^2/\text{ndf} < 10$  are retained;
- To select  $J/\psi$  mesons originating from the decay of a  $B^+$ , a cut on the proper decay length,  $\lambda > 0.1$  mm, is imposed to reduce combinatorial background from prompt  $J/\psi$ . If this cut is not imposed, the algorithm identifies all possible combinations consistent with  $J/\psi$  decaying to muons in the event;
- $J/\psi$  candidates inside a mass window of 120 MeV around  $m_{J/\psi}$  are retained.

The efficiency for all previously mentioned cuts is presented in Table 2, where the efficiency after each cut is computed with respect to the previous.

Given that the sample used does not contain any prompt  $J/\psi$ , the effect of the cut on the proper decay length  $\lambda$  in the table indicates the loss in signal events. As it is explained in the following section, this cut is not applied for the lifetime measurement. The  $J/\psi$  reconstruction efficiency is also given for the case of no cut on the  $J/\psi$  proper decay length  $\lambda$ .

The  $J/\psi$  invariant mass distribution without a cut on  $\lambda$  is shown in Figure 1. The shape can be described by a Gaussian with exponential tails. The  $J/\psi$  mass and its resolution, obtained from a Gaussian fit, is 3098 MeV and 57.4 MeV respectively.

cut	with $\lambda$ cut		no $\lambda$ cut	
$J/\psi$ cut	$N_{J/\psi}$	$\epsilon_{J/\psi}$ [%]	$N_{J/\psi}$	$\epsilon_{J/\psi}$ [%]
after vertexing	123 489	84.8	123 489	84.8
after vtx $\chi^2$ cut	115 156	93.3	115 156	93.3
after $\lambda$ cut	84 829	73.6	-	-
after mass cut	81 293	95.8	105 827	91.9
<b>Total eff</b>		55.8		72.7

Table 2:  $J/\psi$  reconstruction efficiencies with and without  $\lambda$  cut.

In order to study the effect of misalignment, displaced magnetic field and incorrect material map on the  $J/\psi$  observed mass position and resolution, a systematic study using different ATLAS geometry configurations was performed, with different combinations of possible misalignments of the calorimeter and the muon spectrometer, as well as a displaced magnetic field map and distorted material in the inner

Figure 1:  $J/\psi$  invariant mass distribution with a Gaussian fit superimposed.

detector and the calorimeter. These studies were performed using a dedicated  $B_s^0 \rightarrow J/\psi\phi$  dataset. It was found that the width of the  $J/\psi$  mass fit  $\sigma(m_{J/\psi})$  is rather stable, varying between 51 and 59 MeV.

The trigger efficiency is about 99 % and was computed from the  $J/\psi$  candidates that have at least one muon with  $p_T > 6$  GeV in the trigger. This is expected, since at the generation level it is required that both muons from the  $J/\psi$  have  $p_T > 6$  GeV and  $p_T > 4$  GeV.

## 4 Analysis of the $B^+ \rightarrow J/\psi K^+$ Channel

The analysis that follows for the selection of  $B^+$  events can equally well be applied for the charge conjugate state. Negligible direct  $CP$  violation is expected in the  $B^\pm \rightarrow J/\psi K^\pm$  because for  $b \rightarrow c + \bar{c}s$  transitions the standard model predicts that the leading and higher order diagrams are characterized by the same weak phase. A measurement of the asymmetry is given in [11]. The main source of asymmetry is the different interaction probabilities for  $K^+$  and  $K^-$  with the detector material. Other non- $CP$ -violating sources of asymmetry are expected to lead to a lepton energy asymmetry and estimated to be negligible [12].

### 4.1 Event selection

The  $B^+$  mesons are reconstructed from a  $J/\psi$  and a  $K^+$  candidate. The  $J/\psi$  selection is described in Section 3 and the  $K^+$  candidates are identified using information from the inner detector. Specifically, the procedure comprises the following steps:

- The original collection of tracks is scanned once again (excluding those already denoted as muons) and those with  $p_T > 1.5$  GeV and  $|\eta| < 2.7$  are retained;
- From this collection, the tracks with positive charge and inconsistent with coming from the primary vertex at one standard deviation level ( $|d_0|/\sigma_{d_0} > 1$ , where  $d_0$  is the impact parameter of the track) are considered to be  $K^+$  candidates;
- The  $\mu^+\mu^-$  pair considered to be originating from the  $J/\psi \rightarrow \mu^+\mu^-$  decay and the  $K^+$  candidate are fitted to a common vertex. The vector defined by the sum of the  $J/\psi$  and  $K^+$  momentum vectors is required to point to the primary vertex, and the two muon tracks are constrained to  $m_{J/\psi}$ ;

- Only combinations with vertex  $\chi^2/\text{ndf} < 6$ ,  $p_T(\mu) > 5$  GeV and  $\lambda > 0.1$  mm are retained;
- In case that more than two  $B^+$  candidates were found in the same event, the one with the smallest vertex  $\chi^2/\text{ndf}$  is accepted.

Figure 2: Invariant mass  $M(K^+\mu^+\mu^-)$  distribution with the  $B^+$  mass peak for signal (red) and combinatorial  $b\bar{b}$ -background (blue).

## 4.2 Mass fit

The  $B^+$  mass determination has been performed using the sample of  $b\bar{b} \rightarrow J/\psi X$  decays. The  $B^+$  invariant mass distribution  $m(K^+\mu^+\mu^-)$  of the candidates fulfilling all cuts is presented in Fig. 2. In the same figure the signal and background events can be seen separately, where the distinction between them is made using the Monte Carlo truth information. The fit to the mass distribution is done by using the maximum-likelihood method, where the probability density function is a Gaussian for the signal region and a linear function for the background:

$$\begin{aligned}
 L &= \alpha f_{\text{sig}} + (1 - \alpha) f_{\text{bkg}} \\
 f_{\text{sig}} &= \frac{1}{\sqrt{2\pi}\sigma} e^{-\frac{1}{2}(\frac{m_i - m}{\sigma})^2}, \\
 f_{\text{bkg}} &= b(m_i - \frac{w}{2}) + \frac{1}{w},
 \end{aligned} \tag{4}$$

where  $\alpha$  is the fraction of signal events in the fitted region,  $m$  the  $B^+$  mass,  $b$  is the slope of the background distribution and  $w$  defines the range of the fit. The mass range of the fit is taken from 5.15 GeV to 5.8 GeV. This is done in order to reduce contributions from partially reconstructed  $B$  meson decays that populate the left side of Fig. 2. The background at the right of the mass peak originates from misidentified  $\pi^+$  from  $B^+ \rightarrow J/\psi \pi^+$  decays.

The result of the  $B^+$  mass fit is:  $M(B^+) = (5279.3 \pm 1.1)$  MeV with a width of  $\sigma(B^+) = (42.2 \pm 1.3)$  MeV. The relative errors scaled properly for an integrated luminosity of  $10 \text{ pb}^{-1}$  are about 0.02% and 3.5% respectively. The corresponding fit is presented in Fig. 3. The slight shoulder to the left of the mass distribution is due to the background shape.

Figure 3:  $B^+$  mass fit with the both signal (red) and background (blue) contributions shown separately.

### 4.3 Differential and total production cross-section

The feasibility of the measurement of the  $B^+ \rightarrow J/\psi K^+$  total and differential production cross-sections at LHC, with the first  $10 \text{ pb}^{-1}$ , is explored in this section. The dataset used is the  $b\bar{b} \rightarrow J/\psi X$  and the reconstructed  $B^+ \rightarrow J/\psi K^+$  candidates were selected based on the event selection described in Section 4.1. The  $B^+$  mass fit method described previously was then used to extract the efficiencies in bins of  $p_T$  as well as the total efficiency.

The differential cross-section  $d\sigma/dp_T$  can be obtained from:

$$\frac{d\sigma(B^+)}{dp_T} = \frac{N_{\text{sig}}}{\Delta p_T \cdot \mathcal{L} \cdot \mathcal{A} \cdot \text{BR}} \quad (5)$$

where  $N_{\text{sig}}$  is the number of reconstructed  $B^+$  mesons obtained from the mass fit. The size of the  $p_T$  bin is denoted with  $\Delta p_T$ . Furthermore,  $\mathcal{L}$  is the total luminosity and  $\mathcal{A}$  the overall efficiency. The branching ratio BR is the product of the world average [5] branching ratios of  $\text{BR}(B^+ \rightarrow J/\psi K^+) = (10.0 \pm 1.0) \times 10^{-4}$  and  $\text{BR}(J/\psi \rightarrow \mu^+ \mu^-) = (5.88 \pm 0.10) \times 10^{-2}$ . The invariant mass spectra of the  $B^+$  candidates are fitted in each  $p_T$  range using an extended unbinned maximum likelihood fit. The probability density function is a Gaussian for the signal and a linear function for the background region:

$$L = \frac{N_{\text{sig}}}{N_{\text{total}}} \cdot f_{\text{sig}} + \frac{N_{\text{total}} - N_{\text{sig}}}{N_{\text{total}}} \cdot f_{\text{bkg}} \quad (6)$$

where  $f_{\text{sig}}$  and  $f_{\text{bkg}}$  are the fit functions as described in Equation 4. For this fit, the  $B^+$  mass has been fixed to the value obtained from the mass fit in the previous Section 4.2,  $m = 5279.3 \text{ MeV}$ . The results for the overall efficiencies and the mass widths of the fits, for the individual  $p_T$  bins, are summarized in Table 3. The mass fits in the various  $p_T$  regions are presented in Figure 4 whereas the fit over the full  $p_T$  range is shown in Fig. 3.

To measure the  $B^+$  total cross-section a similar procedure to the one used for the calculation of the differential cross-section is followed, but in this case all  $B^+$  with  $p_T > 10 \text{ GeV}$  are used to calculate the total efficiency  $\mathcal{A}$ . The  $B^+$  mass distribution is shown in Fig. 3. The results of the total efficiency and the mass width from the fit, for the  $B^+$  total cross-section measurement, are presented in Table 4.

$p_T$ range [GeV]	$p_T \in [10, 18]$	$p_T \in [18, 26]$	$p_T \in [26, 34]$	$p_T \in [34, 42]$
$\mathcal{A}$ [%]	$20.1 \pm 1.0$	$37.3 \pm 1.7$	$45.0 \pm 3.1$	$51.6 \pm 4.7$
$\sigma(B^+)$ [MeV]	$38.5 \pm 2.0$	$42.3 \pm 2.1$	$46.1 \pm 3.2$	$46.6 \pm 4.0$

Table 3: Efficiency  $\mathcal{A}$  and  $B^+$  mass width  $\sigma(B^+)$  for the various  $p_T$  bins.

Figure 4: Fit of the  $B^+$  mass in various  $p_T$  ranges:  $p_T \in [10, 18]$  GeV (a),  $p_T \in [18, 26]$  GeV (b),  $p_T \in [26, 34]$  GeV (c),  $p_T \in [34, 42]$  GeV (d).

total cross-section	
$\mathcal{A}$ [%]	$29.8 \pm 0.8$
$\sigma(B^+)$ [MeV]	$42.2 \pm 1.3$

Table 4: Overall efficiency and  $B^+$  mass width for all  $B^+$  with  $p_T > 10$  GeV.

#### 4.4 Lifetime measurement

The measurement of the lifetime  $\tau$  of the selected  $B^+$  candidates is a sensitive tool to confirm the beauty contents in a sample, in particular the number of the reconstructed  $B^+ \rightarrow J/\psi K^+$  decays obtained in the  $b\bar{b} \rightarrow J/\psi X$  dataset. The proper decay time is defined as  $t = \lambda/c$ . For this analysis, no cut on the proper decay length  $\lambda$  (Equation 2) of the  $J/\psi$  candidate or the  $B^+$  candidate should be applied.

The proper decay time distribution in the signal region  $B^+ \rightarrow J/\psi K^+$  can be parametrised as a convolution of an exponential function with a Gaussian resolution function, while the background distribution

parametrisation consists of two different exponential functions, where each is convoluted with a Gaussian resolution function. In the  $b\bar{b} \rightarrow J/\psi X$  no additional zero lifetime events are expected because there are no prompt  $J/\psi$  produced. In the realistic case, where zero lifetime events will be present, an extra Gaussian centered at zero is needed in order to properly describe those events. With the model used here, the Gaussian resolution functions depend on the reconstructed uncertainties on an event-by-event basis. In addition, it is assumed, that the distribution of the uncertainties per event are different for the signal and the corresponding background probability density functions (pdf) [13]. The use of conditional pdfs was required in order to take into account the proper decay time error per event. The exponential part of the lifetime distribution has the usual form:

$$F_t(t) = e^{-\frac{t}{\tau}}, \quad (7)$$

where  $t$  is the proper decay time and  $\tau$  is the lifetime. Accordingly, the convoluted function is then

$$F_c(t) = e^{-\frac{t}{\tau}} \otimes G(t, \mu, s \cdot \sigma_i), \quad (8)$$

where  $\mu$  is the mean value of the Gaussian resolution function which parametrises the average bias in each proper decay time measurement. The scale factor of the error is  $s$  and  $\sigma_i$  is the per event proper decay time error. The conditional pdf on the per event uncertainty is then:

$$F_t(t) = F_c(t|\sigma_i) \cdot P(\sigma_i), \quad (9)$$

where  $P(\sigma_i)$  is the distribution of the proper decay time error. The distribution of the proper decay time uncertainty is approximated by a superposition of Gaussian functions. In order to separate between the signal and the background, the proper decay time pdf is multiplied with the  $B^+$  mass pdf, described in Section 4.2. A two-dimensional fit to the  $B^+$  proper decay time and  $B^+$  mass is then performed.

The results of the lifetime fit are presented in Table 5 and shown in Figure 5. The background can be best described with the two lifetime components ( $\tau_1$  and  $\tau_2$ ) which are also shown in Table 5. For the events in the mass region of the signal within  $M(B^+) \in [5.15, 5.8]$  GeV the proper decay time found from the decay length is compared to the generated  $B^+$  lifetime. The result of the comparison is shown in Fig. 5. The differences are well centered at zero with a Gaussian distribution and sigma 0.088 ps. It should be noted that the resolution as well as its  $\sigma$  in  $\eta$  bins of 0.25 is found to be independent of  $\eta$ .

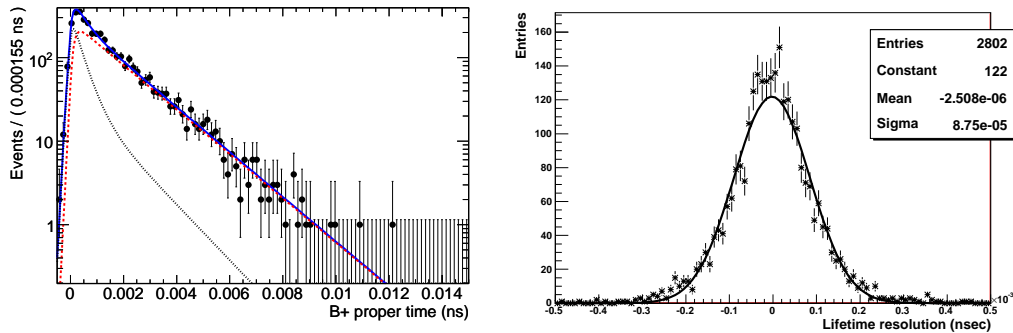

Figure 5:  $B^+$  lifetime fit (left) with the signal (dashed red) and the background (dashed black) contributions shown separately and  $B^+$  lifetime resolution (right).

Signal lifetime $\tau$ [ps]	$1.637 \pm 0.036$
BG lifetime $\tau_1$ [ps]	$1.320 \pm 0.24$
BG lifetime $\tau_2$ [ps]	$0.370 \pm 0.067$

Table 5: Results for the lifetime fit.

## 5 Statistical and Systematic Uncertainties

From the analysis presented above, the expected number of reconstructed  $B^+$  candidates amounts to 160 per  $\text{pb}^{-1}$ . This implies that sufficient statistics can be collected for a reliable cross-section measurement, after just a few months of data taking at the initial low luminosity phase of the LHC. This scenario is valid for a luminosity less than  $\mathcal{L} = 10^{32} \text{ cm}^{-2}\text{s}^{-1}$ , since the analysis was performed without pileup events and contains no special trigger requirements or prescaling other than a single muon with  $p_T^\mu > 6 \text{ GeV}$  at level-1.

For the measurements presented in this note the main sources of systematic uncertainties are the same. The uncertainty from the luminosity in the initial phase is estimated to be 10 % and will be reduced to about 6.5 % after  $0.3 \text{ fb}^{-1}$  of data. The uncertainty from the PDF's is estimated to be 3 %, while the scale uncertainty of the NLO calculations is about 5 %. Finally, the uncertainty originating from the muon identification is about 3 %. Assuming Gaussian distributions for the above mentioned uncertainties, the total systematic uncertainty of the signal varies from 9.2 % to 12 % and is dominated by the uncertainty in the luminosity.

Given that a statistical precision of  $\mathcal{O}(1 \text{ %})$  will be reached with an integrated luminosity of  $0.1 \text{ fb}^{-1}$ , the contribution of the systematics will dominate the uncertainties of the first measurements. This is the case even for the differential cross-section measurement. Although the statistics in each  $p_T$  bin is limited, the total uncertainty is dominated by the systematic uncertainties in the branching ratio of the  $B^+ \rightarrow J/\psi K^+$  and in the luminosity, which are of the same order. For the exclusive cross-section measurement in the  $B^+ \rightarrow J/\psi K^+$  channel, the relative uncertainties of the differential and total cross-sections are given in Table 6. Therein, the first row of the table contains the quadratic sum of the statistical uncertainty corresponding to an integrated luminosity of  $0.01 \text{ fb}^{-1}$  and the uncertainty in the efficiency. The latter is based on the statistics of the Monte Carlo dataset used. The second row is calculated by adding in quadrature the above uncertainty to the systematic uncertainty of the luminosity and the branching ratio for every  $p_T$  bin.

For the high statistics  $p_T$  bins as well as for the total cross-section, the total relative uncertainty is dominated by systematic errors, originating mainly from the uncertainty in the luminosity, which is assumed to be 10 % for the initial phase, and the 10 % uncertainty in the branching ratio of  $B^+ \rightarrow J/\psi K^+$ . The effect of the assumed background shape on the measurements is estimated to be less than 1 %. Finally, the precision of the lifetime measurement, for the same integrated luminosity is 2.5 %, where no systematic effects are taken into account.

$p_T$ range [GeV]	$p_T \in [10, 18]$	$p_T \in [18, 26]$	$p_T \in [26, 34]$	$p_T \in [34, 42]$	$p_T \in [10, \text{inf})$
stat. + $\mathcal{A}$ [%]	7.7	6.9	10.5	13.9	4.3
total [%]	16.1	15.8	17.6	19.8	14.8

Table 6: Statistical and total uncertainties for the  $B^+ \rightarrow J/\psi K^+$  differential and total cross-section measurements for an integrated luminosity of  $0.01 \text{ fb}^{-1}$ . Total uncertainties include luminosity and BR systematic uncertainties.

## 6 Summary and Conclusions

In this note, the  $B^+ \rightarrow J/\psi K^+$  channel using an inclusive  $b\bar{b} \rightarrow J/\psi(\mu\mu\mu\mu)X$  dataset has been studied by developing the  $J/\psi$  selection methods and understanding their efficiencies. A method for measuring the  $B^+$  mass using a likelihood fit, in order to separate signal and background, is established. The  $B^+$  selection efficiency  $\mathcal{A}$ , both in  $p_T$  bins and in the whole  $p_T$  region, needed for the calculation of the differential and total cross-sections from real data, is extracted with fit methods similar to those used in the  $B^+$  mass measurement case. Finally a likelihood fit, which takes into account the per-event primary vertex error, is performed for the measurement of the  $B^+$  lifetime.

The total  $B^+ \rightarrow J/\psi K^+$  production cross-section can be measured with a statistical precision better than 5% with the first  $10\text{pb}^{-1}$  of data. The differential cross-section with precision of the order of 10%. With the same statistics, adequate detector performance studies can be realised using the  $B^+$  mass and lifetime measurements.

# Physics and Detector Performance Measurements with the Decays $B_s^0 \rightarrow J/\psi\phi$ and $B_d^0 \rightarrow J/\psi K^{0*}$ with Early Data

## Abstract

The decay processes  $B_d^0 \rightarrow J/\psi K^{0*}$  and  $B_s^0 \rightarrow J/\psi\phi$  are expected to be observed in large numbers with the ATLAS experiment. During the early data taking period, with an integrated luminosity of around  $\sim 10 - 150 \text{ pb}^{-1}$ , it will be possible to measure the masses and proper lifetimes for these decays with sufficient precision to allow them to be used for detector performance checks. Methods for the determination of the mass and lifetime when the performance of the detector and reconstruction software will not be fully understood are presented. A powerful simultaneous fitting technique is used. Understanding the potential for flavour tagging methods will be one of the important goals for  $B$ -physics with early data. The performance of the jet charge tagger for the self-calibrating decay,  $B_d^0 \rightarrow J/\psi K^{0*}$ , is presented. The implications for the jet charge tag in the  $B_s^0 \rightarrow J/\psi\phi$  decay are also discussed.

## 1 Introduction

The decay  $B_s^0 \rightarrow J/\psi\phi$  is one of the most promising channels at the LHC due to its rich physics potential. This will begin with the earliest data taken by ATLAS. Due to the high  $b\bar{b}$  cross-section [1] and dedicated  $J/\psi$  trigger in ATLAS [2], large statistics data will be quickly accumulated. This will allow the channel to be used for basic measurements of the  $B$  mass and lifetime, which will provide a sensitive test of the understanding of the tracking system after only  $150 \text{ pb}^{-1}$  of data. After collecting only  $1 \text{ fb}^{-1}$  of data, ATLAS will begin to improve world precisions for these measurements. A similar analysis will also be performed for the channel  $B_d^0 \rightarrow J/\psi K^{0*}$ , where the expected statistics are higher by about a factor of 15.

The analysis methods to be used will evolve with increasing statistics and understanding of the detector and backgrounds. This paper concentrates on the early phase of data taking. More advanced studies of the angular dependence of the decays and CP violation are not covered. In the very early data taking period, the low statistics will not allow an investigation of the full list of theoretical parameters, but rather will concentrate on the mass and lifetime. As the backgrounds will not be well understood either, no hard cuts will be made to reject them, but rather backgrounds topologically similar to the signal will be admitted. This will also reduce the dependence on reconstruction algorithms and trigger behaviour, neither of which will be thoroughly tested when ATLAS starts to take data. In particular, no secondary vertex displacement cuts will be applied, and the dominant background admitted will be from direct  $J/\psi$  production.

The simulation of the decays and their backgrounds is described in Section 2, and the reconstruction of the events in Section 3. The methods developed to extract the  $B$  hadron mass and lifetime as well as the precision expected to be reached with early data are described in Section 4. A study of the possibilities for flavour-tagging with early data, an important initial step for the CP violation measurements to be done later, is presented in Section 5.

## 2 Monte Carlo production

Table 1 lists the Monte Carlo data samples used in this study. The beauty events were generated by PYTHIA 6.4 [3] using a method described in [4]. For the direct  $J/\psi$  decays a special tuning of the

Colour Octet Model was prepared within PYTHIA [5]. In order to make the simulation studies more efficient the initial cuts on the transverse momentum,  $p_T$ , and the pseudorapidity,  $\eta$ , were applied at the generator level. To ensure that most of the generated events passed the trigger at the reconstruction stage, only events containing decays of  $J/\psi$  into dimuons, with  $p_T$  larger than 6 GeV and 4 GeV, both detected within  $|\eta| < 2.4$ , were retained for detector simulations.

Table 1: Monte Carlo samples used in this study. Cross sections are given by PYTHIA after applying cuts  $|\eta| < 2.4$  and  $p_T$  larger than 6 GeV and 4 GeV for the first and second muons from  $J/\psi$ .

Process	MC Statistics	Cross section
$b\bar{b} \rightarrow J/\psi X$	150 000	11.1 nb
$pp \rightarrow J/\psi X$	150 000	21.7 nb
$B_s^0 \rightarrow J/\psi \phi$	50 000	0.02 nb
$B_d^0 \rightarrow J/\psi K^{0*}$	30 000	0.24 nb

### 3 Analysis of the decays $B_s^0 \rightarrow J/\psi \phi$ and $B_d^0 \rightarrow J/\psi K^{0*}$

#### 3.1 Strategy for analysis of early data

The strategies deployed during the early period of the experiment will differ from those used later. In particular, the low statistics available will not allow a determination of the complete list of physics variables that can in principle be determined from the  $B_s^0 \rightarrow J/\psi \phi$  and  $B_d^0 \rightarrow J/\psi K^{0*}$  decays [6]. During the early phase, the compositions of the backgrounds will not be well understood. Furthermore, at this time, the detector and reconstruction software performance will also not be fully understood, and restrictive selection cuts to remove backgrounds may bias the signal in an uncontrolled way. The strategy in these early stages will therefore be to use loose cuts, which will admit more of the background decays. In particular, omitting vertex selections allows a statistically meaningful contribution from prompt  $J/\psi$  events. Most of these events fall outside the signal region of the study, and allow a better determination of the vertex resolution, which in turn allows a better overall  $B$  lifetime determination. This approach is consistent with the  $B$  trigger strategy for early data where no cut on secondary vertex displacement is required.

#### 3.2 Reconstruction

Monte Carlo events of signal and background processes, as described in Table 1, were passed through full detector simulation and reconstruction. Trigger algorithms were applied during the reconstruction. Only events accepted by the  $J/\psi \rightarrow \mu^+ \mu^-$  trigger [2] (with thresholds of  $p_T > 6$  GeV and  $p_T > 4$  GeV for the fastest and second fastest muon) were retained for offline analysis. The reconstructed data objects were then processed as follows.

$J/\psi \rightarrow \mu^+ \mu^-$  candidates were sought by forming all possible pairs of oppositely charged muon tracks passing the cuts  $p_T > 4$  GeV and  $|\eta| < 2.4$ . Pairs containing at least one muon track with  $p_T > 6$  GeV were fitted to a common vertex. Pairs were assumed to be muons from  $J/\psi$  decays if the vertex fit resulted in a fit  $\chi^2/n.d.f < 6$  and the invariant mass of the muon pair fell within a  $3\sigma$  window around the nominal  $J/\psi$  mass, with  $\sigma = 58$  MeV. This window was chosen by fitting a Gaussian distribution to the invariant mass of the muon pairs in the events  $pp \rightarrow J/\psi X$  and  $b\bar{b} \rightarrow \mu^+ \mu^- X$ , see Figure 1. The background from non resonant  $\mu^+ \mu^-$  pairs in the  $3\sigma$  window is 10%.

Figure 1: Reconstructed invariant mass distributions of  $J/\psi \rightarrow \mu^+\mu^-$  (left),  $\phi \rightarrow K^+K^-$  (middle) and  $K^{0*} \rightarrow K^\pm\pi^\mp$  (right) candidates.

The  $\phi \rightarrow K^+K^-$  candidates were reconstructed from all pairs of oppositely charged tracks, not identified as muons, with  $p_T > 0.5$  GeV and  $|\eta| < 2.5$ , which were fitted to a common vertex. These tracks were assumed to be kaons from  $\phi$  decays if the vertex fit resulted in a  $\chi^2/n.d.f < 6$ , and the invariant mass of the track pairs (under the assumption that they were left by kaons) fell within the interval 1009.2 – 1029.6 MeV. This interval is based on a fit to the invariant mass distribution of the reconstructed  $\phi \rightarrow K^+K^-$  decay candidates shown in Figure 1. The signal fit used a Breit-Wigner correctly accounting for phase space convoluted with a Gaussian to represent the detector resolution. The background was approximated by a linear function. (Additional terms up to quadratic have no significant influence on the fit.)

The  $K^{0*} \rightarrow K^\pm\pi^\mp$  candidates were reconstructed by selecting all tracks that had  $p_T > 0.5$  GeV and  $|\eta| < 2.5$  that had not been previously identified as muons, forming them into oppositely charged pairs and fitting them to a common vertex. These pairs were assumed to be  $K^\pm\pi^\mp$  from  $K^{0*}$  decays if the fit resulted in a  $\chi^2/n.d.f < 6$ , the transverse momentum of the  $K^{0*}$  candidate was greater than 3 GeV, and the invariant mass of the track pair fell within the interval 790-990 MeV, under the assumption that they were left by  $K^\pm\pi^\mp$  hadrons. In Figure 1, the signal has been fitted to a Breit-Wigner function convoluted with a Gaussian and the background has been fitted to a second degree polynomial function.

To find the  $B_d^0 \rightarrow J/\psi K^{0*}$  candidates, the tracks from each combination of  $J/\psi \rightarrow \mu^+\mu^-$  and  $K^{0*} \rightarrow K^\pm\pi^\mp$  candidates were fitted to a common point. The two muon tracks were constrained to the PDG  $J/\psi$  mass. These quadruplets of tracks were assumed to be from  $B_d^0 \rightarrow J/\psi K^{0*}$  decays if the transverse momentum of the  $B_d^0$  candidate was greater than 10 GeV and the fit resulted in a  $\chi^2/n.d.f < 6$ . In the case of more than one candidate per event, the candidate with the lowest  $\chi^2/n.d.f$  was retained.

$B_s^0 \rightarrow J/\psi \phi$  candidates were sought by fitting the tracks from each combination of  $J/\psi \rightarrow \mu^+\mu^-$  and  $\phi \rightarrow K^+K^-$  candidates fitted to a common vertex. The two muon tracks were constrained to the PDG  $J/\psi$  mass. These quadruplets of tracks were assumed to be from  $B_s^0 \rightarrow J/\psi \phi$  decays if the transverse momentum of the  $B_s^0$  candidate was greater than 10 GeV and the fit resulted in a  $\chi^2/n.d.f < 6$ . If there was more than one candidate per event then the candidate with the lowest  $\chi^2/n.d.f$  was chosen.

Accepted  $B_s^0$  and  $B_d^0$  candidates contain a negligible background from non-resonant  $\mu^+\mu^-$  pairs, 0.1% and 0.2% respectively, and therefore the background from non-resonant  $bb \rightarrow \mu^+\mu^-X$  events are not considered in this analysis.

Events were accepted in a wide invariant mass window of  $\pm 12 \cdot \sigma$  around  $B$  hadron mass, where the mass resolution  $\sigma$  was determined from reconstruction of the  $B_d^0$  and  $B_s^0$  masses for the two signal channels. The mass resolutions were obtained from fitting a single Gaussian to the Monte Carlo signal. Table 2 shows the number of events that can be expected using the above procedure for an integrated

Table 2: Signal and background statistics of  $B_s^0$  and  $B_d^0$  candidates expected with  $10 \text{ pb}^{-1}$ .

	Selected candidates expected with $10 \text{ pb}^{-1}$
Signal $B_d^0 \rightarrow J/\psi K^{0*}$	1024
$pp \rightarrow J/\psi X$ background	1419
$b\bar{b} \rightarrow J/\psi X$ background	3970
Signal $B_s^0 \rightarrow J/\psi \phi$	76
$pp \rightarrow J/\psi X$ background	2449
$b\bar{b} \rightarrow J/\psi X$ background	1660
All events satisfying $B_d^0$ or $B_s^0$ selections	10323

luminosity of  $10 \text{ pb}^{-1}$ .

By the time the LHC reaches a luminosity of  $10^{33} \text{ cm}^{-2} \text{ s}^{-1}$  and the detector is better understood, it will be safe to apply displaced secondary vertex cuts, which will remove most of the backgrounds. In the studies of exclusive channels of  $B$  decays, vertex displacement selections are replaced by cuts on the  $B$  hadron decay time. This method avoids any bias on the proper decay time measurements. Table 3 shows the reconstruction efficiencies with and without decay time cuts. In particular, by requiring that the proper decay time of the  $B_s^0$  candidate is greater than 0.5 ps, additional rejection by a factor of 260 for the  $pp \rightarrow J/\psi X$  can be achieved while losing 25% of the signal.

Table 3:  $B_d^0 \rightarrow J/\psi K^{0*}$  ( $B_s^0 \rightarrow J/\psi \phi$ ) signal and background reconstruction efficiencies before and after the cut on  $B_d^0$  ( $B_s^0$ ) decay time  $t$ . The applied cut was  $t > 0.5 \text{ ps}$ .

	efficiency [%]	
	before time cut	after time cut
Signal $B_d^0 \rightarrow J/\psi K^{0*}$	42.0	30.4
$pp \rightarrow J/\psi X$ background	0.67	0.0064
$b\bar{b} \rightarrow J/\psi X$ background	3.05	1.52
Signal $B_s^0 \rightarrow J/\psi \phi$	40.5	30.0
$pp \rightarrow J/\psi X$ background	1.5	0.0058
$b\bar{b} \rightarrow J/\psi X$ background	1.1	0.8

## 4 Simultaneous fit of mass and lifetime of $B_d^0$ and $B_s^0$ with early data

We now turn to methods for extracting physically interesting parameters from the decays of the  $B_s^0$  and  $B_d^0$  mesons. The first measurements with early data will comprise the mean lifetimes and masses of these mesons.

We perform a simultaneous maximum likelihood fit for each  $B_s^0$  and  $B_d^0$  mass and proper decay time distributions. The likelihood function  $L$  is defined by:

$$L = \prod_{i=1}^N \left[ \frac{n_{sig}}{N} \times p_{sig}(t_i, m_i) + \frac{n_{bckl}}{N} \times p_{bckl}(t_i, m_i) + \frac{N - n_{sig} - n_{bckl}}{N} \times p_{bkg2}(t_i, m_i) \right] \quad (1)$$

where the index  $i$  runs over the events,  $N = n_{sig} + n_{bck1} + n_{bck2}$  is the total number of reconstructed events in the fit and  $n_{sig}$ ,  $n_{bck1}$  and  $n_{bck2}$  are the numbers of signal and background events. The terms  $p_{sig}$ ,  $p_{bkg1}$  and  $p_{bkg2}$  are products of two probability density functions that model the mass  $m$  and proper decay time  $t$  of the signal and the prompt and non-prompt backgrounds respectively (see Section 2). The number of expected events for the prompt background is  $n_{bck1}$  and the corresponding probability density function in formula 1 is  $p_{bkg1}$ . The probability density function for the non-prompt background is  $p_{bkg2}$ .

For the signal, the mass distribution is modeled by a Gaussian distribution, whose mean value is the  $B$  hadron mass  $m(B)$  and its width  $\sigma_m$  is given by the detector mass resolution. Both  $m(B)$  and  $\sigma_m$  are determined from the fit. The reconstructed proper decay time distribution for the signal is parameterised by the function:

$$p_{sig}(t_i) = \frac{\int_0^\infty e^{-\Gamma t} \rho(t - t_i) dt}{\int_{-\infty}^\infty (\int_0^\infty e^{-\Gamma t} \rho(t - t') dt) dt'} \quad (2)$$

where the decay time resolution function  $\rho(t - t_i)$  was approximated by a Gaussian of width  $\sigma$  which is a free parameter of the fit.

For the background, the mass distribution of the prompt component is assumed to follow a flat distribution as observed in simulated data (see Figure 2). The non-prompt component is modeled with a second order polynomial function where the coefficient of the linear (quadratic) terms, denoted as  $c_1$  ( $c_2$ ) in Table 4, are determined from the fit.

The decay time distribution of the prompt background component is parametrised by a Gaussian of width  $\sigma$ . The non-prompt component was modeled by the sum of two exponential functions, convoluted with the decay time resolution function  $\rho$ . The two exponential functions are denoted as  $\Gamma_1$  and  $\Gamma_2$ , the constant coefficient between them is  $b_1$ .

$$p_{bck2}(t_i) = \frac{\int_0^\infty (\Gamma_1 e^{-\Gamma_1 t} + b_1 \times \Gamma_2 e^{-\Gamma_2 t}) \rho(t - t_i) dt}{\int_{-\infty}^\infty (\int_0^\infty (\Gamma_1 e^{-\Gamma_1 t} + b_1 \times \Gamma_2 e^{-\Gamma_2 t}) \rho(t - t') dt) dt'} \quad (3)$$

#### 4.1 $B_d^0 \rightarrow J/\psi K^{0*}$ decay

The likelihood function,  $-2\ln L$  is minimised to extract the  $B_d^0$  lifetime  $\tau = 1/\Gamma$  and mass  $m(B)$  from the reconstructed events containing a  $B_d^0 \rightarrow J/\psi K^{0*}$  candidates and backgrounds. This fit corresponds to an integrated luminosity of  $10 \text{ pb}^{-1}$ . The distributions of the reconstructed masses and lifetimes are shown in Figure 2. Table 4 summarises the results of the likelihood fit. The values obtained from the fit agree with the input values used in the simulation (given in the first column) within the statistical errors of the fit. The average lifetime of the  $B_d^0$  can be measured with an uncertainty of 10% for  $10 \text{ pb}^{-1}$ .

#### 4.2 $B_s^0 \rightarrow J/\psi \phi$ decay

The  $B_s^0 \bar{B}_s^0$  system exhibits two mass eigenstates with two lifetimes; the lifetime difference  $\Delta\Gamma_s/\Gamma_s$  is expected to be  $\mathcal{O}(10^{-1})$ . However, with early data (a few hundred  $\text{pb}^{-1}$ ), the statistics are insufficient to determine both lifetimes. For the initial period of LHC running, it is assumed that  $\Delta\Gamma_s = 0$ . The method for the  $B_s^0$  fit is the same as for the  $B_d^0$  case, the main difference being the smaller fraction of signal events, as shown in the mass and lifetime distributions for the reconstructed events after cuts selecting the  $B_s^0$  signal (Figure 3).

Statistics of reconstructed events corresponding to an integrated luminosity of  $150 \text{ pb}^{-1}$  enables measurements to be made with relative precisions on the  $B_s^0$  lifetime of 10% (Table 5). In the fit the background events are weighted by factor of 15, since Monte Carlo statistics were limited to the equivalent of  $10 \text{ pb}^{-1}$  for the current study.

Table 4: Results of the fit to reconstructed  $B_d^0$  candidates corresponding to  $10 \text{ pb}^{-1}$ . The first column shows input values used in simulation.

Parameter	Simulated value	Fit result with statistical error
$\Gamma, \text{ps}^{-1}$	0.651	$0.73 \pm 0.07$
$m(B), \text{GeV}$	5.279	$5.284 \pm 0.006$

## 5 The performance of the jet charge tagger with early data

Most studies of CP-violation and mixing require the identification of the flavour of the neutral  $B$  mesons; this is known as *flavour tagging*. Understanding the potential for flavour tagging methods will be one of the important goals with early data. In studies of CP-violation and mixing of neutral  $B$  mesons, one must know the flavour of a  $B$  meson both at the time of production ( $t = 0$ ) and at the time of decay.

In a small number of cases, the flavour at production can be inferred from the charge of the highest

Table 5: Results from the fit to reconstructed  $B_s^0$  candidates corresponding to  $150 \text{ pb}^{-1}$ .

	Input	Fit result with statistical error
$\Gamma_s, \text{ps}^{-1}$	0.683	$0.743 \pm 0.051$
$m(B), \text{GeV}$	5.343	$5.359 \pm 0.006$
$\sigma, \text{ps}$		$0.152 \pm 0.001$
$\sigma_m, \text{GeV}$		$0.061 \pm 0.006$
$n_{\text{sig}}/N$	0.018	$0.031 \pm 0.005$
$n_{\text{bck1}}/N$	0.397	$0.379 \pm 0.006$
$b_1$		$0.023 \pm 0.01$

$\Gamma_2, \text{ps}^{-1}$		$0.44 \pm 0.08$
$c_1$		$-1.44 \pm 0.07$
$c_2$		$2.14 \pm 0.49$

Figure 3: Plots to show the distributions of the reconstructed  $B_s^0$  mass and decay time expected with  $150 \text{ pb}^{-1}$ . Background distributions constructed from simulated events corresponding to  $10 \text{ pb}^{-1}$  were scaled by a factor of 15.

$p_T$  lepton unassociated with the signal decay, with the assumption that this tagging lepton originates from a semi-leptonic decay of the other  $B$  hadron in the event. For the majority of the events, one must use the jet charge tagging method. According to fragmentation models, the particles are ordered in the momentum component parallel to the original quark direction, while charge conservation also imposes charge ordering [7]. These two facts may be used to form a jet charge, which is related to the  $b$ -quark charge at production. The jet used in this method consists of all tracks that are unassociated with the

signal decay with  $p_T > 500$  MeV,  $|\eta| < 2.5$ , inside a cone of opening angle  $\Delta R$  around the  $B$  meson in the laboratory frame. The opening angle of the jet cone,  $\Delta R$ , is defined:

$$\Delta R = \sqrt{\Delta\eta^2 + \Delta\phi^2} \quad (4)$$

where  $\Delta\eta$  and  $\Delta\phi$  are the differences in pseudorapidity and azimuthal angle between the cone wall and the  $B$  meson. The jet charge,  $Q_{\text{jet}}$ , tends to be positive for  $\bar{b}$ -jets and negative for  $b$ -jets, thus allowing the  $B^0$  meson flavour at production to be inferred. The jet charge is defined as:

$$Q_{\text{jet}} = \frac{\sum_i q_i p_i^\kappa}{\sum_i |p_i|^\kappa} \quad (5)$$

where the  $q_i$  is the charge of the  $i^{\text{th}}$  track in the jet and  $p_i$  is a measure of the tracks momentum that can be, for example, the transverse momentum of the track or a projection of the track's momentum along the axis of the  $B$  meson's direction. These are referred to as the  $p_T$  method and the  $p_L$  method respectively. The parameter  $\kappa$  controls the relative contribution of the hard and soft tracks in the jet charge. One possible improvement in the algorithm is to remove ambiguous cases such as events with  $Q_{\text{jet}}$  close to zero; the smallest allowed value of  $|Q_{\text{jet}}|$  is called the “exclusion cut”. The opening angle of the jet cone, the exclusion cut and  $\kappa$  are free parameters and must be tuned to get the best performance from the tagger.

### 5.1 Quantifying the performance of a flavour tagger

The effectiveness of the discrimination between  $B^0$  and  $\bar{B}^0$  mesons at production time is characterized by two quantities: its *efficiency*,  $\epsilon_{\text{tag}}$ , and the *dilution*,  $D_{\text{tag}}$ . The efficiency is the fraction of  $B$  mesons that were tagged either correctly or incorrectly and is described by:

$$\epsilon_{\text{tag}} = \frac{N_r + N_w}{N_t} \quad (6)$$

where  $N_r$  and  $N_w$  are the numbers of correctly and incorrectly tagged  $B$  mesons respectively, and  $N_t$  is the total number of reconstructed  $B$  mesons. The *dilution*, also known as the *purity*, is given by:

$$D_{\text{tag}} = \frac{N_r - N_w}{N_r + N_w} = 1 - 2w_{\text{tag}} \quad (7)$$

where  $w_{\text{tag}}$  is the wrong tag fraction:

$$w_{\text{tag}} = \frac{N_w}{N_r + N_w} \quad (8)$$

In a typical CP violation study, where the aim is to identify a difference in some property between a particle and its anti-particle, the relationship between the true asymmetry of this property,  $A_{\text{true}}$ , and the asymmetry as measured in the data,  $A_{\text{meas}}$ , will be

$$A_{\text{true}} = \frac{1}{D_{\text{tag}}} A_{\text{meas}} \quad (9)$$

which is derived in, for instance, [8]. For the small asymmetries expected in the  $B$  decays, the statistical uncertainty on  $A_{\text{true}}$  is, to a good approximation:

$$\sigma_A \approx \frac{1}{\sqrt{\epsilon_{\text{tag}} D_{\text{tag}}^2 N_t}} \quad (10)$$

The tag algorithm effectiveness is indicated by the *quality factor* or *tagging power*,  $Q_{\text{tag}}$ :

$$Q_{\text{tag}} = \epsilon_{\text{tag}} D_{\text{tag}}^2 \quad (11)$$

The quality factor is used as a measure of success when optimising the flavour tagger.

## 5.2 Understanding the jet charge tagger using $B_d^0 \rightarrow J/\psi K^{0*}$ decays

During the early data taking phase, there will be too few  $B_s^0 \rightarrow J/\psi \phi$  decays reconstructed to allow a detailed comparison between the jet charge distribution obtained from the data and that predicted by the Monte Carlo. However, there will be a sufficient number of the analogous  $B_d^0 \rightarrow J/\psi K^{0*}$  decays to allow such a comparison to be made. Additionally, the final state of the  $B_d^0 \rightarrow J/\psi K^{0*}$ , with a subsequent decay of  $K^{0*}$  to charged mesons, allows the initial flavour to be determined in a statistical way, and therefore the decay mode is considered as self-calibrating. The jet charge tagger thus produced will be important for the CP violation studies with  $B_d^0 \rightarrow J/\psi K_S$ , and the study of  $B_d^0 \rightarrow J/\psi K^{0*}$  will allow us to gain confidence in the tagging performance for  $B_s^0 \rightarrow J/\psi \phi$ .

For this study, the signal decays were reconstructed as described in the Section 3 for both  $B_d^0 \rightarrow J/\psi K^{0*}$  and  $B_s^0 \rightarrow J/\psi \phi$  decays. A reconstructed sample of 15000 decays was used for each channel, corresponding to  $150 \text{ pb}^{-1}$  for  $B_d^0 \rightarrow J/\psi K^{0*}$  and  $1.5 \text{ fb}^{-1}$  for  $B_s^0 \rightarrow J/\psi \phi$ ; this defines our working point for the two channels in this study. The quality factor was then maximised by systematically varying the jet charge tagger input parameters  $\Delta R$ ,  $\kappa$  and exclusion cut. It was found that optimal results for both  $B_s^0$  and  $B_d^0$  mesons were obtained using the projection of the track momentum in the direction of the  $B$  meson (the  $p_L$  method) as the measure of momentum in Equation 5. The other optimal parameters are shown in Table 6. Using these optimised parameters, the jet charge distribution for both  $B_d^0 \rightarrow J/\psi K^{0*}$  and  $B_s^0 \rightarrow J/\psi \phi$  are shown in Figure 4.

Table 6: The optimised parameters of the flavour tagging algorithm for both  $B_d^0 \rightarrow J/\psi K^{0*}$  and  $B_s^0 \rightarrow J/\psi \phi$ .

Parameter	$B_d^0 \rightarrow J/\psi K^{0*}$	$B_s^0 \rightarrow J/\psi \phi$
$\kappa$	0.9	0.8
$\Delta R$ cut	0.7	0.6
Exclusion cut	0.05	0.2

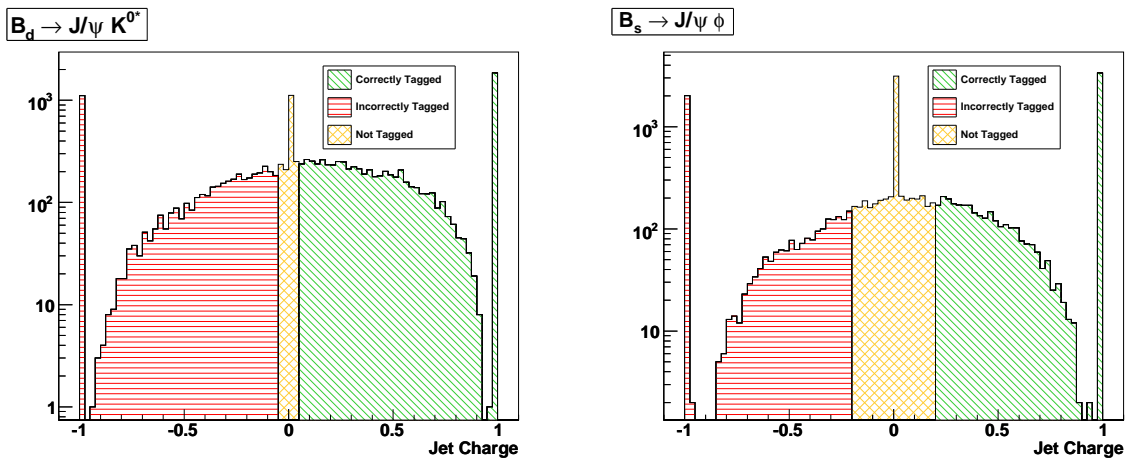

Figure 4: Plots of  $Q_{\text{jet}}$  for  $B_d^0 \rightarrow J/\psi K^{0*}$  (left) and  $B_s^0 \rightarrow J/\psi \phi$  (right) using their optimised parameters of Table 6 and the equivalent luminosity of Table 7.

One might expect that the different flavour content in the formation of the  $B$  mesons will result in a different jet charge behavior for  $B_d^0 \rightarrow J/\psi K^{0*}$  and  $B_s^0 \rightarrow J/\psi \phi$ . This is indeed what is observed, both

in the optimisation of these jet charges and their distributions. However, one should also note that both the shapes and the optimised parameters, except the exclusion cut, are similar.

The numbers in Table 7 characterise the expected performance of the jet charge tagger. With an integrated luminosity of  $150 \text{ pb}^{-1}$ , it will be possible to calibrate the jet charge tagger for the  $B_d^0$ , from the data, with an efficiency of  $87.0 \pm 0.3\%$  and a wrong tag fraction of  $38.0 \pm 0.4\%$ . Calibrating with real data for the  $B_s^0$  is more challenging as there is no readily available and clean self-tagging mode. In this case, the Monte Carlo dependent calibration will be used, but the agreement of the Monte Carlo with real data will be tested indirectly through the  $B_d^0 \rightarrow J/\psi K^{0*}$  channel.

Table 7: Performance of the flavour tagging algorithm for the optimised values given in Table 6. The errors given in the table are statistical.

Parameter	$B_d^0 \rightarrow J/\psi K^{0*}$	$B_s^0 \rightarrow J/\psi \phi$
Equivalent luminosity	$150 \text{ pb}^{-1}$	$1.5 \text{ fb}^{-1}$
Number of Reconstructed Events	13948	15784
Efficiency, $\epsilon_{\text{tag}}$	$0.870 \pm 0.003$	$0.625 \pm 0.005$
Wrong Tag Fraction, $w_{\text{tag}}$	$0.380 \pm 0.004$	$0.374 \pm 0.005$
Dilution, $D_{\text{tag}}$	$0.240 \pm 0.009$	$0.251 \pm 0.010$
Quality, $Q_{\text{tag}}$	$0.050 \pm 0.004$	$0.039 \pm 0.003$

## 6 Summary and conclusion

With the early data, the decays  $B_d^0 \rightarrow J/\psi K^{0*}$  and  $B_s^0 \rightarrow J/\psi \phi$  can be used to measure  $B$  hadron masses and lifetimes with sufficient precision to permit sensitive tests of the detector performance. In particular, the  $B_d^0$  lifetime can be determined with a relative statistical error of 10%, with an integrated luminosity of  $10 \text{ pb}^{-1}$ , and the same precision will be achieved for the  $B_s^0$  lifetime with  $150 \text{ pb}^{-1}$ . The proposed method of a simultaneous fit of background and signal events allows a sensitive determination of the masses and decay times of  $B$  mesons. With early data, the optimal overall precision will be obtained with no cuts on the secondary vertex displacement. This is appropriate for the early data when the performance of the detector and reconstruction algorithms may not be well understood. This strategy is consistent with that of the early  $B$ -physics triggers, where no displacement cuts on the  $J/\psi$  will be applied at the trigger level.

In the early data taking phase, the self-tagging decay  $B_d^0 \rightarrow J/\psi K^{0*}$  will be used to calibrate the jet charge tag for jets containing a  $B_d^0$ . This will be of use for physics studies involving  $B_d^0$  decays, but also this good understanding for the tagging performance for  $B_d^0 \rightarrow J/\psi K^{0*}$  will allow the fragmentation modelling for  $B_s^0 \rightarrow J/\psi \phi$  decays to be improved.

# Plans for the Study of the Spin Properties of the $\Lambda_b$ Baryon Using the Decay Channel $\Lambda_b \rightarrow J/\psi(\mu^+\mu^-)\Lambda(p\pi^-)$

## Abstract

This note summarizes the results of a study of the feasibility of measuring certain spin properties of  $\Lambda_b$  baryon in the ATLAS experiment. We present an assessment of approaches for extracting the inclusive  $\Lambda_b$  polarization and the parity violating  $\alpha_{\Lambda_b}$  parameter for the decay  $\Lambda_b \rightarrow J/\psi(\mu^+\mu^-)\Lambda(p\pi^-)$  from the reconstructed four final state charged particles. As a key test, we generated Monte Carlo samples of  $\Lambda_b$  events of fixed polarization in the ATLAS detector and evaluated our ability to precisely extract the input polarization from the reconstructed events. The physics motivation for the planned measurements in ATLAS include the search for an explanation of the anomalous spin effects in hyperon inclusive production observed at lower energies, tests of various decay models based on HQET, tests of CP in an area not yet directly explored, and the development of  $\Lambda_b$  polarimetry as a possible tool for spin analysis in future SUSY and other studies.

## 1 Introduction

We report here plans for the measurement of spin parameters of the  $\Lambda_b$  hyperon. We utilize the decay mode  $\Lambda_b \rightarrow J/\psi(\mu^+\mu^-)\Lambda(p\pi^-)$  to extract the  $\Lambda_b$  signal from what is expected to be a low background environment, given that the final state has four charged particles and a displaced secondary vertex. The polarization and parity violating  $\alpha_{\Lambda_b}$  parameter will be determined from the relevant angular correlations between the final state particles. We expect to accumulate approximately 13000  $\Lambda_b$  events (and a similar number of  $\bar{\Lambda}_b$ ) with an integrated luminosity of  $30 \text{ fb}^{-1}$ . This estimation is based on the latest reconstruction software and trigger simulation for the ATLAS experiment.

The  $\Lambda_b$  is the lightest baryon containing a  $b$  quark, and since its discovery in 1991 by the UA1 Collaboration [1] it has created a great deal of interest. Besides the so-called  $\Lambda_b$  lifetime puzzle [2], the  $\Lambda_b$  has been the subject of various theoretical studies ranging from proposed tests of CP violation [3], T violation tests and new physics studies [4], measurement of top quark spin correlation functions [5] and the extraction of the weak phase  $\gamma$  of the CKM matrix [6]. Specific physics interest in the  $\Lambda_b$  parity violating  $\alpha_{\Lambda_b}$  parameter studies derives from its ability to serve as a test for various heavy quark factorization models and perturbative QCD (PQCD).  $\Lambda_b$  studies are also of interest because of the continuing mystery of why hyperons have consistently displayed large polarizations when produced at energies even up to several hundred GeV and at large  $p_T$  where most models predict zero polarization. It is not known if these effects can be explained by some not yet understood effect of existing physics or if they point to new physics altogether.  $\Lambda_b$  polarization holds the possibility of illuminating just how polarized  $b$  quarks are produced and, indeed, it may have relevance to how fermions are produced in all  $pp$  induced processes.

Interest in the studies of the  $\Lambda_b$  lifetime parameter derives from the current controversy from Tevatron experiments concerning the question of how much longer the  $b$  quark lives in a meson vs. in a hyperon. With an expected increase of a factor of 100 in the statistics at the LHC, we expect to make a definitive statement on this puzzle. Again, this will further constrain the theoretical models which have as their basis PQCD and the Heavy Quark Model. Lifetime measurements will not be examined in this article, since it is not the focus of the current study, though many of the event selection issues, discussed here, might be applicable in the  $\Lambda_b$  lifetime studies.

We have examined the primary technical challenges in the measurement of  $\Lambda_b$  polarization in ATLAS by generating large samples of  $\Lambda_b$  baryons with various known polarizations, allowing them to decay in the detector using model–predicted amplitudes, and then reconstructing these events using standard ATLAS packages. These samples have permitted us to test our ability to reconstruct events and to confirm that we can recover the input polarization and the decay amplitudes. They also have allowed us to compare various polarization extraction methods and to assess the impact of detector corrections and detector resolution effects. We provide here a report on the results of these studies, and on the work we undertook to adapt the EVTGEN [7] decay package to produce polarized  $\Lambda_b$  within the ATLAS software framework.

## 2 Theoretical overview

In the quark model the  $\Lambda_b$  is a fermion consisting of a  $b$  quark accompanied by a di–quark ( $ud$ ) of total spin zero. In this model the polarization of the  $\Lambda_b$  is thus expected to be totally due to the  $b$  quark polarization. QCD calculations suggest that the  $b$  quark polarization would be small. However, there are models of quark scattering [8], in which spin effects are expected to scale with the mass of the heavy quark, and where the possibility exists for  $\Lambda_b$  polarizations to be quite large. We further note that QCD has not been able to predict the very large polarizations that have been observed in the inclusive production of  $\Lambda$  hyperons at energies of several hundred GeV. It is hoped that the huge mass difference in the  $b$  and  $s$  quarks will help elucidate the origin of these unexplained spin effects.

Interest in the  $\alpha_{\Lambda_b}$  parameter for the  $\Lambda_b$  stems from the fact that HQET models [9] purport to calculate this quantity from rather basic principles of PQCD and factorization. We have an interest in comparing our ultimate measurements of this quantity with these predictions and assessing what constraints they can provide for these models. We provide below a brief overview of the theoretical basis for the polarization and  $\alpha_{\Lambda_b}$  measurements.

### 2.1 Heavy quark polarization in QCD

In the Standard Model heavy quark production is dominated by gluon–gluon fusion and  $q\bar{q}$  annihilation processes. A non–zero polarization requires an interference between non–flip and spin–flip helicity amplitudes for the  $\Lambda_b$  production, with the latter containing an imaginary part. In QCD this complex part can only be generated through loop corrections, so that the relevant diagrams for polarized quarks are  $\mathcal{O}(\alpha_s^4)$ . The polarization expected from all QCD sub–processes ( $g-g$  fusion,  $q\bar{q}$  annihilation and  $q-q$ ,  $q-g$  scattering) have been calculated [10]. The formulae for the polarization for each one of the four processes is directly proportional to  $\alpha_s$ , and it depends just on the ratio  $x_Q = m_Q/p_Q$  and the scattering angle  $\theta_Q$ , (all defined in the center of mass frame), and are thus valid for any final–state quark  $Q$ . The expected polarization in single  $b$  quark production by gluon–gluon fusion and  $q\bar{q}$  annihilation has been found to be a maximum of 5% for gluon–gluon fusion, and a maximum 10% for  $q\bar{q}$  annihilation. When these predictions are compared to the observed  $\Lambda$  polarization (due to the  $s$  quark polarization) [11], they are found to be an order of magnitude too small. One might not be surprised if the  $\Lambda_b$  polarization is, as well, greater than predicted in QCD.

An important result in [10] is the dependence of the polarization on the quark mass. The heaviest quark produced is the most polarized, and the maximum polarization is reached around  $x_Q \simeq 0.3$ . The  $b$  quark polarization is predicted to be an order of magnitude greater than the  $s$  quark polarization, which from  $\Lambda$  polarization measurements has been found to reach values over 20% at 400 GeV [12].

The measurement of the  $\Lambda_b$  polarization in ATLAS in the exclusive channel  $\Lambda_b \rightarrow J/\psi \Lambda$  proposed here would cover  $p_T(\Lambda_b) > 8000$  MeV (because of trigger and reconstruction constraints on the transverse momentum of the final–state particles, see Table 2) and  $x_F(\Lambda_b) < 0.1$ . It could make a significant

contribution to testing different models of production of polarized baryons in this new kinematic region.

An idea that the heavy quark pre-exists in the incoming proton before scattering and becomes polarized through a direct scattering from an incoming quark provides another pathway for the  $\Lambda_b$  to be polarized. This possibility has been discussed by Neal and Burelo [13]. If polarizations are observed in inclusive  $\Lambda_b$  production that exceed a few percent, such a mechanism should be given careful attention, since no other existing models can account for such large values.

## 2.2 $\Lambda_b \rightarrow J/\psi(\mu^+\mu^-)\Lambda(p\pi^-)$ decay and angular distributions

The proposed study of  $\Lambda_b$  polarization would probe not only the production process but also explore the decay of  $\Lambda_b$ . Decay models predict values for various quantities that can be experimentally observed, thus providing a test of specific HQET/Factorization model [14] assumptions.

Figure 1: The weak decay of  $\Lambda_b$ :  $\Lambda_b \rightarrow J/\psi \Lambda$ .

The fact that  $\Lambda_b$  has a significant lifetime suggests that it decays weakly. The dominant decay process would involve the emission of a  $W^-$  boson, as illustrated in Figure 1. The spin and parity of the particles involved in the  $\Lambda_b \rightarrow J/\psi(\mu^+\mu^-)\Lambda(p\pi^-)$  decay are well known. The  $\Lambda_b$  with  $J^P = \frac{1}{2}^+$  decays to  $\Lambda$  with  $J^P = \frac{1}{2}^+$  and  $J/\psi$  with  $J^P = 1^-$ . The general amplitudes for the decay of  $\Lambda_b(\frac{1}{2}^+) \rightarrow \Lambda(\frac{1}{2}^+)J/\psi(1^-)$  is given by:

$$\mathcal{M} = \bar{\Lambda}(p_\Lambda) \varepsilon_\mu^*(p_{J/\psi}) \left[ A_1 \gamma^\mu \gamma^5 + A_2 \frac{p_{\Lambda_b}^\mu}{m_{\Lambda_b}} \gamma^5 + B_1 \gamma^\mu + B_2 \frac{p_{\Lambda_b}^\mu}{m_{\Lambda_b}} \right] \Lambda_b(p_{\Lambda_b}), \quad (1)$$

which is parameterized by the four complex decay amplitudes  $A_1, A_2, B_1, B_2$  and where  $\varepsilon_\mu$  is the polarization vector of the  $J/\psi$ .

Given the general amplitude, we may compute the helicity amplitudes. We use helicity amplitudes, because they have a direct physical relationship to the spin parameters we wish to study. Four helicity amplitudes are required to describe the decay completely. We will use the notation  $H_{\lambda_\Lambda, \lambda_{J/\psi}}$  for the helicity amplitudes of the decay  $\Lambda_b \rightarrow J/\psi(\mu^+\mu^-)\Lambda(p\pi^-)$ , where  $\lambda_\Lambda = \pm 1/2$  is the helicity of  $\Lambda$  and  $\lambda_{J/\psi} = +1, 0, -1$  is the helicity of  $J/\psi$ . These four helicity amplitudes:  $a_+ = H_{1/2,0}$ ,  $a_- = H_{-1/2,0}$ ,  $b_+ = H_{-1/2,1}$ ,  $b_- = H_{1/2,-1}$  are normalized to unity:

$$|a_+|^2 + |a_-|^2 + |b_+|^2 + |b_-|^2 = 1. \quad (2)$$

In this notation, the  $\Lambda_b$  decay asymmetry parameter  $\alpha_{\Lambda_b}$  is given by [15]:

$$\alpha_{\Lambda_b} = \frac{|a_+|^2 - |a_-|^2 + |b_+|^2 - |b_-|^2}{|a_+|^2 + |a_-|^2 + |b_+|^2 + |b_-|^2}. \quad (3)$$

The helicity amplitudes  $a_+$ ,  $a_-$ ,  $b_+$ ,  $b_-$  are computed directly from the decay amplitudes  $A_1$ ,  $A_2$ ,  $B_1$ ,  $B_2$  according to the following equations:

$$\begin{aligned} a_+ &= \frac{1}{m_{J/\psi}} \left\{ \sqrt{Q_+} \left[ (m_{\Lambda_b} - m_\Lambda) A_1 - \frac{Q_-}{2m_{\Lambda_b}} A_2 \right] + \sqrt{Q_-} \left[ (m_{\Lambda_b} + m_\Lambda) B_1 + \frac{Q_+}{2m_{\Lambda_b}} B_2 \right] \right\}, \\ a_- &= \frac{1}{m_{J/\psi}} \left\{ -\sqrt{Q_+} \left[ (m_{\Lambda_b} - m_\Lambda) A_1 - \frac{Q_-}{2m_{\Lambda_b}} A_2 \right] + \sqrt{Q_-} \left[ (m_{\Lambda_b} + m_\Lambda) B_1 + \frac{Q_+}{2m_{\Lambda_b}} B_2 \right] \right\}, \\ b_+ &= \sqrt{2} \left( \sqrt{Q_+} A_1 \mp \sqrt{Q_-} B_1 \right), \\ b_- &= -\sqrt{2} \left( \sqrt{Q_+} A_1 \mp \sqrt{Q_-} B_1 \right), \end{aligned} \quad (4)$$

where  $Q_\pm = (m_{\Lambda_b} \pm m_\Lambda)^2 - m_{J/\psi}^2$  and  $m_{\Lambda_b}$  and  $m_\Lambda$  are the  $\Lambda_b$  and  $\Lambda$  masses respectively [16, 17].

The polarization of the  $\Lambda_b$  can be determined from the angular correlations between the  $\Lambda_b \rightarrow J/\psi \Lambda$  final decay products. The  $\Lambda_b$  polarization reveals itself in the asymmetry of the distribution of the angle  $\theta$ . This angle is defined as the angle between the normal to the beauty baryon production plane and the momentum vector of the  $\Lambda$  decay daughter, as seen in the  $\Lambda_b$  rest frame. The decay angular distribution can be expressed as:

$$w \sim 1 + \alpha_{\Lambda_b} P \cos(\theta), \quad (5)$$

where  $\alpha_{\Lambda_b}$  is the decay asymmetry parameter of  $\Lambda_b$  and  $P$  is the  $\Lambda_b$  polarization [18].

Using the method described in [17], it can be shown that the full decay angular distribution is:

$$w(\vec{\theta}, \vec{A}, P) = \frac{1}{(4\pi)^3} \sum_{i=0}^{i=19} f_{1i}(\vec{A}) f_{2i}(P, \alpha_\Lambda) F_i(\vec{\theta}) \quad (6)$$

where the  $f_{1i}(\vec{A})$  are bilinear combinations of the helicity amplitudes and  $\vec{A} = (a_+, a_-, b_+, b_-)$ .  $f_{2i}$  stands for  $P\alpha_\Lambda$ ,  $P$ ,  $\alpha_\Lambda$ , or 1, where  $\alpha_\Lambda$  is  $\Lambda$  decay asymmetry parameter.  $F_i$  are orthogonal angular functions defined in Table 1. The  $\Lambda_b$  decay asymmetry parameter  $\alpha_{\Lambda_b}$  is related to the helicity amplitudes as defined in Equation 3. The five angles  $\vec{\theta} = (\theta, \theta_1, \theta_2, \phi_1, \phi_2)$  (see Figure 2) in this probability density function (p.d.f.) have the following meanings:

- $\theta$  is the angle between the normal to the production plane and the direction of the  $\Lambda$  in the rest frame of the  $\Lambda_b$  particle;
- $\theta_1$  and  $\phi_1$  are the polar and azimuthal angles that define the direction of the proton in the  $\Lambda$  rest frame with respect to the direction of the  $\Lambda$  in the  $\Lambda_b$  rest frame;
- $\theta_2$  and  $\phi_2$ , define the direction of  $\mu^+$  in the  $J/\psi$  rest frame with respect to the direction of the  $J/\psi$  in the  $\Lambda_b$  rest frame.

There are nine unknown parameters in Equation 6. They are the polarization  $P$  and four complex helicity amplitudes:  $a_+ = |a_+|e^{i\alpha_+}$ ,  $a_- = |a_-|e^{i\alpha_-}$ ,  $b_+ = |b_+|e^{i\beta_+}$ ,  $b_- = |b_-|e^{i\beta_-}$ . Using the normalization condition (see Equation 2) and using the fact that the overall global phase is arbitrary, we can reduce the number of unknown independent parameters to seven.

### 3 Monte Carlo samples

In order to determine if it is feasible to detect polarized  $\Lambda_b$ 's in the ATLAS experiment and to measure their polarization, Monte Carlo samples of polarized  $\Lambda_b$  particles were generated using the standard ATLAS software packages. The generation of polarized  $\Lambda_b$  particles and the propagation of their polarization in the decay process required a special treatment, and EVTGEN was adapted for this purpose. The next sections describe how this was implemented in the framework of the ATLAS experiment.

$i$	$f_{1i}$	$f_{2i}$	$F_i$
0	$a_+a_+^* + a_-a_-^* + b_+b_+^* + b_-b_-^*$	1	1
1	$a_+a_+^* - a_-a_-^* + b_+b_+^* - b_-b_-^*$	$P$	$\cos \theta$
2	$a_+a_+^* - a_-a_-^* - b_+b_+^* + b_-b_-^*$	$\alpha_\Lambda$	$\cos \theta_1$
3	$a_+a_+^* + a_-a_-^* - b_+b_+^* - b_-b_-^*$	$P\alpha_\Lambda$	$\cos \theta \cos \theta_1$
4	$-a_+a_+^* - a_-a_-^* + \frac{1}{2}b_+b_+^* + \frac{1}{2}b_-b_-^*$	1	$1/2(3\cos^2\theta_2 - 1)$
5	$-a_+a_+^* + a_-a_-^* + \frac{1}{2}b_+b_+^* - \frac{1}{2}b_-b_-^*$	$P$	$1/2(3\cos^2\theta_2 - 1)\cos\theta$
6	$-a_+a_+^* + a_-a_-^* - \frac{1}{2}b_+b_+^* + \frac{1}{2}b_-b_-^*$	$\alpha_\Lambda$	$1/2(3\cos^2\theta_2 - 1)\cos\theta_1$
7	$-a_+a_+^* - a_-a_-^* - \frac{1}{2}b_+b_+^* - \frac{1}{2}b_-b_-^*$	$P, \alpha_\Lambda$	$1/2(3\cos^2\theta_2 - 1)\cos\theta\cos\theta_1$
8	$-3\text{Re}(a_+a_-^*)$	$P, \alpha_\Lambda$	$\sin\theta\sin\theta_1\sin^2\theta_2\cos\varphi_1$
9	$3\text{Im}(a_+a_-^*)$	$P\alpha_\Lambda$	$\sin\theta\sin\theta_1\sin^2\theta_2\sin\varphi_1$
10	$-\frac{3}{2}\text{Re}(b_-b_+^*)$	$P\alpha_\Lambda$	$\sin\theta\sin\theta_1\sin^2\theta_2\cos(\varphi_1 + 2\varphi_2)$
11	$\frac{3}{2}\text{Im}(b_-b_+^*)$	$P\alpha_\Lambda$	$\sin\theta\sin\theta_1\sin^2\theta_2\sin(\varphi_1 + 2\varphi_2)$
12	$-\frac{3}{\sqrt{2}}\text{Re}(b_-a_+^* + a_-b_+^*)$	$P\alpha_\Lambda$	$\sin\theta\cos\theta_1\sin\theta_2\cos\theta_2\cos\varphi_2$
13	$\frac{3}{\sqrt{2}}\text{Im}(b_-a_+^* + a_-b_+^*)$	$P\alpha_\Lambda$	$\sin\theta\cos\theta_1\sin\theta_2\cos\theta_2\sin\varphi_2$
14	$-\frac{3}{\sqrt{2}}\text{Re}(b_-a_-^* + a_+b_+^*)$	$P\alpha_\Lambda$	$\cos\theta\sin\theta_1\sin\theta_2\cos\theta_2\cos(\varphi_1 + \varphi_2)$
15	$\frac{3}{\sqrt{2}}\text{Im}(b_-a_-^* + a_+b_+^*)$	$P\alpha_\Lambda$	$\cos\theta\sin\theta_1\sin\theta_2\cos\theta_2\sin(\varphi_1 + \varphi_2)$
16	$\frac{3}{\sqrt{2}}\text{Re}(a_-b_+^* - b_-a_+^*)$	$P$	$\sin\theta\sin\theta_2\cos\theta_2\cos\varphi_2$
17	$-\frac{3}{\sqrt{2}}\text{Im}(a_-b_+^* - b_-a_+^*)$	$P$	$\sin\theta\sin\theta_2\cos\theta_2\sin\varphi_2$
18	$\frac{3}{\sqrt{2}}\text{Re}(b_-a_-^* - a_+b_+^*)$	$\alpha_\Lambda$	$\sin\theta_1\sin\theta_2\cos\theta_2\cos(\varphi_1 + \varphi_2)$
19	$-\frac{3}{\sqrt{2}}\text{Im}(b_-a_-^* - a_+b_+^*)$	$\alpha_\Lambda$	$\sin\theta_1\sin\theta_2\cos\theta_2\sin(\varphi_1 + \varphi_2)$

 Table 1: The coefficients  $f_{1i}$ ,  $f_{2i}$  and  $F_i$  of the probability density function in Equation 6.

 Figure 2: Angles describing the  $\Lambda_b \rightarrow J/\psi(\mu^+\mu^-)\Lambda(p\pi^-)$  decay.

### 3.1 The generation of polarized $\Lambda_b$ particles

To generate  $\Lambda_b$  particles, the PYTHIA 6.4 generator [19] is used. Since PYTHIA does not incorporate polarization information from the decay of  $\Lambda_b$  particles, EVTGEN was used to generate the  $\Lambda_b$  decay. EVTGEN provides a general framework for implementation of B hadron decays using spinor algebra and decay amplitudes. This framework permits the proper management of spin correlations of very complicated decay processes. EVTGEN is a Monte Carlo generation package itself, but in this case it is used only to decay the  $\Lambda_b$  particles produced by PYTHIA.

### 3.1.1 Re-hadronization process and cuts at PYTHIA level

PYTHIA provides mechanisms to produce  $b$  quarks, referred to as gluon–gluon fusion,  $q\bar{q}$  annihilation, flavor excitation, and gluon splitting. If all these processes are taken into account, beauty quark events would constitute only 1% of the total number of generated events. In addition, the fraction of  $b$  quarks hadronizing to  $\Lambda_b$  is less than 10%. These make the process of  $\Lambda_b$  generation computationally slow. To optimize the generation process, a re-hadronization step of the same event in the  $b\bar{b}$  pairs production is used. In order to avoid repetition of  $\Lambda_b$  events due to the re-hadronization process, a  $\Lambda_b$  pre-selection is implemented at this stage to filter on average only one of the re-hadronized copies of the same event. An additional reason that the  $\Lambda_b$  generation process is slow is that around 95% of final state particles (two muons, a proton, and a pion) of the generated  $\Lambda_b$  events are outside of the  $\eta$  limits ( $|\eta| < 2.5$ ) of the ATLAS detector. In addition, all events must pass the level-1 trigger of the ATLAS trigger system and some pre-reconstruction requirements, such as having a minimum reconstructable transverse momentum. We could not apply these cuts in the PYTHIA step since the kinematics information of the  $\Lambda_b$  children is available only at a later stage, when EVTGEN decays the  $\Lambda_b$  particles. However, by analyzing the  $p_T$  and  $\eta$  distributions of  $\Lambda_b$  particles before and after cuts (emulating level-1 and level-2 triggers, and requiring  $|\eta| < 2.5$ ) on the final state particles, we estimated  $p_T$  and  $\eta$  limits, below which the  $\Lambda_b$  can not be selected and then applied these cuts in the PYTHIA selection. Figure 3 shows the  $p_T$  and  $\eta$  distributions from which the  $p_T(\Lambda_b) > 6000$  MeV and  $|\eta(\Lambda_b)| < 3$  cuts were selected to filter  $\Lambda_b$  particles in PYTHIA.

Figure 3: Distributions of  $p_T$  (left) and  $\eta$  (right) for  $\Lambda_b$  particles generated using PYTHIA, without cuts (hollow circle), applying  $\eta$  cuts only (cross) and applying all cuts (solid circle) from Table 2.

### 3.1.2 Setting $\Lambda_b$ polarization in EVTGEN

To set the polarization of  $\Lambda_b$  particles we used the spin density matrix description of EVTGEN. For the case of spin-1/2 particles like  $\Lambda_b$  the density matrix is defined as:

$$\rho = \frac{1}{2}(I + \vec{P} \cdot \vec{\sigma}) \quad (7)$$

where  $\vec{P}$  is the polarization vector, and  $\vec{\sigma} = (\sigma_1, \sigma_2, \sigma_3)$ , where  $\sigma_i$  is  $i$ -th Pauli matrix. In our case  $\vec{P}$  is defined as:

$$\vec{P} = P \left( \frac{\hat{z} \times \vec{p}_{lab}(\Lambda_b)}{|\hat{z} \times \vec{p}_{lab}(\Lambda_b)|} \right) \quad (8)$$

where  $P$  is the magnitude of the polarization,  $\vec{p}_{lab}$  is the momentum of the  $\Lambda_b$  in the laboratory frame, and  $\hat{z}$  is the  $z$ -axis (along the beam direction) in the ATLAS reference system.

To decay polarized  $\Lambda_b$  we use the HELAMP model of EVTGEN. This model is capable of simulating a generic two body decay with arbitrary spin configuration, taking as input the helicity amplitudes describing the process. In the case of the decay  $\Lambda_b \rightarrow J/\psi(\mu^+\mu^-)\Lambda(p\pi^-)$ , as it has been shown in the previous section, there are four complex helicity amplitudes:  $a_+$ ,  $a_-$ ,  $b_+$ , and  $b_-$ .

The  $\Lambda$  decay into a proton and a pion has been simulated with the same model, using as input parameters the two helicity amplitudes  $H_{\lambda_\Lambda, \lambda_p}$  defined in terms of the  $\Lambda$  helicity  $\lambda_\Lambda$  and the proton  $\lambda_p$  helicity as

$$h_- = H_{-\frac{1}{2}, -\frac{1}{2}}, \quad h_+ = H_{+\frac{1}{2}, +\frac{1}{2}}. \quad (9)$$

The choice of  $h_\pm$  is constrained by the experimentally well known  $\Lambda \rightarrow p\pi^-$  asymmetry parameter [20]

$$\alpha_\Lambda = |h_+|^2 - |h_-|^2 = 0.642 \pm 0.013. \quad (10)$$

Finally, the decay  $J/\psi \rightarrow \mu^+\mu^-$  has been described with the EVTGEN VLL (Vector into Lepton Lepton) model [7].

### 3.1.3 Filtering of $\Lambda_b \rightarrow J/\psi(\mu^+\mu^-)\Lambda(p\pi^-)$ events

As a last step in the generation process, we apply kinematic cuts on muons, pion and proton to emulate the fiducial acceptance, level-1 trigger, and pre-reconstruction requirements. These cuts are summarized in Table 2.

Particles	Minimum $p_T$ [MeV]	Maximum $ \eta $
Protons and $\pi$ 's	500	2.7
Most energetic muon	4000	2.7
Other muon	2500	2.7

Table 2: Cuts applied at the particle level.

## 3.2 Monte Carlo samples and input model for $\Lambda_b$ decays

As input to the HELAMP class of EVTGEN, the result obtained within the framework of PQCD formalism and the factorization theorem [9] has been used to model the  $\Lambda_b$  decay. From the complex amplitudes calculated in this model,  $A_1, A_2, B_1, B_2$  in Equation 1, the helicity amplitudes  $a_+$ ,  $a_-$ ,  $b_+$ ,  $b_-$  are calculated by using Equation 4. This is summarized in Table 3. In this model, the  $\Lambda_b$  decay asymmetry parameter, defined in Equation 3, is  $\alpha_{\Lambda_b} = -0.457$ <sup>1</sup>.

$A_1 = -18.676 - 185.036i$	$a_+ = -0.0176 - 0.4229i$
$A_2 = -7.461 - 351.242i$	$a_- = 0.0867 + 0.2425i$
$B_1 = 15.818 - 162.663i$	$b_+ = -0.0810 - 0.2837i$
$B_2 = -4.252 + 266.653i$	$b_- = 0.0296 + 0.8124i$

Table 3: PQCD model amplitudes  $A_i$  and  $B_i$ , are given in units of  $10^{-10}$  and helicity amplitudes  $a_\pm$  and  $b_\pm$  are normalized to unity.

By using this decay model as input, two Monte Carlo samples were generated with polarizations of -25% and -75%. These Monte Carlo samples were generated, simulated, and fully reconstructed by using the Athena framework [21].

<sup>1</sup>There is an ERRATA in [9] in the reported value of  $\alpha_{\Lambda_b}$  [14].

To show how the angular distributions behave, fast Monte Carlo samples (see section 3.3) were generated using an accepted–rejected method based on the p.d.f. defined in Equation 6. Figure 4 shows the distributions of the five angles for helicity amplitudes from Table 3 and polarizations of 40%, 0%, -40%.

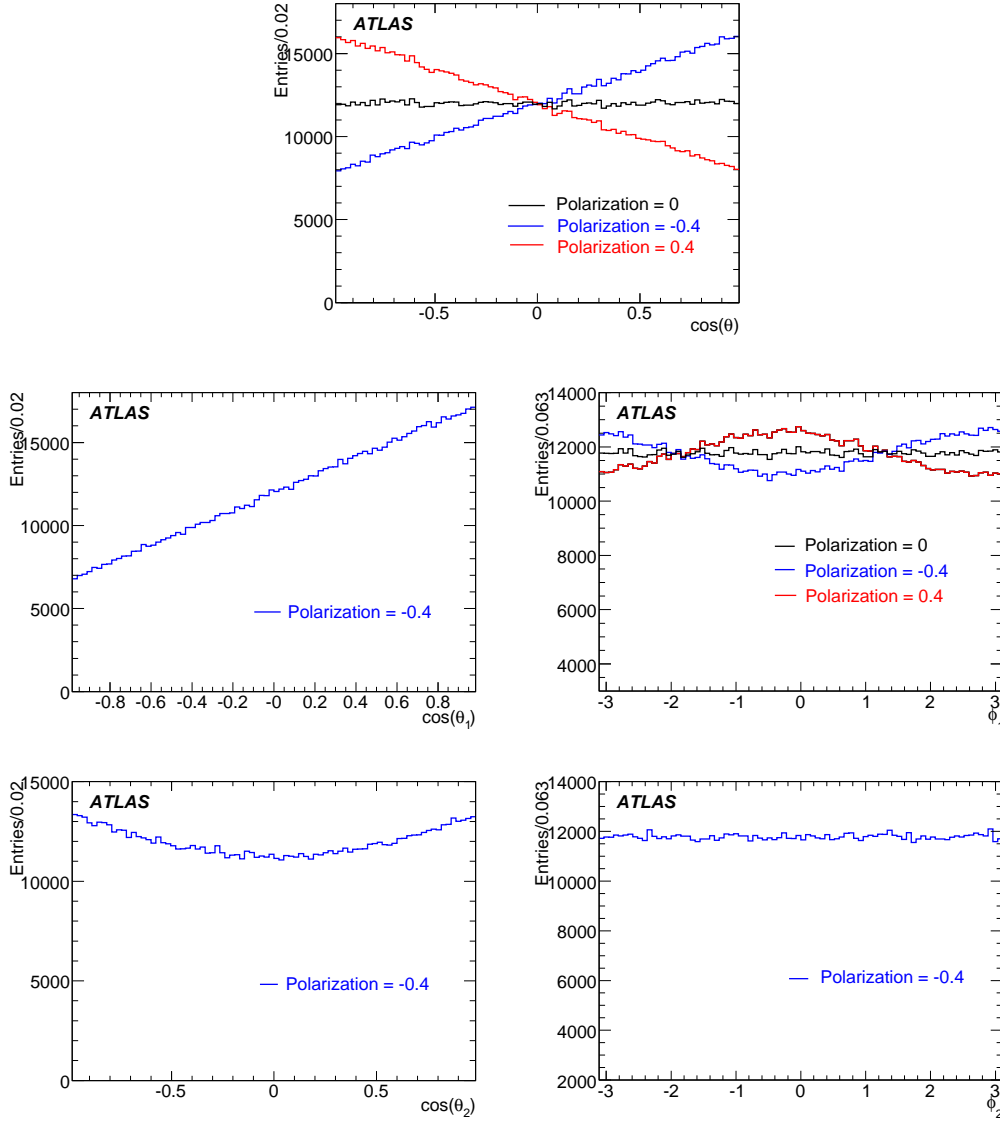

Figure 4: Distributions of the five angles characterizing the decay  $\Lambda_b \rightarrow J/\psi(\mu^+\mu^-)\Lambda(p\pi^-)$  for different polarization values. For  $\cos(\theta_1)$ ,  $\cos(\theta_2)$ , and  $\phi_2$ , all three distributions for the different polarization values look similar, thus only one polarization case is presented.

### 3.3 Fast Monte Carlo generation

In order to do fast tests of different  $\Lambda_b$  decay models and different polarization values, we need to generate large Monte Carlo samples. This represents a problem due to the computer time required to produce a full chain simulated Monte Carlo data. In order to address this problem a fast Monte Carlo generator was

developed. This generator uses Equation 6 to generate angular distributions for the daughters of the  $\Lambda_b$  in the  $\Lambda_b$  rest frame, and then uses a  $(p, \eta)$  distribution derived from phase space of generated events in PYTHIA to compute the kinematic variables of the daughter particles in the laboratory frame. Detector effects are incorporated by using  $p_T$  and  $\eta$  cuts on final state particles to mimic di-muon triggers and pre-reconstruction requirements. Figure 5 illustrates the strong agreement between angular distributions produced by using PYTHIA and EVTGEN Monte Carlo events and fast Monte Carlo events.

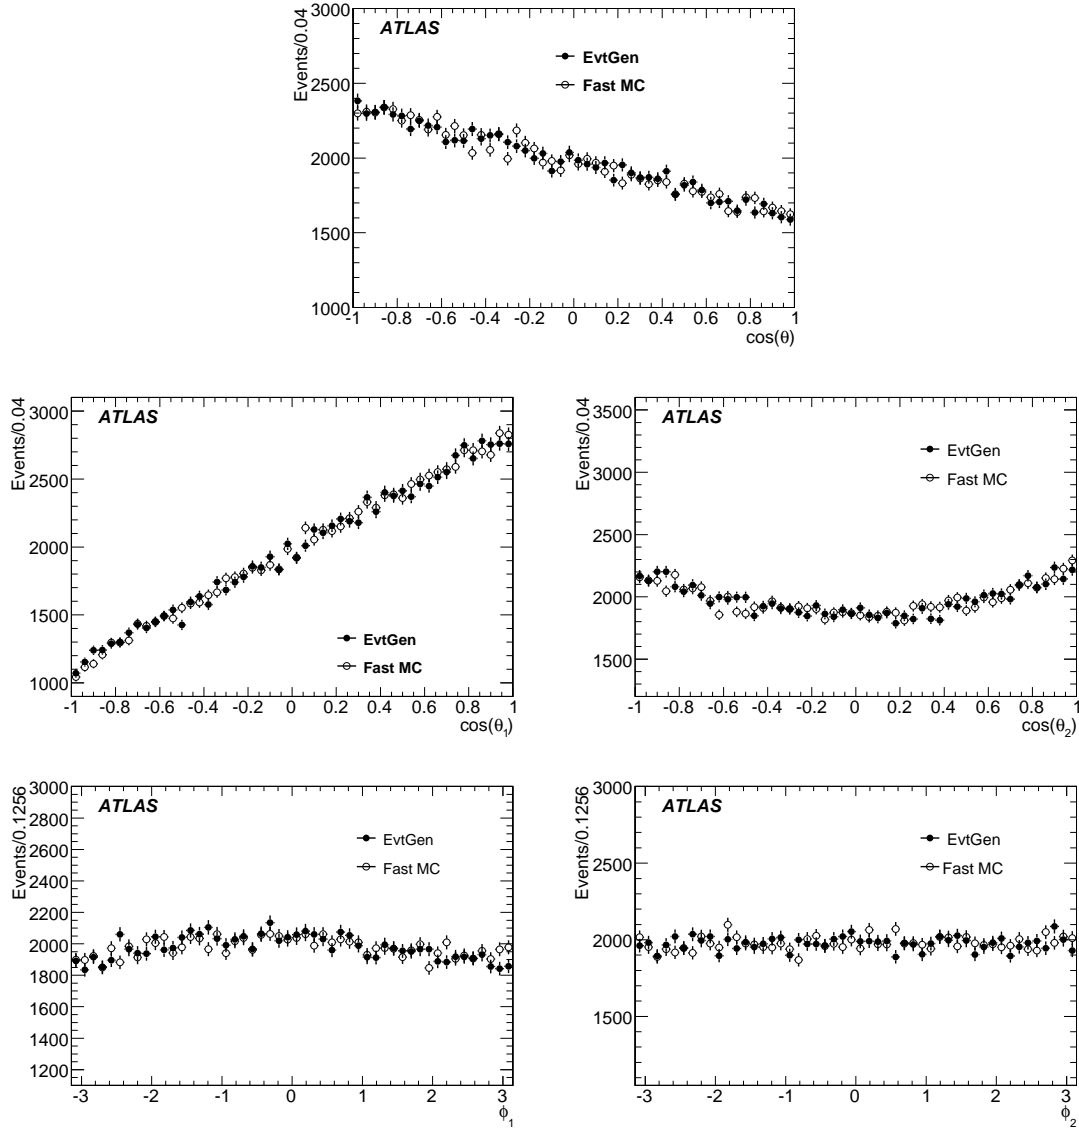

Figure 5: Comparison of Monte Carlo events (PYTHIA + EVTGEN) with fast Monte Carlo generated events. Solid dots represent the Monte Carlo events.

## 4 $\Lambda_b$ reconstruction

The reconstruction of  $\Lambda_b$  candidates begins with a search for events with  $J/\psi$  candidates. Among these events we search for  $\Lambda \rightarrow p\pi^-$  candidates, which are then combined with the  $J/\psi$  to reconstruct the  $\Lambda_b$ .

#### 4.1 Selection of $J/\psi \rightarrow \mu^+\mu^-$ candidates

We search for  $J/\psi$  candidates which satisfy the following selection criteria:

- The  $\mu^+\mu^-$  candidates must originate at the same reconstructed vertex and the  $\chi^2$  of the vertex must be lower than 20;
- The invariant mass of  $\mu^+\mu^-$  candidates  $M(\mu^+\mu^-)$  should be within 2800 MeV and 3400 MeV.

The invariant mass distribution of  $\mu^+\mu^-$  candidates before applying the invariant mass cuts to select  $\Lambda_b$  is shown in Figure 6.

Figure 6: Invariant mass of  $\mu^+\mu^-$  candidates. The dark color represents all  $J/\psi$  candidates after reconstruction and vertexing requirement. The circles represent  $J/\psi$  candidates when level-1 and level-2 trigger signature are required.

#### 4.2 Selection of $\Lambda \rightarrow p\pi^-$ candidates

From the previously selected events containing a  $J/\psi$ ,  $\Lambda$  candidates are selected by applying the following requirements:

- Two opposite charged tracks originating from the same reconstructed vertex.
- The invariant mass of two tracks  $M(p\pi^-)$  should be within 1105 MeV and 1128 MeV range, where for computing  $M(p\pi^-)$ , the track with the highest transverse momentum was assumed to be the proton, as observed in 100% of the times in Monte Carlo generations, while the other track was assumed to be a pion.

Many of the  $\Lambda$  particles decay outside of the high-precision part of the Inner Detector, which covers a radius of about 40 cm from the beam line, and thus are lost in reconstruction. The decay vertex position of  $\Lambda$ 's in the  $RZ$  plane is presented in Figure 8. If the  $\Lambda$  decays outside the 40 cm radius, the number of reconstructed space points (hits in the pixel or silicon layers) is not sufficient for a successful track reconstruction. This effect reduces the fraction of reconstructible  $\Lambda$  to around 60%. Figure 7 presents the invariant mass distribution of the  $p\pi^-$  candidates before the invariant mass cuts have been applied.

 Figure 7: Invariant mass of  $p\pi^-$  candidates.

 Figure 8: Decay vertex position of  $\Lambda$ 's in the  $RZ$  plane at the generation level (left) and after reconstruction (right)

### 4.3 Selection of $\Lambda_b \rightarrow J/\psi(\mu^+\mu^-)\Lambda(p\pi^-)$ candidates

A previous study [22] based on early ATLAS simulation software estimated that the number of  $\Lambda_b$  and  $\Lambda_b$  events which we expect to collect for the integrated luminosity of  $30 \text{ fb}^{-1}$  is 75000. Using the new fully reconstructed sample we made a new estimation. We used the following expression to calculate the number of events:

$$\mathcal{N} = \mathcal{L} \sigma(\Lambda_b) \mathcal{E}, \quad (11)$$

where  $\mathcal{L}$  is the integrated luminosity,  $\sigma(\Lambda_b) = 7.4 \text{ pb}$  is the cross section of  $\Lambda_b \rightarrow J/\psi(\mu(p_T > 4000 \text{ MeV})\mu(p_T > 2500 \text{ MeV}))\Lambda(p(p_T > 500 \text{ MeV})\pi(p_T > 500 \text{ MeV}))$ , see details of the calculation in Table 4, and  $\mathcal{E}$  is an overall  $\Lambda_b$  acceptance, which includes the level-1 and level-2 acceptance for  $\Lambda_b \rightarrow J/\psi(\mu^+\mu^-)\Lambda(p\pi^-)$ .

For selecting events with  $b$  hadrons at a luminosity below about  $10^{33} \text{ cm}^{-2} \text{ s}^{-1}$ , the first level trigger will require the presence of a muon with  $p_T > 6000 \text{ MeV}$  within the trigger geometric acceptance of  $|\eta| < 2.4$ . The effect of the level-1 trigger threshold on muon  $p_T$  is not a sharp cut and a fraction of

$\sigma(pp \rightarrow \Lambda_b X)$	0.00828113 mb
BR ( $\Lambda_b \rightarrow J/\psi \Lambda$ )	$(4.7 \pm 2.8) \times 10^{-4}$ [20]
BR ( $\Lambda \rightarrow p \pi^-$ )	$(63.9 \pm 0.5) \times 10^{-2}$ [20]
BR ( $J/\psi \rightarrow \mu^+ \mu^-$ )	$(5.93 \pm 0.06) \times 10^{-2}$ [20]
Including cuts	0.05
<b>Overall cross-section</b>	<b>7.4 pb</b>

 Table 4: The cross-section calculation of  $\Lambda_b \rightarrow J/\psi(\mu^+ \mu^-) \Lambda(p \pi^-)$  decay.

muons with  $p_T$  lower than 6000 MeV will be collected. Figure 9 shows the efficiency of the level–1 simulation with nominal  $p_T$  threshold of 6000 MeV as function of  $p_T$ . Around 69% of events with  $J/\psi \rightarrow \mu^+ \mu^-$ , where one muon has  $p_T > 4000$  MeV and the second muon has  $p_T > 2500$  MeV, passed the level–1 trigger simulation. Therefore a signal dataset with  $p_T$  less than 6000 MeV has been chosen to study all possible triggered events with low  $p_T$  muons instead of a usual sharp 6000 MeV cut.

 Figure 9: The level–1 trigger simulation efficiency as a function of muon  $p_T$ , obtained from the  $\Lambda_b$  signal sample over the whole detector volume.

Further selections in the high level trigger are based on the Region of Interest (RoI) identified at level–1, as follows: a search for a second muon close to the trigger muon is used to select channels containing two final state muons, for example from  $J/\psi$ . It is based on expanding the level–1 muon RoI to find a second muon which was not triggered by level–1. This increases the efficiency of the di–muon trigger by extending the  $p_T$  acceptance for the second muon down below 6000 MeV. The size of the increased RoI is based on the distribution of angular distance in  $\eta$  and  $\phi$  between two muons decayed from  $J/\psi$ . The Inner Detector tracks which are reconstructed within these RoI, are then extrapolated to the muon system to find the corresponding hits within the window. The Inner Detector tracks associated with the muon spectrometer hits can be identified as muons. The level–2 trigger efficiency is found to be around 78% for  $\Lambda_b \rightarrow J/\psi(\mu(p_T > 4000 \text{ MeV})\mu(p_T > 2500 \text{ MeV}))\Lambda(p(p_T > 500 \text{ MeV})\pi(p_T > 500 \text{ MeV}))$ .

We reconstruct the  $\Lambda_b$  by performing a constrained fit to a common vertex for the two muon tracks and  $\Lambda$ , with the two muon tracks constrained to the  $J/\psi$  mass of 3097 MeV [20]. The reconstruction efficiency depends on the cuts which will be applied on all Inner Detector tracks in the reconstruction stage to reduce the fake rate. The overall efficiency is found to be around 6.1% if the  $p_T$  threshold is 500 MeV, see Table 5. Figure 10 shows the invariant mass distribution of  $\Lambda_b$  candidates. Simulation of the level–1 trigger with level–1  $p_T$  thresholds of 6000 MeV and 4000 MeV and level–2 trigger, explained above,

included in the analysis. We expect to collect around 13500 (13100)  $\Lambda_b \rightarrow J/\psi(\mu^+\mu^-)\Lambda(p\pi^-)$  events using 4000 MeV (6000 MeV) level–1 muon threshold for the integrated luminosity of about  $30 \text{ fb}^{-1}$ .

level–1 trigger: with $p_T$ threshold	one muon		two muons	
	4 GeV	6 GeV	4GeV	6GeV
level–2 trigger:	TrigDiMuon		Topological trigger	
$J/\psi$ reconstruction efficiency including level-1 and level-2 triggers	42%	39%	27.5%	10%
$\Lambda$ reconstruction efficiency	15%			
$\Lambda_b$ overall efficiency	6.1%	5.9%	5.4%	3.5%

Table 5: The overall  $\Lambda_b$  efficiency depending on the trigger strategy.

Figure 10:  $\mu^+\mu^- \Lambda$  invariant mass distribution. The dark color represents all  $\Lambda_b$  candidates after reconstruction and vertexing requirement, and the light color represents the case when a level–1 and level–2 trigger signature is required in addition. Filled circles represents data after all selection cuts. The fit is the result of using double Gaussian and Polynomial functions.

We need to acknowledge that there are other inefficiencies that will appear when we analyze the real data. For example, even if the individual track reconstruction efficiency is as high as 98%, we will have an overall reduction in event rate of about 10%. Even if such reductions occur, we still expect the final sample to be sufficient for a meaningful measurement of the  $\Lambda_b$  polarization.

#### 4.4 Angular distributions and angular resolutions

The reconstruction efficiency modifies the angular distributions used in the polarization determination. Figure 11 shows how the angular distributions change due to detector acceptance for a Monte Carlo sample with polarization of -75%.

The angular resolution of the five angles is presented in Figure 12. We used this angular resolution in the statistical uncertainty study.

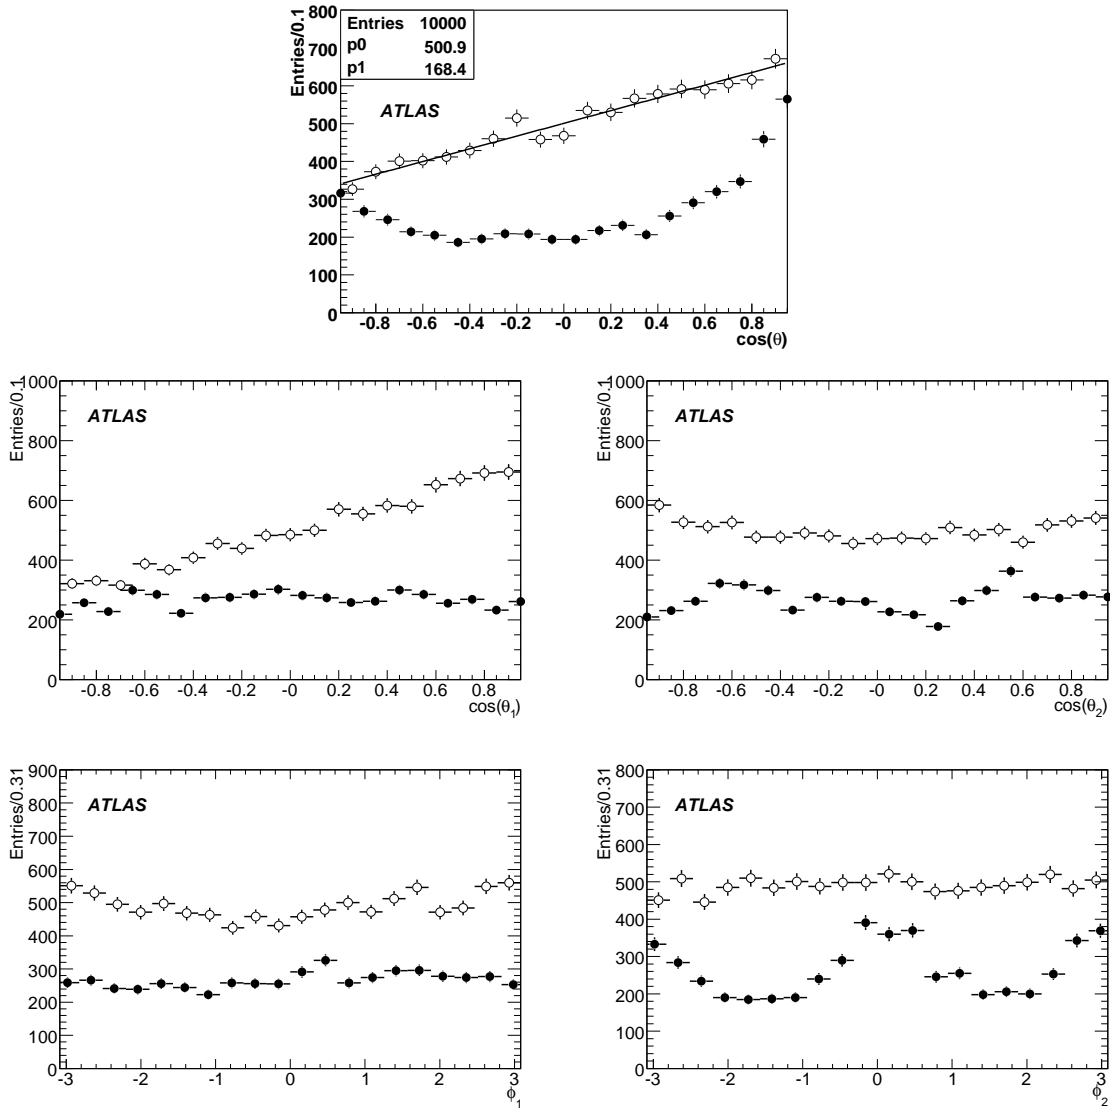

Figure 11: Comparison of fast Monte Carlo events without kinematics and detector acceptance cuts (open circles) and Monte Carlo events after full detector simulation and reconstruction (solid circles).

## 4.5 Background

Due to its production rate the main background source for our  $\Lambda_b$  reconstruction will be the prompt production and decay of  $J/\psi \rightarrow \mu^+ \mu^-$  which are then combined with  $\Lambda$  candidates in the event. However, the long lifetime of the  $\Lambda_b$  allows us to reduce significantly this kind of background by applying a lifetime cut. After a  $\Lambda_b$  lifetime cut (a cut of 200  $\mu\text{m}$  on the proper transverse decay length), this background was found to be negligible and it is not considered in this study.

In order to investigate the different contributions of long-lived background particles not removed by the lifetime cut mentioned above, we used an inclusive  $J/\psi$  Monte Carlo sample of  $b\bar{b} \rightarrow J/\psi X$  requiring in addition to a  $J/\psi$ , a  $\Lambda$  in each event ( $b\bar{b} \rightarrow J/\psi \Lambda X$ ). This  $\Lambda$  could be produced along with the  $J/\psi$  from a B hadron decay or just be part of the event, and the invariant mass of the  $J/\psi + \Lambda$  combination should be within 5100 - 6100 MeV. Figure 13 shows the invariant mass distributions of  $\Lambda_b$  candidates

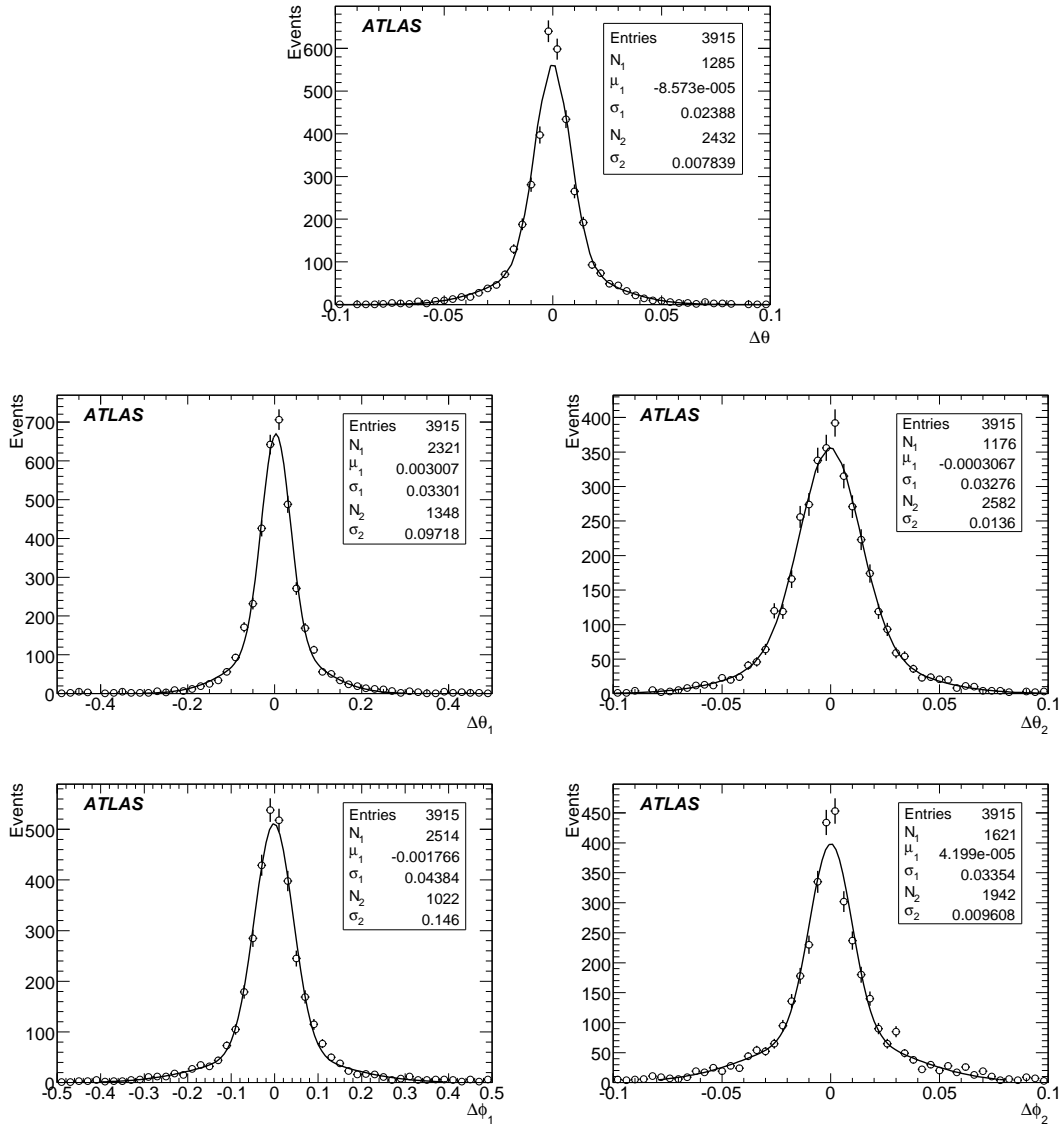

Figure 12: Angular resolution from fully simulated Monte Carlo data. The fit is the result of using double Gaussian distributions.

reconstructed in this Monte Carlo sample. The observed level of background under the  $\Lambda_b$  signal is of few percents, and it is considerably reduced after extra cuts like the lifetime cut mentioned above. In Figure 13 another wider distribution due to  $\Lambda_b \rightarrow J/\psi \Sigma^0(\Lambda\gamma)$  is observed very close to our  $\Lambda_b \rightarrow J/\psi \Lambda$  signal. This is due to the branching ratios of both decays channels being the same as set by default in PYTHIA. This behavior has not been observed at Tevatron experiments where hundreds of  $\Lambda_b \rightarrow J/\psi \Lambda$  events are reconstructed. Therefore we expect the branching ratio of the  $\Lambda_b \rightarrow J/\psi \Sigma^0(\Lambda\gamma)$  decay to be considerably smaller than the branching ratio of the  $\Lambda_b \rightarrow J/\psi \Lambda$ , and that the resulting background will be much smaller than shown.

Figure 13: Invariant mass distribution from  $\Lambda_b$  candidates identified in  $b \rightarrow J/\psi \Lambda X$  Monte Carlo sample. Composition at generation level with smearing from reconstruction (left) and fit to the fully reconstructed events (right) after vertexing requirement are shown.

## 5 Extracting $\Lambda_b$ polarization and decay parameters

### 5.1 Fitting method

#### 5.1.1 Likelihood function

To extract polarization and decay amplitudes we performed an un-binned maximum likelihood fit to the angular distributions. The log-likelihood function  $\mathcal{L}$  is defined by:

$$\mathcal{L} = -2 \sum_{j=1}^N \log(w_{obs}(\vec{\theta}', \vec{A}, P)), \quad (12)$$

where

$$w_{obs}(\vec{\theta}', \vec{A}, P) = \frac{\int w(\vec{\theta}', \vec{A}, P) T(\vec{\theta}, \vec{\theta}') d\vec{\theta}}{\int \int w(\vec{\theta}', \vec{A}, P) T(\vec{\theta}, \vec{\theta}') d\vec{\theta} d\vec{\theta}'} \quad (13)$$

$w(\vec{\theta}', \vec{A}, P)$  is the p.d.f defined in Equation 6,  $\vec{\theta}'$  are the measured angles,  $\vec{\theta}$  are angles without detector effects, and  $T(\vec{\theta}, \vec{\theta}')$  is defined as

$$T(\vec{\theta}, \vec{\theta}') = \varepsilon(\vec{\theta}) R(\vec{\theta}, \vec{\theta}'), \quad (14)$$

where  $\varepsilon(\vec{\theta})$  is the efficiency function and  $R(\vec{\theta}, \vec{\theta}')$  is the resolution function.

In the ideal case the resolution function is:

$$R(\vec{\theta}, \vec{\theta}') = \delta(\vec{\theta} - \vec{\theta}'), \quad (15)$$

then we have

$$w_{obs}(\vec{\theta}', \vec{A}, P) = \frac{w(\vec{\theta}', \vec{A}, P) \varepsilon(\vec{\theta}')}{\sum_{i=0}^{19} f_{1i}(\vec{A}) f_{2i}(P \alpha_\Lambda) \mathcal{F}_i}, \quad (16)$$

where  $\mathcal{F}_i = \int F_i(\vec{\theta}) \varepsilon(\vec{\theta}) d\vec{\theta}$  are the acceptance corrections values, which have to be calculated in advance to perform the fit.

The final log-likelihood may be re-written as a sum of two terms:

$$L = -2 \sum_{j=1}^N [\log(\frac{w(\vec{\theta}', \vec{A}, P)}{\sum_{i=0}^{19} f_{1i}(\vec{A}) f_{2i}(P \alpha_\Lambda) \mathcal{F}_i}) + \log(\varepsilon(\vec{\theta}'))]. \quad (17)$$

Since the second term does not depend on the parameters we want to measure, the main challenge is to find the acceptance function.

### 5.1.2 Detector acceptance corrections

The acceptance corrections integral  $\mathcal{F}_i = \int F_i(\vec{\theta}) \varepsilon(\vec{\theta}) d\vec{\theta}$  can be approximated by the following form, using the Monte Carlo integration techniques

$$\mathcal{F}_i \approx \frac{1}{N_{gen}} \sum_{j=0}^{j=N_{acc}} \frac{F_i(\vec{\theta})}{G(\vec{\theta})}, \quad (18)$$

where  $N_{gen}$  is the number of generated events,  $N_{acc}$  is the number of accepted events after the simulation of the fiducial acceptance and  $p_T$  cut and  $G$  is the p.d.f which has been used to generate the  $\theta$ .

If the generation of the events is done using certain p.d.f ( $w$ ), the acceptance can be calculated by the simple expression:

$$\mathcal{F}_i \approx \frac{1}{N_{gen}} \sum_{j=0}^{j=N_{acc}} \frac{F_i(\vec{\theta})}{w(\vec{\theta}, \vec{A}, P)}. \quad (19)$$

We used this expression to calculate the acceptance in the case when  $w$  is the p.d.f from Equation 6.

This method can be used under the assumption that the acceptance does not depend on the measured parameters, and that the angular resolutions are close enough to the ideal resolutions. In order to check the first assumption we plotted the ratio

$$\frac{\int w(\vec{\theta}, \vec{A}, P) \varepsilon(\vec{\theta}, \vec{A}, P) d\vec{\theta}}{\int w(\vec{\theta}, \vec{A}, P) \varepsilon(\vec{\theta}, \vec{A}, P=0) d\vec{\theta}} \quad (20)$$

for the different polarization values (see Figure 14). No significant dependence of the acceptance on the polarization is observed in this test.

Figure 14: Ratio defined in Equation 20 as a function of polarization.

The angular resolutions are shown in Figure 12. To test the effect of these resolutions, Monte Carlo fits were performed including a smearing of the data based on the Gaussian fits in Figure 12. Fit results with and without smearing are consistent within the statistical uncertainty. Figure 15 shows, as an example, a comparison of fit results for a sample of 2000 events with polarization of -75% when fits are performed on the sample of generated Monte Carlo events.

Figure 15: Comparison of fit outputs from generation level Monte Carlo with and without Gaussian smearing due to finite angular resolution. Error bars are statistical uncertainties from the fit with Gaussian smearing included.

## 5.2 Fits to fully simulated Monte Carlo data

In order to extract polarization and decay parameters from the Monte Carlo data samples, final  $\Lambda_b$  selection cuts were applied. A proper transverse decay length greater than  $200 \mu m$  is required to remove contamination from prompt produced  $J/\psi$  events. The proper transverse decay length for the  $\Lambda_b$  candidate is given by:

$$\lambda = \frac{L_{xy}}{(\beta\gamma)_T^{\Lambda_b}} = L_{xy} \frac{cM_{\Lambda_b}}{p_T}, \quad (21)$$

where  $(\beta\gamma)_T^{\Lambda_b}$  and  $M_{\Lambda_b}$  are the transverse boost and the mass of the  $\Lambda_b$ , and  $L_{xy}$  is a transverse decay length. The transverse decay length is defined as  $L_{xy} = \mathbf{L}_{xy} \cdot \mathbf{p}_T / p_T$  where  $\mathbf{L}_{xy}$  is the vector that points from the primary vertex to the  $\Lambda_b$  decay vertex and  $\mathbf{p}_T$  is the transverse momentum vector of the  $\Lambda_b$ . A minimum  $p_T$  of 500 MeV is required for any track used in the  $\Lambda_b$  reconstruction. In addition, a  $p_T > 4000$  MeV is required for the muon with larger  $p_T$ , and  $p_T > 2500$  MeV for the second muon. These cuts reduce the  $\Lambda_b$  sample by 21%, mainly due to the lifetime cut.

Table 6 shows the results of performing a likelihood fit to our fully simulated Monte Carlo data, for a sample of 2000  $\Lambda_b$  events, corresponding to around  $5 \text{ fb}^{-1}$  of collected data. Figure 16 shows the difference between the input values in Monte Carlo and the extracted values of polarization and decay parameters by the likelihood fit. We used as fitting parameters:  $|a_+|$ ,  $|a_-|$ ,  $|b_+|$ ,  $\alpha_+ - \beta_-$ ,  $\alpha_- - \beta_-$ ,  $\beta_+ - \beta_-$ , and the polarization  $P$ .

Detector acceptance corrections in Equation 19 were computed separately from the two Monte Carlo samples with different polarizations which are used in this study. Corrections computed in the Monte Carlo sample of -75% polarization were used in the fit of the Monte Carlo sample of -25% polarization, and vice versa. Due to the limited statistics in the Monte Carlo samples used to calculate the acceptance corrections defined in Equation 19, a bagging (from bootstrap aggregating) technique [23] was used to generate multiple samples in order to avoid the effect of statistical fluctuations. This technique consists of generating replicates of a data set by selecting at random events from the original data set allowing repetition of events. We generated 1000 bootstrap replicates of the fully simulated Monte Carlo data sample. The  $\mathcal{F}_i$  factors (Equation 19) were computed from each generated data sample and the average was taken as the value for each of the twenty  $\mathcal{F}_i$  correction factors. Systematic uncertainty due to the width of the correction factors distributions in these 1000 generated data sets was estimated by repeating the fit to fully simulated Monte Carlo using the  $\mathcal{F}_i$  values from the each of the generated samples, and

Parameter	Value $\pm$ Uncertainty (Polarization = -25%)	Value $\pm$ Uncertainty (Polarization = -75%)	Value (Input at generation level)
Polarization	$-0.213 \pm 0.069$	$-0.882 \pm 0.064$	-0.25/-0.75
$ a_+ $	$0.461 \pm 0.051$	$0.413 \pm 0.023$	0.429
$ a_- $	$0.289 \pm 0.058$	$0.161 \pm 0.035$	0.260
$ b_+ $	$0.259 \pm 0.071$	$0.370 \pm 0.027$	0.295
$\alpha_+ - \beta_-$	$-0.991 \pm 0.640$	$-2.050 \pm 0.134$	-1.612
$\alpha_- - \beta_-$	$0.856 \pm 0.364$	$0.681 \pm 0.342$	1.231
$\beta_+ - \beta_-$	$-1.442 \pm 0.666$	$-2.624 \pm 0.187$	-1.849

Table 6: Fit results from fully simulated and reconstructed Monte Carlo events with input polarization of -25% and -75%.

assigning the width of the distribution of fitted parameters as a systematic uncertainty. This systematic error (also shown in Figure 16) can be reduced with more Monte Carlo statistics for the  $\mathcal{F}_i$  calculation.

Figure 16: Comparison of fit results for polarization of -25% (left) and -75% (right) with respect to input values from Monte Carlo generation. The statistical and systematic uncertainties are included.

### 5.3 Estimate of statistical uncertainties

To estimate statistical uncertainties as a function of polarization, we used a fast Monte Carlo probabilistic approach to generate polarized  $\Lambda_b$  particles. The fast Monte Carlo includes angular resolution from the fully reconstructed samples and detector acceptance simulation. We generated a large number of samples with different values of polarization. A maximum likelihood fit was used to extract the decay parameters and the polarization. Detector acceptance corrections were calculated from high statistics fast Monte Carlo data simulated without polarization. Figure 17 presents the expected statistical uncertainty in the polarization  $P$  and in  $\alpha_{\Lambda_b}$  as a function of the polarization value for the integrated luminosity of  $30 \text{ fb}^{-1}$ . The study was done for  $\alpha_{\Lambda_b} = -0.457$  with the same input model as used in fully simulated Monte Carlo. In Figure 17 also the correlation between  $\alpha_{\Lambda_b}$  and  $P$  is shown as a function of polarization. The correlation values were extracted from the Maximum Likelihood fit results.

In our study we used specific set of decay amplitudes, presented in Table 3, to demonstrate our ability to extract these parameters. To insure that the success of our analysis techniques did not depend on the amplitudes chosen, we conducted a fast Monte Carlo study using a different model with  $\alpha_{\Lambda_b} = 0.1$  [24] to test our procedure in a case of smaller  $\alpha_{\Lambda_b}$  value. We found that it is possible to satisfactorily extract  $\alpha_{\Lambda_b}$  and the polarization even with such a change in the amplitude values.

Figure 17: Expected statistical uncertainty on polarization (top) and on  $\alpha_{\Lambda_b}$  (center) as a function of the polarization  $P$ . Bottom plot shows the expected correlation between  $\alpha_{\Lambda_b}$  and the polarization  $P$ . All plots show results from the fast Monte Carlo study, obtained for the expected number of  $\Lambda_b$  events in data sample of  $30 \text{ fb}^{-1}$ .

## 6 Results and conclusions

In this note we have presented the results from a series of studies to determine if polarized  $\Lambda_b$  baryons can be reconstructed in ATLAS and have their polarization and  $\alpha_{\Lambda_b}$  parameter measured. Our results

indicate that the answer is affirmative.  $\Lambda_b$  events should be identifiable through the reconstruction of their four charged final state particles, and the angles between these particles can be measured with sufficient accuracy to determine the parent's polarization. With trigger constraints and detector cuts fully specified, our more complete analysis suggests that the number of events we should expect after  $30 \text{ fb}^{-1}$  of data will only be 13,000, compared to the 37,500 noted in the ATLAS-TDR [22]. Different additional detector and background effects, which are difficult to model at the current level of detector description, can further reduce the signal sensitivity. These effects could include the detector and trigger inefficiency, misalignment, pile-up events and increased combinatorial background due to e.g. the fake tracks. Nevertheless, even with a reduction of 50%, a polarization measurement with a statistical uncertainty of several percent should be possible in a regime where polarization is larger than 25% as experimentally measured at lower energies. Efforts will continue to develop algorithms to improve the various reconstruction and trigger efficiencies and in consequence providing an enhanced yield of reconstructed particles in data samples.

We note that almost all models predict that the  $\Lambda_b$  polarization at the LHC at small Feynman  $x$  should be vanishingly small. Measurement of a significant polarization would have to be regarded as a signal of an unexplained effect, either from the domain of existing physics, or of new physics altogether.

We further note that the development of  $\Lambda_b$  polarimetry as a tool for studying spin effects at the LHC could be important. For example, members for the SUSY community are quite interested in knowing what fraction of the  $b$  quark polarization ends up in the polarization of a  $\Lambda_b$ , since this could provide a way to test if  $b$  quark SUSY partners have the correct handedness. Only a few hundred  $\Lambda_b$  decays would be required to, for example, determine if its polarization were 100% or -100%. Challenges clearly exist, however, in determining the polarization transfer fraction, which requires a source of  $b$ 's such as from  $Z \rightarrow b\bar{b}$ , and in dealing with the fact that only  $10^{-5}$  of  $b$ 's generate decay into the  $\Lambda_b$  channel we have described here. Our work on this topic will continue.

Other related studies that should continue include mechanisms for comparing the  $\alpha_{\Lambda_b}$  parameters from  $\Lambda_b$  and its antiparticle as a test of CP. We will accumulate data on both. If CP is conserved, the two parameters should be equal in magnitude but opposite in sign. While the precision of this test will not be high, and while models predict that any CP violation would be small in this sector, nevertheless, such a test would be unique in this domain and should be made.

Finally, as noted in Section 1, the lifetime of the  $\Lambda_b$  remains a topic of significant interest. Such a measurement will be a natural by-product of our efforts to extract the  $\Lambda_b$  spin parameters.

# Study of the Rare Decay $B_s^0 \rightarrow \mu^+ \mu^-$

## Abstract

We investigate the feasibility of measuring of the rare decay  $B_s^0 \rightarrow \mu^+ \mu^-$  in ATLAS. The contribution of inclusive and of the most important non-combinatorial background is studied.

## 1 Introduction

The rare decays,  $B_s^0 \rightarrow \ell^+ \ell^-$  with  $\ell^\pm = e^\pm, \mu^\pm$ , or  $\tau^\pm$ , are mediated by flavour-changing neutral currents that are forbidden in the Standard Model at tree level. The lowest-order contributions in the Standard Model involve weak penguin loops and weak box diagrams that are CKM suppressed. Examples of the lowest-order diagrams are shown in Figure 1. Since the  $B_s^0$  meson is a pseudoscalar that has positive C parity and the transition proceeds in an  $\ell = 0$  state, the electromagnetic penguin loop is forbidden. The two leptons are either both right-handed or both left-handed leading to additional helicity suppression. Thus, branching fractions expected in the Standard Model are tiny.

Figure 1: Lowest order Standard Model contributions to  $B_s^0 \rightarrow \mu^+ \mu^-$ .

The early searches for rare  $B$  meson decays started with radiative penguin decays, first observed by CLEO in 1993, where they presented evidence for the exclusive decay  $B \rightarrow K^* \gamma$  and for the inclusive decay  $B \rightarrow X_s \gamma$  a year later [1, 2].

The  $B$  factory experiments, BaBar and Belle, have measured these decay modes with more precision. The present world average for the inclusive mode is  $\mathcal{B}(B \rightarrow X_s \gamma) = (3.55 \pm 0.26) \times 10^{-4}$  [3]. BaBar and Belle also observed the decays  $B \rightarrow K^{(*)} \ell^+ \ell^-$  and  $B \rightarrow X_s \ell^+ \ell^-$  that are two orders of magnitude smaller than  $B \rightarrow X_s \gamma$  [4, 5]. The decay  $B_s^0 \rightarrow \mu^+ \mu^-$  is expected to be further reduced by three orders of magnitude.

In extensions of the Standard Model, the  $B_s^0 \rightarrow \mu^+ \mu^-$  branching fraction may be enhanced by several orders of magnitude. Thus, several experiments have searched for these decays. The largest  $B_s^0$  samples have been collected by CDF and D0 corresponding to a luminosity of  $2 \text{ fb}^{-1}$  but no signal has been observed. The lowest branching fraction upper limit was set recently by CDF yielding  $\mathcal{B}(B_s^0 \rightarrow \mu^+ \mu^-) < 5.8 \times 10^{-8}$  @95% confidence level [6]. This is still about an order of magnitude higher than the Standard Model prediction. As ATLAS has an elaborate muon system extended over a large region of the solid angle, the dimuon final state is expected to be reconstructed with high efficiency and good mass resolution. Thus, there are good prospects for observing this decay in the dimuon channel and measuring its branching fraction with reasonable precision.

## 2 Theoretical description

The Standard Model amplitude for the process  $B_{s,d} \rightarrow \ell^+ \ell^-$  is calculated from the effective Hamiltonian

$$H_{\text{eff}} = -\frac{G_F}{\sqrt{2}} \frac{\alpha}{\pi \sin^2 \theta_W} V_{tb}^* V_{tq} (C_{10}(\mu) \mathcal{O}_{10}(\mu) + C_S(\mu) \mathcal{O}_S(\mu) + C_P(\mu) \mathcal{O}_P(\mu)) + h.c., \quad (1)$$

where  $C_i(\mu)$  are Wilson coefficients that present the perturbatively calculable short-distance effects and  $\mathcal{O}_i(\mu)$  are local operators that describe the non-perturbative long-distance effects of the transition. The scale parameter  $\mu$  is of the order of the  $b$ -quark mass ( $\sim 5$  GeV),  $\theta_W$  is the weak mixing angle,  $\alpha$  is the electromagnetic coupling constant and  $V_{tb}^* V_{tq}$  are CKM matrix elements for  $t \rightarrow b$  and  $t \rightarrow q = s, d$  transitions, respectively.

The dominant contribution results from the axial-vector operator  $\mathcal{O}_{10}$ , [7]:

$$\mathcal{O}_{10} = (\bar{b}_L \gamma^\mu q_L)(\bar{\ell} \gamma_\mu \gamma_5 \ell). \quad (2)$$

The Wilson coefficient  $C_{10}$  has been determined in the next-to-leading order (NLO) of QCD. The NLO corrections are in the percent range and higher-order corrections are not relevant [8]. In NLO an excellent approximation in terms of the  $\overline{MS}$  mass of the top quark,  $\bar{m}_t$ , is given by:

$$C_{10}(\bar{m}_t) = 0.9636 \left[ \frac{80.4 \text{ GeV}}{M_W} \frac{\bar{m}_t}{164 \text{ GeV}} \right]^{1.52}. \quad (3)$$

The measurements of the top quark mass at the Tevatron,  $m_t^{pole} = 171.4 \pm 2.1$  GeV [9], yield an  $\overline{MS}$  mass of  $\bar{m}_t = 163.8 \pm 2.0$  GeV and the world average of the W-boson mass is  $m_W = 80.403 \pm 0.029$  GeV. The accuracy of this approximation is  $5 \times 10^{-4}$  for masses of  $149 \text{ GeV} < \bar{m}_t < 179 \text{ GeV}$ .

The other two operators represent scalar and pseudoscalar couplings to the leptons:

$$\mathcal{O}_S = m_b(\bar{b}_R q_L)(\bar{\ell} \ell), \mathcal{O}_P = m_b(\bar{b}_R q_L)(\bar{\ell} \gamma_5 \ell). \quad (4)$$

The Wilson coefficients,  $C_S$  and  $C_P$ , are determined from penguin diagrams that involve the Higgs boson or the neutral Goldstone boson, respectively. Although they are not helicity suppressed, their contributions are tiny in the Standard Model and they may be safely neglected in Standard Model calculations.

The  $B_q \rightarrow \mu^+ \mu^-$  branching fractions including the scalar and pseudoscalar contributions are given by:

$$\begin{aligned} \mathcal{B}(B_q^0 \rightarrow \mu^+ \mu^-) &= \frac{G_F^2 \alpha^2}{64 \pi^3 \sin^4 \theta_W} |V_{tb}^* V_{tq}|^2 \tau_{B_q} M_{B_q}^3 f_{B_q}^2 \sqrt{1 - \frac{4m_\mu^2}{M_{B_q}^2}} \\ &\times \left[ \left( 1 - \frac{4m_\mu^2}{M_{B_q}^2} \right) M_{B_q}^2 C_S^2 + \left( M_{B_q} C_P - \frac{2m_\mu}{M_{B_q}} C_{10} \right)^2 \right], \end{aligned} \quad (5)$$

where  $M_{B_q}$ ,  $\tau_{B_q}$ , and  $f_{B_q}$  respectively are mass, lifetime and decay constants of the  $B_q$  meson. The decay constant is determined in different models, including quark models, QCD sum rules and unquenched lattice theory. The accuracy is presently of the order of 10 – 15%. Evaluating  $\alpha$  at the Z-mass scale,  $\alpha(M_Z) = 1/128$ , the following predictions were made for the  $B_q \rightarrow \mu^+ \mu^-$  branchings fractions in the Standard Model [8]:

$$\begin{aligned} Br(B_s^0 \rightarrow \mu^+ \mu^-) &= (3.86 \pm 0.15) \times \frac{\tau_{B_s^0}}{1.527 \text{ ps}} \frac{|V_{ts}^* V_{tb}|^2}{1.7 \times 10^{-3}} \frac{f_{B_s}}{240 \text{ MeV}} \times 10^{-9}, \\ Br(B_d^0 \rightarrow \mu^+ \mu^-) &= (1.06 \pm 0.04) \times \frac{\tau_{B_d^0}}{1.527 \text{ ps}} \frac{|V_{td}^* V_{tb}|^2}{6.7 \times 10^{-5}} \frac{f_{B_d}}{200 \text{ MeV}} \times 10^{-10}. \end{aligned} \quad (6)$$

In extensions of the Standard Model, such as supersymmetry (SUSY), Higgs doublet models or models with extra gauge bosons, scalar-current, pseudoscalar-current or axial-vector current interactions

may arise with new particles in the loop. This yields new contributions in the Wilson coefficients  $C_{10}, C_S$ , and  $C_P$ . Since the scalar and pseudoscalar operators are not helicity suppressed, they may give rise to a large enhancement of the branching fraction. Furthermore, the contribution of the pseudoscalar operator may produce destructive or constructive interference with the axial vector operator. Thus, new physics may increase or decrease the branching fraction with respect to the Standard Model value. For example, in the minimal supersymmetric Standard Model (MSSM), the  $B_s^0 \rightarrow \mu^+ \mu^-$  branching fractions are proportional to  $\tan^6(\beta)$ <sup>1</sup>. The branching fraction of  $B_d \rightarrow \mu^+ \mu^-$  is expected to be a factor of 40 lower than that for  $B_s \rightarrow \mu^+ \mu^-$ , hence, the latter is the focus of this note.

### 3 ATLAS strategy for $B_s^0 \rightarrow \mu^+ \mu^-$ study

Measurements of the properties of  $B$  decays with such extremely low branching fractions in ATLAS is possible namely due to the large beauty cross-section and luminosity of the LHC machine. Thus at luminosity  $10^{33} \text{ cm}^{-2} \text{ s}^{-1}$   $10^{12}$   $B$  hadron pairs will be produced each year. It is expected that ATLAS will record  $10^8$  events with  $B$  decays each year by using  $B$ -physics triggers [10]. Triggers dedicated to rare dimuon  $B_s^0 \rightarrow \mu^+ \mu^-$  decays will be described in the Section 4.2 of this document.

Since the branching fraction is so small in the Standard Model, semileptonic  $B$  decays and even some rare  $B$  decays may yield substantial backgrounds. The key issue for  $B_s^0 \rightarrow \mu^+ \mu^-$  discovery at the LHC is the suppression of the backgrounds. The ATLAS strategy for observing  $B_s^0 \rightarrow \mu^+ \mu^-$  is as follows.

The first step is to trigger on events containing a  $B_s^0 \rightarrow \mu^+ \mu^-$  candidate using dedicated trigger algorithms which are described in this document. In the offline analysis the selections will be refined to reduce backgrounds. To achieve final separation of signal from background we will employ statistical methods based on several variables. Both parts of the offline selection are described in this paper.

Once recorded data are available, the background in the signal region will be estimated using sidebands in the distribution of the muon pair invariant mass. In the current study the background was estimated using simulated events. Two categories of backgrounds were simulated: the so called combinatorial background from  $b\bar{b}$  pairs producing two muons in the final state; and the exclusive backgrounds, coming from two-body hadronic  $B$  decays and from the process  $B_s^0 \rightarrow K^- \mu^+ \nu$ . The exclusive backgrounds contribute to the signal region and the lower mass sideband only. They do not occur in the higher mass sideband, so their contribution to the signal is estimated separately.

After the number of background events in the signal region has been determined, the number of signal events  $N_B$  can be determined from a comparison of the total number of events found in the signal region, and the estimated background. For low statistics an upper limit on  $N_B$  corresponding to certain confidence level is determined using appropriate statistical methods. Once  $N_B$  is determined the  $B_s^0 \rightarrow \mu^+ \mu^-$  branching fraction,  $\mathcal{B}(B_s^0 \rightarrow \mu^+ \mu^-)$ , can be calculated using a relative normalisation to the reference channel  $B^+ \rightarrow J/\psi(\mu^+ \mu^-) K^+$ .

This document presents a Monte Carlo simulation study which follows the strategy described above. We start from the trigger level in Section 4.2. This is followed by the offline analysis, optimisation of discriminating variables and finally the determination of background and signal contribution in the signal regions, in Section 4.4. Systematic uncertainties are analysed in Section 5, followed by the start-up strategy in Section 6.

It should be stressed that due to large uncertainty in the predictions of the  $b\bar{b}$  production cross-section at the LHC energy this paper cannot derive a precise sensitivity to  $\mathcal{B}(B_s^0 \rightarrow \mu^+ \mu^-)$  at ATLAS but rather to show the ATLAS potential for this study and its discovery capability under some assumptions.

---

<sup>1</sup> $\tan(\beta)$  is the ratio of vacuum expectation values for charged and neutral Higgs bosons.

## 4 Monte Carlo study

### 4.1 Simulation and event selection

The Monte Carlo simulation samples used in the analysis have been generated as part of the central ATLAS Monte Carlo data production runs, and details of this simulation have been given in the introduction to this chapter.

The list of generated signal and background events is given in Table 1. To ensure that most of the

Process	# Events
$B_s^0 \rightarrow \mu^+ \mu^-$	47.5k
$b\bar{b} \rightarrow \mu^+ \mu^- X$	146.5k
$B_s^0 \rightarrow K^- \pi^+$	50k
$B_s^0 \rightarrow K^- \mu^+ \nu$	50k

Table 1: List of processes and number of events analysed

generated dimuon events passed the trigger, only events containing two muons with  $p_T$  larger than 6 GeV and 4 GeV, were retained for detector simulation. For the signal channel  $B_s^0 \rightarrow \mu^+ \mu^-$ , multiplying the cross-section reported by PYTHIA with the branching ratio  $3.42 \times 10^{-9}$  gave a cross-section of 15 fb. 47.5k events have been generated and passed through the full detector simulation and reconstruction. Simulation of pileup has not been available, thus it was not simulated for either the signal or the background events.

The sample of dominant background process events,  $b\bar{b}$  decaying semileptonically giving two muons in the final state, were simulated with the same versions of the software, and with the same kinematic cuts as for the signal. The PYTHIA cross-section for such a sample is estimated to be 110 nb and a total of 146.5k background events that passed the reconstruction stage were used in the physics analysis.

In addition to the combinatorial background, there are several  $B$  backgrounds that may contribute to the signal region. These include two and three body decays where two of the final state particles are  $K^\pm$ ,  $\pi^\pm$  or  $\mu^\pm$ . Although the rate for misidentification of kaons or pions as muons, due to punchthrough or decay in flight, is only of the order 0.5%, the small  $\mathcal{B}(B_s^0 \rightarrow \mu^+ \mu^-)$  requires investigation of the other rare  $B$  decays. The decay modes which we consider to be most important are summarised in Table 2.

process	branching fraction	Ref.
$B^0 \rightarrow K^+ \pi^-$	$(1.82 \pm 0.08) \times 10^{-5}$	[11]
$B^0 \rightarrow \pi^+ \pi^-$	$(4.6 \pm 0.4) \times 10^{-6}$	[11]
$B^0 \rightarrow K^+ K^-$	$< 3.7 \times 10^{-7} @ 90\%CL$	[11]
$B_s^0 \rightarrow \pi^+ \pi^-$	$< 1.7 \times 10^{-4} @ 90\%CL$	[11]
$B_s^0 \rightarrow \pi^+ K^-$	$< 2.1 \times 10^{-4} @ 90\%CL$	[11]
$B_s^0 \rightarrow K^+ K^-$	$< 5.9 \times 10^{-5} @ 90\%CL$	[11]
$B_s^0 \rightarrow K^- \mu^+ \nu$	$\sim 1.36 \times 10^{-4}$	* 2
$B^0 \rightarrow \pi^- \mu^+ \nu$	$(1.36 \pm 0.15) \times 10^{-4}$	[11]

Table 2:  $B$  meson decays contributing to the non-combinatorial background

<sup>2</sup>An estimation based on isospin symmetry and the measurement of  $B^0 \rightarrow \pi^- \mu^+ \nu$ .

We have studied one of the two-body and one of the three-body decays with full simulation, namely  $B_s^0 \rightarrow K^- \pi^+$  and  $B_s^0 \rightarrow K^- \mu^+ \nu$ . Contributions from the other channels were estimated to be similar or smaller. To enable the production of a sizable event sample with decay in flight, a special GEANT simulation option which forces kaons and pions from selected  $B$  mesons to decay in the inner detector volume was developed [12]. The position of the decay is randomly selected from a uniform distribution between the origin and the exit point from the inner detector.

## 4.2 Trigger strategy

We describe trigger methods for selection of the  $B_s^0 \rightarrow \mu^+ \mu^-$  channel developed by the  $B$  trigger group as part of the project presented in this document. The full description of the ATLAS B-physics triggers is given in the introduction to the B-physics chapter [10]. The first level trigger (L1) performance for dimuon channels can be found in [13] and details of the second level (L2) dimuon trigger implementation in [12].

At the LHC start-up, the luminosity level is expected to be of order  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  and a  $p_T$  threshold as low as 4 GeV can be used at L1. The dimuon rate after L1 is expected to be only a few Hz. This admits the possibility of applying L2 track reconstruction in the full volume of the inner detector. This detailed approach allows the study of dimuon background features to understand of their composition. With the subsequent rise of luminosity the L1  $p_T$  threshold will increase to 6 GeV. The dimuon rate after L1 is expected to rise to about 360 Hz at  $L = 10^{33} \text{ cm}^{-2} \text{ s}^{-1}$  and the L2 track reconstruction in the full volume of inner detector will be replaced by the Region of Interest (RoI) guided mode, documented in [12].

The simulation of the trigger in the current study is performed by applying the strategies for luminosity  $L = 10^{33} \text{ cm}^{-2} \text{ s}^{-1}$ . At L1 the threshold of  $p_T > 6$  GeV has been applied and events containing two L1 muon signatures are analysed further using the L2 topological dimuon trigger algorithm with a threshold of  $p_T > 6$  GeV. Following the RoI defined at L1, the muon candidates are reconstructed in the muon spectrometer, then matched to the tracks reconstructed in the inner detector (inside the RoI) and combined into one track. The invariant mass of two opposite sign muons is required to be less than 7 GeV. These muons should also be successfully fitted to a common vertex. Only loose selection criteria are used at this step ( $\chi^2 < 10$ ). Implementation of the third level trigger, the event filter (EF), is not finalised yet and the offline reconstruction efficiency is used to estimate the EF efficiency (the same reconstruction algorithms are supposed to be used at EF).

Results on the L1 and L2 efficiencies as well as an estimated EF efficiency for signal  $B_s^0 \rightarrow \mu^+ \mu^-$  are given in Table 3. The L1 efficiency is defined as the ratio of the  $B_s^0 \rightarrow \mu^+ \mu^-$  events passing the L1 trigger and the input events generated with  $p_T > 6$  GeV and  $|\eta| < 2.5$  for both muons from the  $B_s^0 \rightarrow \mu^+ \mu^-$  decay. The L2 efficiency is defined as the fraction of events accepted by L1 satisfying the above L2 reconstruction and selection cuts. The efficiency of the event filter is estimated as the fraction of events that both satisfy L2 and also are successfully reconstructed at EF. These values of the efficiency have been used in the subsequent analysis.

Various types of trigger algorithms and trigger thresholds will be used in the real experiment depending on the luminosity achieved, dedicated computing resources available for the online event processing and the actual beauty yield at LHC energies.

Table 3: Trigger efficiency of signal  $B_s^0 \rightarrow \mu^+ \mu^-$ . The methods of calculating efficiencies at L1, L2 and EF levels are given in the relevant place in the text.

L1*L2 efficiency	EF w.r.t L2	Overall trigger eff.
0.52	0.88	0.46

### 4.3 Event reconstruction and analysis.

Muon reconstruction quality is of high importance for the  $B_s^0 \rightarrow \mu^+ \mu^-$  channel. The muon candidates produced by the STACO [14] method were used. This method combines the independently reconstructed inner detector and muon spectrometer tracks. Figure 2 shows the muon reconstruction efficiency as a function of a true muon  $p_T$ . The efficiency is defined as the number of muon candidates reconstructed and matched to the Monte Carlo particle tracks in the corresponding  $p_T$  bin divided by number of generated muons. The  $p_T$  spectrum of generated muons is superimposed on the efficiency plot.

Figure 2: Muon offline reconstruction efficiency as a function of  $p_T$ . The superimposed histogram -  $p_T$  spectrum of muons in the signal events (right scale).

For the physics analysis, we select events containing identified muon pairs with opposite charges. Aside of the kinematic cuts ( $p_T^{\mu_1(\mu_2)} > 6(4)$  GeV and  $|\eta_{\mu_1, \mu_2}| < 2.5$ ) no additional cuts have been applied. These two muons then constitute a  $B$  meson candidate. The VKalVrt vertexing package [15] is used to fit tracks into a vertex. We require the vertex quality to have  $\chi^2 < 10$ . The momentum resolution is important as a narrow mass search window reduces the background contribution. Figure 3 shows the dimuon mass distribution for the cases when both muons are in the barrel region ( $|\eta_{\mu_1, \mu_2}| < 1.1$ ) or in the end-cap ( $|\eta_{\mu_1, \mu_2}| > 1.1$ ). The Gaussian fit (using bins with contents  $> 10\%$  of maximum) gives  $\sigma = 70$  MeV for the barrel and  $\sigma = 124$  MeV for the end-cap. We used 90 MeV as an estimate of the invariant mass resolution for the signal events.

In this document we present a cut-based method for signal extraction and background rejection. For the future, we are investigating another method using a boosted decision tree [16].

In the cut based analysis a set of discriminating variables is chosen and using the signal and background simulated events the optimal set of cuts is determined. The signal events are identified by requiring that the dimuon invariant mass is consistent with the mass of  $B_s$  meson. To reduce background events where two muons originate from different sources (e.g. independent semileptonic decays of  $b$  and  $\bar{b}$  quarks), the following discriminating variables were chosen (values used in the final analysis are given in parentheses):

- Transverse decay length of the  $B_s$  candidate  $L_{xy}$  ( $L_{xy} > 0.5$  mm )

Figure 3: Reconstructed  $B_s$  mass in barrel - when both muons have  $|\eta| < 1.1$ (left) and in the end-cap - both muons have  $|\eta| > 1.1$  (right)

- The pointing angle  $\alpha$  between the dimuon pair summary momentum and the direction of the decay vertex as seen from the primary vertex ( $\alpha < 0.017$  rad )
- Isolation  $I_{\mu\mu} = p_T^{\mu\mu} / (p_T^{\mu\mu} + \sum_i p_T^i (\Delta R < 1))$  , where the sum is over all tracks with  $p_T > 1$  GeV (excluding the muon pairs) within a cone of  $\Delta R < 1$ , where  $\Delta R = \sqrt{(\Delta\eta)^2 + (\Delta\phi)^2}$  and  $\Delta\eta$  and  $\Delta\phi$  are the pseudorapidity and azimuthal angle of track  $i$  with respect to the momentum vector of the muon pair ( $I_{\mu\mu} > 0.9$ ).
- An asymmetric search window for  $M_{\mu\mu} \in [M_{B_s^0} - \sigma, M_{B_s^0} + 2\sigma]$ , is used to avoid a possible contribution from  $B_d^0 \rightarrow \mu^+ \mu^-$  decay.

Figures 4, 5 and 6 show distributions of discriminating variables for signal and background events. Due to the low Monte Carlo statistics, it is not feasible to perform a cut analysis as in a real experiment (i.e. applying all cuts simultaneously) since this will leave no events for the analysis. However, some of the discriminating variables show no (or small) correlations between each other. This allows the estimation of the rejection power of such variables separately. Then the product of all efficiencies can provide a reasonable estimate of the total rejection. Table 4 shows a correlation matrix for the variables used in this study. The correlation between the pointing angle  $\alpha$  and the transverse decay length  $L_{xy}$  is higher than among other variables so the pointing angle and the transverse decay length are examined simultaneously to take their correlation into account. The systematic uncertainty due to this correlation is estimated as +50%.

Figure 7 illustrates the rejection power of each cut. One cut is applied at a time to the combinatorial background events and to the  $B_s^0 \rightarrow K^- \mu \nu$  and  $B_s^0 \rightarrow K^- \pi^+$  events where one or two hadrons are misidentified as a muon. The combinatorial background is effectively suppressed by these cuts while the non-combinatorial events are less well rejected.

Table 5 summarizes the output of this cut-based analysis. For the  $b\bar{b} \rightarrow \mu\mu X$  background in the left column the efficiencies are given separately for each cut, whilst in the right column the combined

Figure 4: Transverse decay length of reconstructed  $B_s^0$  candidates. The signal is shown as closed circles, background as opened circles. Distributions are normalised to 1. The vertical line indicates the lowest transverse decay length allowed for selected events.

Figure 5: Distribution of isolation variable  $I_{\mu\mu}$  for the reconstructed  $B_s^0$  candidates. The signal is shown as closed circles, background as opened circles. Distributions are normalised to 1. The vertical line indicates the lowest values of variable  $I_{\mu\mu}$  allowed for selected events.

Figure 6: Distribution of pointing angle  $\alpha$  for the reconstructed  $B_s^0$  candidates. The signal is shown as closed circles, background as opened circles. Distributions is normalised to 1. The vertical line indicates the highest values of  $\alpha$  allowed for selected events.

	$M_{\mu\mu}$	$I_{\mu\mu}$	$\alpha$	$L_{xy}$
$M_{\mu\mu}$	1	-0.09	0.04	-0.03
$I_{\mu\mu}$		1	-0.07	-0.03
$\alpha$			1	-0.17
$L_{xy}$				1

Table 4: The linear correlation coefficients among the discriminating variables for background events. The statistical uncertainty is about  $\pm 0.05$  for each coefficient.

efficiency is given for the cuts on the pointing angle and on the transverse decay length. As one can see the total rejection is largely overestimated if all cuts are treated separately, so the combined value is used to estimate a total yield of background events. The contribution from  $B_s^0 \rightarrow K^- \mu \nu$  and  $B_s^0 \rightarrow K^- \pi^+$  is found to be negligible comparing to the combinatorial background contribution. The errors quoted for the efficiencies are statistical only, so they represent only the size of the available Monte Carlo sample, but not the expected accuracy of the experiment where the initial number of background events will be much higher. More details on uncertainties will be given in Section 5.

Figure 8 shows the dimuon mass distribution for signal and background events after all selection cuts have been applied. For the combinatorial background, the contribution for the left and right side of the signal region is estimated in the same way as for the signal region (Table 5).

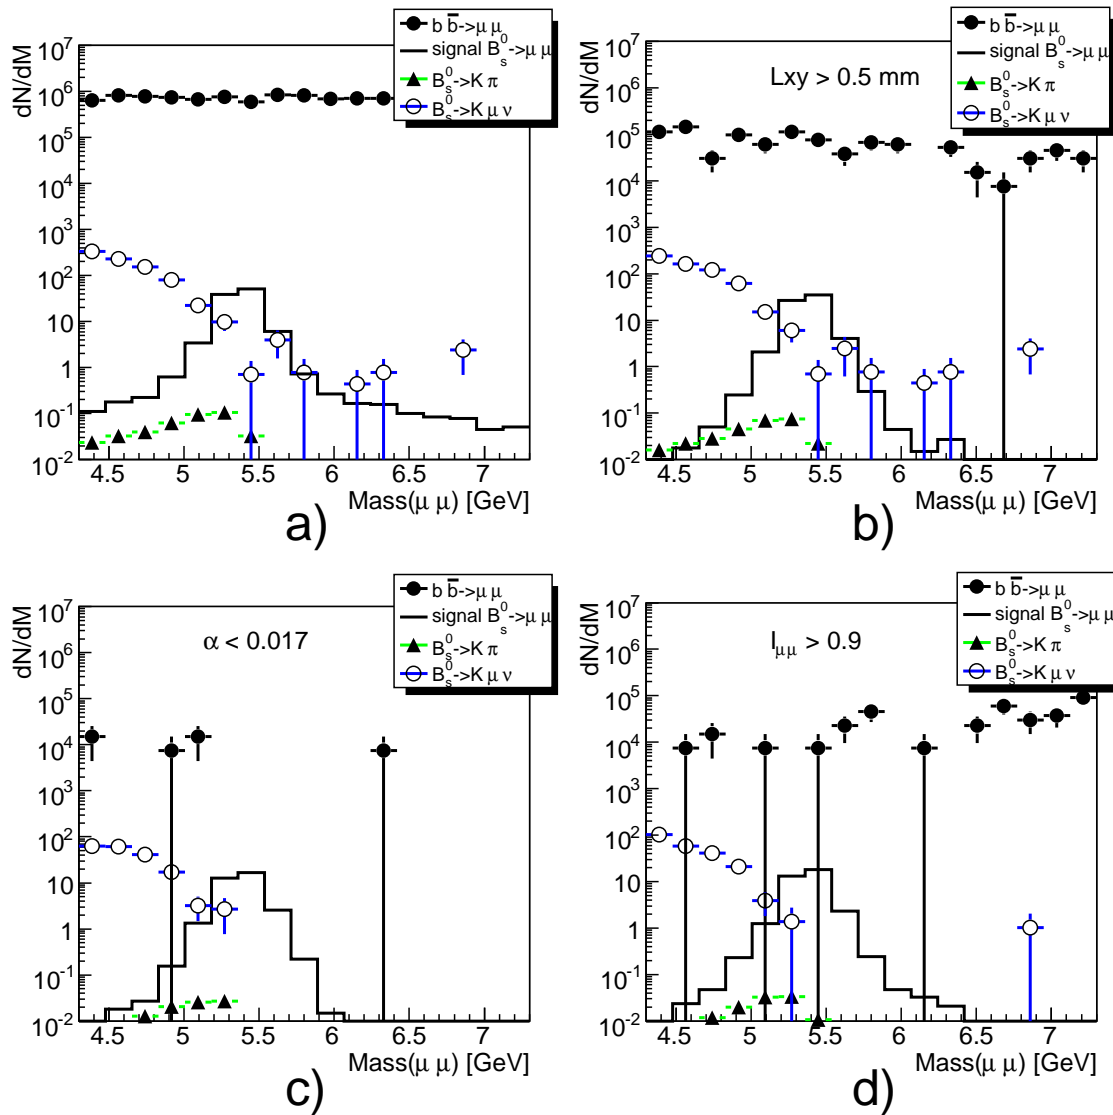

Figure 7: The Monte Carlo di-muon mass distributions for signal  $B_s^0 \rightarrow \mu^+ \mu^-$  (histogram), combinatorial background (closed circles) and non-combinatorial background (open circles and triangles) for (a) preselected events, (b) after cuts on transverse decay length, (c) pointing angle and (d) isolation. The number of events has been scaled to  $10 \text{ fb}^{-1}$  of integrated luminosity.

Figure 8: Dimuon mass distribution for surviving events after applying all three cuts. The signal is shown as histogram, combinatorial background by closed circles and non-combinatorial backgrounds by opened circles and triangles. The combinatorial background is estimated assuming a factorisation of applied cuts. Statistics are given for an integrated luminosity  $10 \text{ fb}^{-1}$ .

Table 5: Selection efficiencies and number of signal and background events for integrated luminosity of  $10 \text{ fb}^{-1}$ . Preselection criteria used:  $4 \text{ GeV} < M(\mu\mu) < 7.3 \text{ GeV}$ , vertex fit  $\chi^2 < 10$ , transverse decay length  $L_{xy} < 20 \text{ mm}$ . Numbers of expected events are computed according to the Standard Model expectation. In the left column for the  $b\bar{b} \rightarrow \mu\mu X$  background the efficiencies are given separately for each cut, in the right column the combined efficiency is given for the cuts on the pointing angle and on the transverse decay length.

Selection cut	$B_s^0 \rightarrow \mu^+ \mu^-$ efficiency	$b\bar{b} \rightarrow \mu^+ \mu^- X$ efficiency	
$I_{\mu\mu} > 0.9$	0.24	$(2.6 \pm 0.3) \cdot 10^{-2}$	
$L_{xy} > 0.5\text{mm}$	0.26	$(1.4 \pm 0.1) \cdot 10^{-2}$	$(1.0 \pm 0.7) \cdot 10^{-3}$
$\alpha < 0.017 \text{ rad}$	0.23	$(8.5 \pm 0.2) \cdot 10^{-3}$	
Mass in $[-\sigma, 2\sigma]$	0.76	0.079	
TOTAL	0.04	$0.24 \cdot 10^{-6}$	$(2.0 \pm 1.4) \cdot 10^{-6}$
Events yield	5.7		$14^{+13}_{-10}$

## 5 Systematic uncertainties

There are several sources of uncertainty in this analysis. Some of them are relevant only for the Monte Carlo study, whilst others should be taken into account with the real data analysis as well.

In this presented analysis, the expected number of signal and background events is estimated by counting directly instead of the normalisation procedure described in Section 3, which is supposed to be used in a real experiment. Consequently the dimuon trigger and reconstruction efficiencies, and acceptance, are not canceled by those from the reference channel and must explicitly be taken into account. Using the methods developed by ATLAS [12] this systematic uncertainty is estimated to be of about few percent.

There is a theoretical uncertainty of a factor of two in the  $b$ -production cross-section at LHC energies,

which clearly affects the Monte Carlo predictions. Consequently all numbers of events from Table 5 scale accordingly.

The difference between the real and simulated kinematic properties of detected particles (e.g., due to not fully accounting for misalignment or material effects) can also introduce a bias in our predictions. However Figure 2 shows that the most of muons from  $B_s^0 \rightarrow \mu^+ \mu^-$  have a  $p_T$  in the region of the efficiency plateau so the possible deformation of  $p_T$  (as well as  $\eta$ ) spectra could change the resulting efficiency by not more than a few percent. The uncertainty from the cuts factorisation hypothesis is assumed to be approximately 50%.

Some uncertainties will, to a large extent, cancel if we use a normalisation channel  $B^+ \rightarrow J/\psi K^+$  to estimate the  $\mathcal{B}(B_s^0 \rightarrow \mu^+ \mu^-)$  as the dimuon trigger conditions are similar for both channels. Without experimental data, it is difficult to estimate the uncertainty in the number of background events in a given mass range. In the D0 analysis [17], the sideband extrapolation method is estimated to give an uncertainty of 20-30%. Indeed, this is the main source of uncertainty in the D0 analysis of  $B_s^0 \rightarrow \mu^+ \mu^-$ . Corrections should also be made for the contribution of  $B_d^0 \rightarrow \mu\mu$  decay in the experimental sample.

In total, the uncertainty from the systematic errors discussed in this Section is approximately  $\pm 25\%$ . In addition, the procedure adopted to estimate backgrounds via cut factorisation has large uncertainties, which are estimated to be of the order of 50%, as discussed above. In addition, a 70% uncertainty arises from Monte Carlo statistics. Overall, we choose to combine these in quadrature to obtain an indicative overall uncertainty on the background of +90%/-75%.

## 6 Start-up strategy

Already at  $1 \text{ fb}^{-1}$  of integrated luminosity, ATLAS can have  $O(10^6)$  of dimuon events in a mass window  $4 \text{ GeV} < M(\mu\mu) < 7 \text{ GeV}$  (after vertexing and quality cuts). It will allow tuning of the selection procedure either for the cut-based analysis or for the multivariate methods for the background discrimination. Events that survive background suppression will be used to estimate the background contribution to the signal search region. The contribution from combinatorial background will be estimated using the sidebands interpolation procedure. The contribution from exclusive backgrounds due to fake dimuons from hadronic two-body  $B$  decays or from  $B_s^0 \rightarrow K^- \mu^+ \nu$ , will be determined on the basis of the study of the hadron/muon misidentification probability. The background estimation will be compared with the number of events observed in the signal region. Following this information an upper limit on the number of signal events  $N_B$  corresponding to certain confidence level will be determined, using appropriate statistical methods. Finally, the value of  $N_B$  will be used to extract the upper limit on the  $B_s^0 \rightarrow \mu^+ \mu^-$  branching fraction,  $\mathcal{B}(B_s^0 \rightarrow \mu^+ \mu^-)$ , using a reference channel  $B^+ \rightarrow J/\psi K^+$ . In this procedure a ratio of geometric and kinematical acceptances of the signal and the reference channels will be determined from the Monte Carlo simulation. Trigger and offline reconstruction efficiencies largely cancel for dimuons in these channels. The reference channel  $B^+ \rightarrow J/\psi K^+$  will also be used to check the Monte Carlo simulation. The efficiency of the final selection cuts on discriminating variables for the signal  $B_s^0 \rightarrow \mu^+ \mu^-$  will be determined using Monte Carlo simulation (validated with the reference channel).

## 7 Conclusions

We have presented the strategy for searching for the rare decay  $B_s^0 \rightarrow \mu^+ \mu^-$  with the ATLAS detector. Whilst we do not expect to observe this decay during the early stages of the LHC, as more luminosity becomes available and our understanding of the backgrounds improves, it should be possible to identify a signal for the process. There are uncertainties due to the relatively unknown beauty production cross-section at the LHC, and also the limited Monte Carlo statistics available for this study. Within these

limitations, assuming the Standard Model, we expect a signal of 5.7 events with a background of  $14_{-10}^{+13}$  events for an integrated luminosity of  $10 \text{ fb}^{-1}$ . It is evident that the background uncertainties are large in this study. However, background estimates based on real data will be able to make use of much higher statistics and these will provide reduced uncertainties, as well as allowing the evaluation of more sophisticated methods of analysis.

# Trigger and Analysis Strategies for $B_s^0$ Oscillation Measurements in Hadronic Decay Channels

## Abstract

The capabilities of measuring  $B_s^0$  oscillations in proton-proton interactions with the ATLAS detector at the Large Hadron Collider are evaluated.  $B_s^0$  candidates in the  $D_s^- \pi^+$  and  $D_s^- a_1^+$  decay modes from semileptonic exclusive events are simulated and reconstructed using a detailed detector description and the ATLAS software chain. For the measurement of the oscillation frequency a  $\Delta m_s$  sensitivity limit of  $29.6 \text{ ps}^{-1}$  and a five standard deviation measurement limit of  $20.5 \text{ ps}^{-1}$  are derived from unbinned maximum likelihood amplitude fits for an integrated luminosity of  $10 \text{ fb}^{-1}$ . The initial flavour of the  $B_s^0$  meson is tagged exclusively with opposite-side leptons. Trigger strategies are proposed for scenarios of different instantaneous luminosities in order to maximise the signal channel trigger efficiencies.

## 1 Introduction

As tests of the Standard Model the CP-violation parameter  $\sin(2\beta)$  will be measured with high precision (at the percent level) as well as properties of the  $B_s^0$ -meson system, like the mass difference of the two mass eigenstates  $\Delta m_s$ , the lifetime difference  $\Delta\Gamma_s/\Gamma_s$  and the weak mixing phase  $\phi_s$  induced by CP-violation, with  $\phi_s \approx 2\lambda^2 \eta$  in the Wolfenstein parametrisation. The different masses of the CP-eigenstates  $B_s^L$  (CP-even) and  $B_s^H$  (CP-odd) give rise to  $B_s$  mixing. The observed  $B_s^0$  and  $\bar{B}_s^0$  particles are linear combinations of these eigenstates, where transitions are allowed due to non-conservation of flavour in weak-current interactions and will occur with a frequency proportional to  $\Delta m_s$ .  $B_s^0$  oscillations have been observed at the Fermilab Tevatron collider by the CDF collaboration [1] measuring a value of  $\Delta m_s = (17.77 \pm 0.10(\text{stat}) \pm 0.07(\text{sys})) \text{ ps}^{-1}$  and D0 collaboration [2] reporting a two-sided bound on the  $B_s^0$  oscillation frequency with a range of  $17 \text{ ps}^{-1} < \Delta m_s < 21 \text{ ps}^{-1}$ . Both results are consistent with Standard Model expectations [3]. In ATLAS, the  $\Delta m_s$  measurement is an important baseline for the B-physics program and an essential ingredient for a precise determination of the phase  $\phi_s$ . CP-violation in  $B_s^0$ - $\bar{B}_s^0$  mixing is a prime candidate for the discovery of non-standard-model physics. For the channel  $B_s^0 \rightarrow J/\psi \phi$ , which has a clean experimental signature, a very small CP-violating asymmetry is predicted in the Standard Model. The measurement of any sizeable effect of the weak-interaction-induced phase  $\phi_s$  in the CKM matrix, which lies above the predicted value, would indicate that processes beyond the Standard Model are involved. Furthermore, the determination of important parameters in the  $B_s^0$  meson system will be valuable input for flavour dynamics in the Standard Model and its extensions.

In this note an estimation of the sensitivity to measure the  $B_s^0$ - $\bar{B}_s^0$  oscillation frequency with the ATLAS detector is presented. The signal channels considered are the hadronic decay channels  $B_s^0 \rightarrow D_s^- \pi^+$  and  $B_s^0 \rightarrow D_s^- a_1^+$  with  $D_s^- \rightarrow \phi \pi^-$  followed by  $\phi \rightarrow K^+ K^-$ . In the case of  $B_s^0 \rightarrow D_s^- a_1^+$  the  $a_1^+$  decays as  $a_1^+ \rightarrow \rho \pi^+$  with  $\rho \rightarrow \pi^+ \pi^-$ . Including the sub-decay  $D_s^- \rightarrow K^{*0} K^-$  [4] would increase the event statistics by about 30%. However, for these sub-channels, which require an additional trigger signature, the increase of the overall trigger rate would be unacceptable. Detailed information of the signal and the exclusive background channels is given in Section 2. The high event rate at the Large Hadron Collider (LHC) imposes very selective requirements onto the B-physics trigger strategies, reducing the rate by about six orders of magnitude for recording events. Since an initial “low-luminosity” running period is scheduled with a luminosity starting at  $10^{31} \text{ cm}^{-2}\text{s}^{-1}$  and rising to  $2 \cdot 10^{33} \text{ cm}^{-2}\text{s}^{-1}$ , followed later on by the design luminosity of the LHC of  $10^{34} \text{ cm}^{-2}\text{s}^{-1}$ , the B-trigger must be flexible enough to cope with the

increasing luminosity conditions. The overall B-trigger strategy as well as the different strategies dealing with the luminosity scenarios in the initial running periods are discussed in Section 3. An important part of the mixing measurement is to identify the flavour at production, i.e., whether the observed  $B_s$  meson initially contained a  $b$  or a  $\bar{b}$  quark. A detailed description of an opposite-side lepton flavour tag and of the various sources of the wrong tag fractions is given in Section 4. The selection of  $B_s^0$  candidates with kinematic cuts as well as mass resolutions of the  $B_s^0$ , are explained and shown in Section 5. A luminosity of  $10^{33} \text{ cm}^{-2}\text{s}^{-1}$  and no pileup is considered for the detailed analysis of signal and background channels. Strategies for lower and higher luminosities are also discussed in the same section. The results of the signal-candidate selection are used as input to a toy Monte Carlo simulation generating a sample of  $B_s^0$  candidates, which is used for the amplitude fit method [5] to obtain the  $\Delta m_s$  measurement limits. The construction of the likelihood function, the Monte Carlo sample and the extraction of the  $\Delta m_s$  sensitivity are discussed in Section 6.

## 2 Simulated Data Samples

Simulated  $b$ -quark pairs are generated using PYTHIA [6], with the  $\bar{b}$ -quark required to decay to one of the specified signal channels. The  $b$ -quark decays semileptonically producing a muon with  $p_T > 6 \text{ GeV}$  within  $|\eta| < 2.5$ . Details on generation, simulation and reconstruction of the simulated data samples are given in the introduction of the B-chapter [7].

In addition to the simulated signal samples  $B_s^0 \rightarrow D_s^-(\phi\pi^-)\pi^+$  and  $B_s^0 \rightarrow D_s^-(\phi\pi^-)a_1^+$ , corresponding exclusive background channels that give an irreducible contribution to the selected  $B_s^0$  signal were investigated. Two  $B_d^0$  decay channels,  $B_d^0 \rightarrow D^-\pi^+/a_1^+$  and  $B_d^0 \rightarrow D_s^+\pi^-/a_1^-$ , and one  $B_s^0$  channel,  $B_s^0 \rightarrow D_s^{*-}\pi^+/a_1^+$ , were simulated for both hadronic decay channels. The dedicated trigger studies described in Section 3 require additional samples, such as the inclusive background channels  $b\bar{b} \rightarrow \mu 6X$ ,  $b\bar{b} \rightarrow \mu 4X$  and  $c\bar{c} \rightarrow \mu 4X$  containing semileptonic  $b$  or  $c$  decays requiring one muon with a generated  $p_T > 4 \text{ GeV}$  (or  $6 \text{ GeV}$ ) and further decay products ( $X$ ). Also, one particular signal sample (as a choice  $B_s^0 \rightarrow D_s^-a_1^+$ ) requiring one muon with a generated  $p_T > 4 \text{ GeV}$  (identified by ( $\mu 4$ )) is used for the trigger studies. A sample of minimum bias events is used for the determination of overall trigger rates. See Table 1 for the number of events generated and the cross-sections calculated from the values given by PYTHIA and the appropriate branching ratios [8]. Errors on the cross-sections include statistical errors and contributions from the uncertainties on the branching ratios.

Effects of pileup and  $B$ -meson mixing were not included in the simulation of any of the samples.

## 3 Trigger Strategies

The trigger strategy used for the  $B_s^0 \rightarrow D_s^-\pi^+$  and  $B_s^0 \rightarrow D_s^-a_1^+$  channels is to identify the  $D_s^\pm$  decaying to  $\phi(\rightarrow K^+K^-)\pi$ , which is common to both decay channels. At level one (LVL1) a muon is required to enrich the content of the triggered data sample with B-events. The high level trigger (HLT) is split into level two (LVL2) and Event Filter (EF). A search for a  $D_s^\pm$  is performed following one of two strategies. The first method, the FullScan approach, performs reconstruction of tracks within the entire Inner Detector. It is an efficient method, but time consuming and its feasibility depends on the background event rate. The second method performs track reconstruction in a limited volume of the Inner Detector only, which is defined by a low- $p_T$  jet region of interest (RoI) identified at LVL1. This RoI-based method is faster but there is a loss in efficiency due to the requirement of a LVL1 jet RoI in the event and the geometrical restriction to the RoI.

The increase of the luminosity after LHC startup affects the trigger in two ways: the trigger rates for the jet and muon trigger will increase, seeding the HLT  $D_s^\pm$  algorithm more frequently, and combinatorial

Table 1: Number of events generated and calculated cross-sections for the different signal and exclusive background simulated data samples for the  $B_s^0 \rightarrow D_s^- \pi^+$  and  $B_s^0 \rightarrow D_s^- a_1^+$  analysis and particular samples used for dedicated trigger studies. Branching ratios for particle decays into final states are included.

\*)The branching fraction has not been measured yet, only an upper limit exists.

	Channel	Events	Cross-section [pb]

background from pileup affects the performance of the selection algorithm. Therefore, trigger menus corresponding to different LHC luminosities are discussed in Sections 3.4 to 3.6.

The trigger efficiencies are presented for the  $B_s^0 \rightarrow D_s^- a_1^+$  channel. Results for the  $B_s^0 \rightarrow D_s^- \pi^+$  channel are expected to be similar within a few percent (see Section 3.2).

### 3.1 LVL1 Trigger Selection

The ATLAS hardware allows three LVL1 low- $p_T$  muon trigger thresholds to be defined at once, which can only be adjusted between runs by reconfiguring the lookup tables implemented in the muon trigger firmware. In order to study more than three thresholds we investigated the two available, pre-defined menus (named A and B) with respect to the low- $p_T$  muon trigger thresholds<sup>1</sup>.

The three implemented low- $p_T$  thresholds for trigger menu A are: 0 GeV<sup>2</sup> (named MU00), 5 GeV (MU05) and 6 GeV (MU06). For trigger menu B, the three low- $p_T$  thresholds are 6 GeV (MU06), 8 GeV (MU08), and 10 GeV (MU10). Figure 1 shows the efficiencies of the low- $p_T$  LVL1 muon trigger signatures as a function of the true  $p_T$  of the muon with the highest  $p_T$  in the event.

The LVL1 trigger efficiency depends strongly on the threshold chosen for the transverse momentum of the muon as shown in Table 2. Note that there is a discrepancy between the MU06 efficiencies from both trigger menus, which will be taken as a systematic uncertainty of the current implementation. Although these dedicated trigger studies have been performed with the  $B_s^0 \rightarrow D_s^- a_1^+$  sample, the LVL1 efficiencies for  $B_s^0 \rightarrow D_s^- \pi^+ (\mu 6)$  have been checked and agree well with those in Table 2.

The input to the LVL1 calorimeter trigger is a set of  $\sim 7\,200$  trigger towers with granularity  $\Delta\phi \times \Delta\eta \approx 0.1 \times 0.1$  formed by the analogue summation of calorimeter cells. There are separate sets of trigger towers for the EM and hadronic calorimeters. The LVL1 jet algorithm employed here uses a

<sup>1</sup>All presented trigger thresholds are meant to be inclusive, i.e. to include all events fulfilling a trigger signature with a  $p_T$  threshold equal to or higher than the indicated one.

<sup>2</sup>This requires a coincidence between the muon chambers without an actual threshold applied. Due to the detector geometry this corresponds to an effective transverse momentum threshold of about 4 GeV.

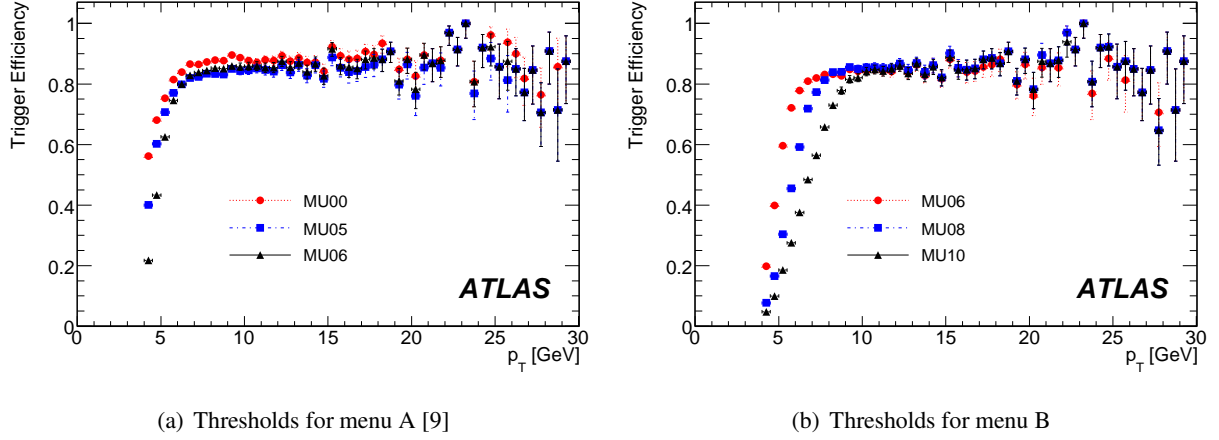

Figure 1: Muon trigger efficiency as a function of the true  $p_T$  of the muon with the highest  $p_T$  in the event for the  $B_s^0 \rightarrow D_s^- a_1^+ (\mu 4)$  for (a) trigger menu A and (b) trigger menu B.

Table 2: LVL1 muon trigger efficiencies for the signal datasets  $B_s^0 \rightarrow D_s^- a_1^+ (\mu 4)$  and  $B_s^0 \rightarrow D_s^- a_1^+ (\mu 6)$  and the exclusive background samples. The first three lines refer to trigger menu A [9], while the last three lines refer to trigger menu B. For  $b\bar{b} \rightarrow \mu 4X$ ,  $b\bar{b} \rightarrow \mu 6X$  and  $c\bar{c} \rightarrow \mu 4X$ , the Monte Carlo data samples are only available using trigger menu A.

Menu	Threshold	Efficiency [%]				
		$B_s^0 \rightarrow D_s^- a_1^+ (\mu 4)$	$B_s^0 \rightarrow D_s^- a_1^+ (\mu 6)$	$b\bar{b} \rightarrow \mu 4X$	$b\bar{b} \rightarrow \mu 6X$	$c\bar{c} \rightarrow \mu 4X$
A	MU00	$75.65 \pm 0.19$	$86.77 \pm 0.15$	$71.74 \pm 0.14$	$86.60 \pm 0.07$	$70.42 \pm 0.22$

cluster of  $\Delta\phi \times \Delta\eta$  of approximately  $0.4 \times 0.4$  (corresponding to  $4 \times 4$  trigger towers). The projections of the vectors of the energy depositions onto the plane perpendicular to the beam axis (transverse energy,  $E_T$ ) are summed over both the electromagnetic and the hadronic layers. The jet algorithm moves the cluster template in steps of 0.2 across the  $\phi \times \eta$  plane. An RoI is produced if the  $4 \times 4$  cluster is a local  $E_T$  maximum (as defined in [10]) and the cluster  $E_T$  sum is greater than the required threshold. The jet RoI is usable if the average number of RoIs per event (RoI multiplicity, see Fig. 2 and Table 3) is small, ideally about 1-2. Clearly, a compromise is required as an increased threshold will reduce the multiplicity, but will also give a reduced efficiency for finding the  $B$  jet in an event.

For a transverse energy threshold of 4 GeV, which is implemented to initiate the LVL2  $D_s^\pm$  trigger in trigger menus A and B, the jet trigger has an acceptance of  $(98.36 \pm 0.06) \%$  based on all events in the  $B_s^0 \rightarrow D_s^- a_1^+$  sample.

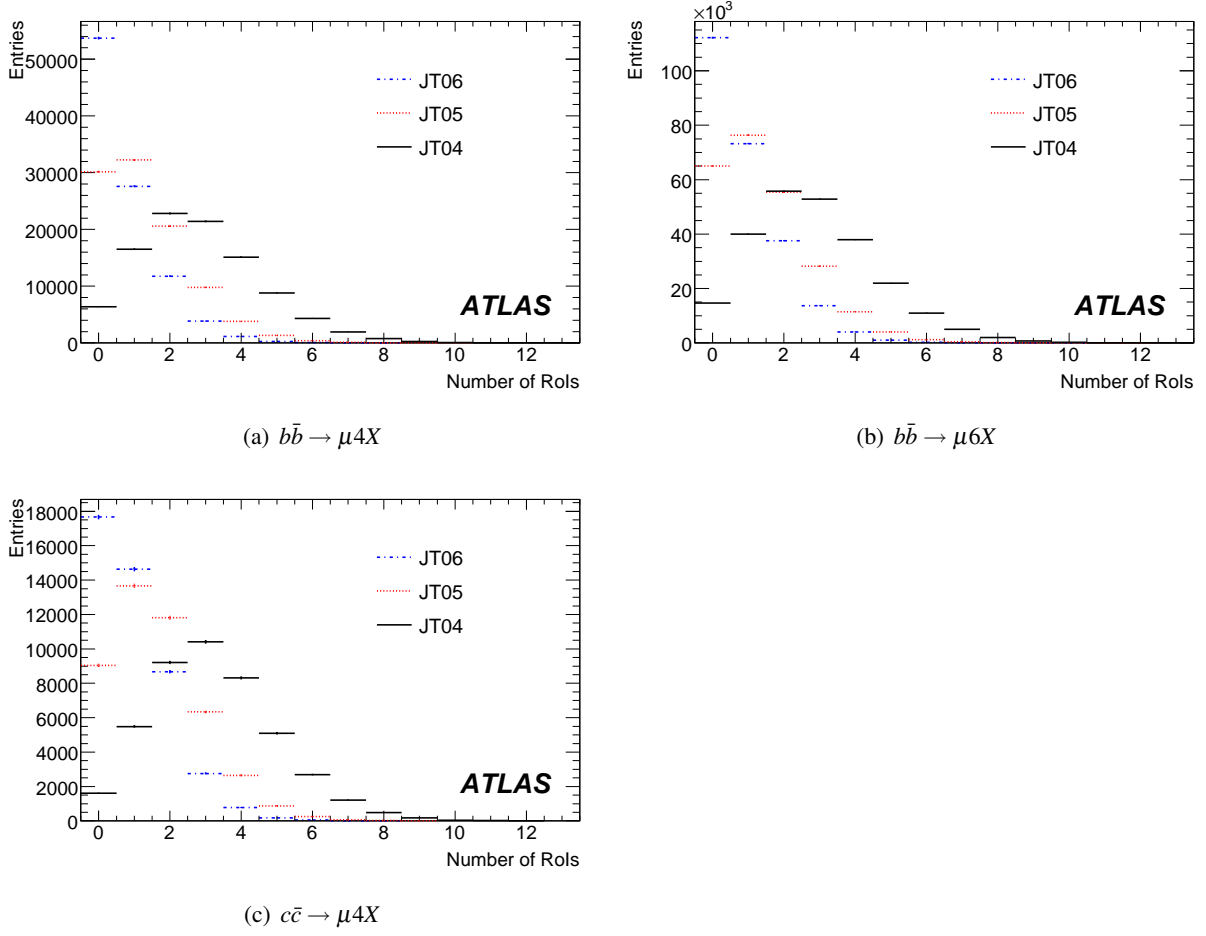

Figure 2: RoI multiplicity distributions for the background samples (a) for  $b\bar{b} \rightarrow \mu 4X$ , (b) for  $b\bar{b} \rightarrow \mu 6X$  and (c) for  $c\bar{c} \rightarrow \mu 4X$  as a function of the jet RoI energy threshold [9]. Only RoIs with  $\eta < 2.4$  have been taken into account. This corresponds to the requirement that the RoI is to be contained within the solid angle covered by the Inner Detector.

Table 3: Mean and root mean square of the RoI multiplicity distributions (Figure 2) for the background samples as a function of the jet RoI transverse energy ( $E_T$ ) threshold [9]. Only RoIs with  $\eta < 2.4$  have been taken into account. A strong anticorrelation between the  $E_T$  threshold and the mean RoI multiplicity is observed.

Threshold [ GeV]	$b\bar{b} \rightarrow \mu 4X$		$b\bar{b} \rightarrow \mu 6X$		$c\bar{c} \rightarrow \mu 4X$

7	0.454	0.786	0.634	0.911	0.703	0.900

### 3.2 LVL2 Trigger Selection

The first step of LVL2 is to confirm the LVL1 muon trigger decision using more precise muon momentum measurement. Secondly, information from Inner Detector and muon chambers are combined to give a further improvement in the momentum measurement.

As described above, the LVL2 tracking can be run in either FullScan or RoI-guided modes. In both cases, the same algorithm (named DsPhiPi) is used to combine the reconstructed tracks and search first for a  $\phi$  and then for a  $D_s^\pm$ . In the RoI-guided approach tracks are reconstructed in a region  $\Delta\phi \times \Delta\eta = 1.5 \times 1.5$  around all jet RoIs with  $E_T$  above a certain programmable threshold [11]. A  $p_T$  cut of 1.4 GeV is applied to all reconstructed tracks.

Opposite sign track pairs are considered as a  $\phi$  candidate if they pass the following cuts:  $|\Delta z| < 3$  mm, where  $z$  is the distance along the beam line of the track's point of closest approach to the centre of the detector,  $|\Delta\phi| < 0.2$  and  $|\Delta\eta| < 0.2$ .

The tracks are combined using a  $K$  mass hypothesis and a cut around the  $\phi$  mass  $m_\phi(\text{PDG}) = 1019.46$  MeV [8] is applied. Track pairs passing the cut are then combined with all other tracks assuming a  $\pi$  mass for the third track. An event is selected if the mass of the track triplet is close to the  $D_s^\pm$  mass  $m_{D_s}(\text{PDG}) = 1968.2$  MeV. The mass cuts used are  $1005 \text{ MeV} < m_{KK} < 1035 \text{ MeV}$  for the  $\phi$  candidates and  $1908 \text{ MeV} < m_{KK\pi} < 2028 \text{ MeV}$  for the  $D_s$  candidates.

The LVL2 track fit masses are shown in Figure 3 and Table 4 for the RoI-guided approach and FullScan. The standard deviations obtained from the Gaussian fits show that the mass cuts used correspond to 3.0 standard deviations for the  $\phi$  mass distribution and 2.8 standard deviations for the  $D_s^\pm$  mass distribution [9]. The results for the RoI-based approach and those for FullScan agree well.

Figure 3: LVL2 track fit mass distributions of (a)  $\phi$  and (b)  $D_s^\pm$  candidates (corresponding to a  $\phi$  or  $D_s^\pm$  particle from the signal decay in the Monte Carlo truth information) for the FullScan- and RoI-based LVL2 trigger signatures from  $B_s^0 \rightarrow D_s^- a_1^+$  events fulfilling the respective LVL2  $D_s^\pm$  trigger signature and MU06 [9].

The acceptances of possible trigger strategies up to LVL2 are given in Table 5 for the signal samples and in Table 6 for the background datasets. The LVL2 trigger rates for the  $B_s^0 \rightarrow D_s^- \pi^+$  channel are expected to be lower by a few percent since the average  $p_T$  of the  $B_s^0$  candidates and consequently the average  $p_T$  of the  $D_s$  candidates is smaller for the  $B_s^0 \rightarrow D_s^- \pi^+$  channel than for the  $B_s^0 \rightarrow D_s^- a_1^+$  channel due to different track selections (see Fig. 5 and Section 5.1).

Table 4: LVL2 track fit masses for the FullScan- and RoI-based LVL2 trigger signatures (only candidates corresponding to a  $\phi$  or  $D_s^\pm$  particle from the signal decay in the Monte Carlo truth information) from  $B_s^0 \rightarrow D_s^- a_1^+$  events fulfilling the respective LVL2  $D_s^\pm$  trigger and MU06. The table shows the results of Gaussian fits within the trigger mass windows to the mass distributions from Fig. 3. The results for both trigger strategies agree within statistical errors.

	FullScan-based LVL2 trigger [9]	RoI-based LVL2 trigger

### 3.3 Event Filter Selection

The muon confirmation at the Event Filter (EF) employs a muon track reconstruction algorithm using muon detector data only, similar to the algorithm used for offline reconstruction.

The EF  $D_s^\pm$  selection is very similar to that at LVL2. The track reconstruction can be performed in FullScan or RoI-guided modes, which share a common EF signature. The search for  $\phi$  and  $D_s^\pm$  particles currently uses the same mass cuts as at LVL2, even though better mass resolutions are expected for the EF than for LVL2. In the future the mass cuts might be tightened and additional selection cuts will be added as discussed in section 3.5. EF output rates, which are only available for the minimum bias sample, are discussed in the following subsections.

### 3.4 Trigger Strategies for Early Running

At the lowest luminosities ( $10^{31} \text{ cm}^{-2}\text{s}^{-1}$  and  $10^{32} \text{ cm}^{-2}\text{s}^{-1}$ ), the trigger selection needs to be as efficient as possible, which means running a loose trigger. To estimate rates and perform timing studies a trigger menu with a different set of muon thresholds [12] is applied to the minimum bias sample. Table 7 shows the expected trigger rates for muons at LVL1 and after confirmation at LVL2. The output rates of the DsPhiPi trigger at LVL2 and the EF are given in Table 8 for  $10^{31} \text{ cm}^{-2}\text{s}^{-1}$ . For a luminosity of  $10^{33} \text{ cm}^{-2}\text{s}^{-1}$  and higher, the rates are expected to increase because of event pile-up and cavern background events.

Table 7: Muon rates based on  $2.6 \cdot 10^6$  minimum bias events. Rates set in *italics* are based on an interpolation using an exponential approximation of the rate dependence on the muon threshold concerned. Effects caused by event pile-up and cavern-background events are not included.

Luminosity [ $\text{cm}^{-2}\text{s}^{-1}$ ]	LVL1				
	L1_MU00		L1_MU06		L1_MU10
$10^{31}$	$1.3 \pm 0.02 \text{ kHz}$		$480 \pm 10 \text{ Hz}$		$266 \pm 8 \text{ Hz}$
$10^{32}$	$13.0 \pm 0.2 \text{ kHz}$		$4.8 \pm 0.1 \text{ kHz}$		$2.7 \pm 0.1 \text{ kHz}$
$1 \cdot 10^{33}$	$130 \pm 2 \text{ kHz}$		$48 \pm 1 \text{ kHz}$		$27 \pm 1 \text{ kHz}$
$2 \cdot 10^{33}$	$260 \pm 4 \text{ kHz}$		$96 \pm 2 \text{ kHz}$		$54 \pm 2 \text{ kHz}$
	LVL2				
	L2_mu0	L2_mu5	L2_mu6	L2_mu8	L2_mu10
$10^{31}$	$450 \pm 11 \text{ Hz}$	$213 \text{ Hz}$	$120 \pm 6 \text{ Hz}$	$50 \text{ Hz}$	$25 \pm 3 \text{ Hz}$
$10^{32}$	$4.5 \pm 0.1 \text{ kHz}$	$2.1 \text{ kHz}$	$1.20 \pm 0.06 \text{ kHz}$	$500 \text{ Hz}$	$250 \pm 30 \text{ Hz}$
$1 \cdot 10^{33}$	$45.0 \pm 1.1 \text{ kHz}$	$21 \text{ kHz}$	$12.0 \pm 0.6 \text{ kHz}$	$5 \text{ kHz}$	$2.5 \pm 0.3 \text{ kHz}$
$2 \cdot 10^{33}$	$90.0 \pm 2.2 \text{ kHz}$	$42 \text{ kHz}$	$24.0 \pm 1.2 \text{ kHz}$	$10 \text{ kHz}$	$5.0 \pm 0.6 \text{ kHz}$

In addition to the overall allowed output rate, the time constraints of the HLT system are limiting the DsPhiPi trigger. The maximum allowed average computing times are 40 ms at LVL2 and 1 s at the EF. Most of the time is taken in the tracking algorithms as can be seen in Table 9 which shows the average CPU time used by the tracking and hypothesis algorithms at LVL2 and EF.

Table 10 summarises the LVL2 efficiencies and the expected numbers for  $B_s^0 \rightarrow D_s^- a_1^+(\mu 4)$  events before and after the application of event selection cuts in the analysis as well as the estimated LVL2 and EF trigger rates for different luminosity scenarios and different trigger choices. The L2 and EF output rates shown in this table are deduced from the rate information given in Tables 7 and 8. The LVL2 muon trigger efficiency estimates presented in Table 10 are based on the LVL2 results obtained with the  $B_s^0 \rightarrow D_s^- a_1^+(\mu 4)$  sample shown in Table 5.

Table 8: Output rates for the DsPhiPi trigger based on  $2.6 \cdot 10^6$  minimum bias events at  $10^{31} \text{ cm}^{-2}\text{s}^{-1}$ . Rates set in *italics* are based on an interpolation using the results from Table 7.

Muon input trigger	LVL2		EF	
	RoI	FullScan	RoI	FullScan
L1_MU00	$23 \pm 3 \text{ Hz}$	$31 \pm 3 \text{ Hz}$	$14 \pm 2 \text{ Hz}$	$19 \pm 2 \text{ Hz}$

	hypothesis	DsPhiPi		< 1 ms

At  $10^{31} \text{ cm}^{-2}\text{s}^{-1}$ , once the improvements discussed in Section 3.5 have been applied to the EF algorithms, it should be possible to run the FullScan-based trigger at the LVL1 4 GeV muon rate and to remain within the constraints given by available trigger resources. As the luminosity is increased to  $10^{32} \text{ cm}^{-2}\text{s}^{-1}$ , we will need to raise the muon threshold for the FullScan-based trigger or to move to a RoI-based trigger. However, the muon threshold should be kept as low as possible in order to achieve the highest possible trigger efficiency and to allow for as many  $B_s^0 \rightarrow D_s^- a_1^+$  events as possible to pass. Compared to earlier publications like [13] the  $b\bar{b}$  cross-section as shown in [7] is at the upper limit of what is expected and therefore the muon rates are likely to be overestimated.

### 3.5 Trigger Strategies for Running at $10^{33} \text{ cm}^{-2}\text{s}^{-1}$

At  $10^{33} \text{ cm}^{-2}\text{s}^{-1}$  the trigger needs to remain as efficient as possible while operating within the constraints of the trigger system's resources. The EF output rate is expected to be about 10-20 Hz for *B*-physics.

The muon rates expected at LVL1 and LVL2 for different thresholds and luminosities are included in Table 7. The LVL2 muon rates are the input rates for the LVL2 tracking algorithms. Using the information on jet RoI multiplicities from Figure 2 and Table 3, the computing times from Table 9 and the muon rates in Table 7, trigger strategies are determined for different luminosities.

For a luminosity of  $10^{33} \text{ cm}^{-2}\text{s}^{-1}$ , a LVL1 trigger muon in combination with the RoI-based  $D_s$  trigger will be used. It is planned to use thresholds of 6 GeV for the trigger muon and 5 GeV for the jet RoI trigger. It is clear from Table 8 that in order to run such a trigger the LVL2 and EF selections will have to be tightened. This may be achieved by introducing vertex fitting and by reconstructing the  $B_s^0$  at the

Table 10: LVL2 and EF output rates for minimum bias events, LVL2 trigger efficiencies and numbers of expected  $B_s^0 \rightarrow D_s^- a_1^+(\mu 4)$  events without or with selection cuts. Rates set in *italics* are estimates based on the interpolated and extrapolated rates given in Table 7. LVL2 output rates marked by  $^\dagger$  are downscaled by a factor two, the estimated rate reduction for a  $D_s$  vertex requirement at LVL2. For EF output rates marked by  $^\ddagger$ , an estimated rate reduction factor of 60 accounting for EF  $B_s^0$  reconstruction is applied. (See section 3.5 for details.) The results in the columns “LVL2 eff.” and  $N_{LVL2\ output}^{B_s^0 \rightarrow D_s^- a_1^+}$  (without and with selection cuts applied) are based on the  $B_s^0 \rightarrow D_s^- a_1^+(\mu 4)$  Monte Carlo data sample. Numbers marked by  $^\#$  are corrected for the estimated efficiency loss by a  $D_s$  vertex requirement at LVL2. The integrated luminosities and expected event numbers correspond to one year running at the given instantaneous luminosity ( $10^7$  seconds).

EF level.

Preliminary studies at LVL2 show that a requirement for a vertex fit to the 3 tracks of the  $D_s$  candidate can achieve a factor 2 rate reduction for a drop in efficiency from 38% to 32%. This estimate is applied to cells marked by  $^\#$  and  $^\dagger$  in Table 10. Also, it might be an option to further reduce the rate by tightening the acceptance windows for  $m_\phi$  and  $m_{D_s}$  on LVL2, but the resulting rate reduction and the expected signal efficiency loss will need to be studied.

A considerable rate reduction at the EF level may be achieved by reconstructing the  $B_s^0$ . A preliminary study using offline selection cuts (see Section 5.1), which have been relaxed to simulate wider mass window and vertexing requirements for the reconstructed particles, has been performed with the  $b\bar{b} \rightarrow \mu 4X$  and  $c\bar{c} \rightarrow \mu 4X$  samples. The resulting rate reduction factor, estimated to be approximately 60, is applied to cells marked by  $^\ddagger$  in Table 10. According to this study, the overall trigger and reconstruction efficiency for the  $B_s^0 \rightarrow D_s^- a_1^+$  signal events will be reduced by about 55%. Although these estimates will need to be confirmed by an implementation of a simplified  $B_s^0$  reconstruction at the EF level, reasonable EF output rates are expected to be achievable.

The numbers of expected  $B_s^0 \rightarrow D_s^- a_1^+(\mu 4)$  events for 10 fb<sup>-1</sup> of data for a luminosity of 10<sup>33</sup> cm<sup>-2</sup>s<sup>-1</sup> are given in Table 10. It will be necessary to establish a muon trigger threshold as low as possible to maximise the signal event yield.

### 3.6 Trigger Strategies for Higher Luminosities

As luminosity increases, it is necessary to stay within the limits of the LVL2 trigger processing times and allowable output rates. As Table 10 shows, this will require increasing the muon threshold to 8 GeV or

10 GeV and to add additional trigger elements in the EF as discussed at the end of Section 3.5. Another option, however a less efficient one, is to prescale the 6 GeV rate before running the track reconstruction.

## 4 Flavour Tagging

The measurement of  $B_s^0$  oscillations needs the knowledge of the flavour of the  $B_s^0$  meson at production time and at decay time in order to classify events as mixed or not mixed. The tagging algorithm tries to determine the flavour at production time, whereas the decay particles of the signal  $B_s^0$  determine the flavour at decay time. In this analysis soft muon tagging (see B-physics chapter of [4]) is used and the general application on the simulated data samples is shown in Section 4.2 without applying trigger conditions or any selection cut. Tagging results specific for the hadronic channels under investigation including trigger and selection cuts for  $B_s^0$  candidates are given in Section 5.3.

### 4.1 Soft Muon Tagging

In proton-proton collisions  $b$  quarks are produced in pairs leaving the signal  $B_s^0$  and the opposite side  $b$  hadron with the opposite flavour. In the case of a semileptonic decay as shown in Fig. 4, the charge of the produced lepton is correlated with the flavour of the signal  $B_s^0$  meson at production time. The charge of the muon with the highest reconstructed  $p_T$  is used for the determination of the flavour. Because of the muon trigger, in hadronic  $B_s^0$  decay channels soft muon tagging has a high tagging efficiency  $\epsilon_{tag} = N_{tag}/N_{all}$  limited by the muon reconstruction efficiency. Details on the aspects of muon reconstruction and identification in ATLAS can be found in [14].

Figure 4: In the case of a signal  $B_s^0$ , the associated opposite side  $b$  hadron decaying semileptonically produces a negatively charged lepton.

The dilution factor is defined as  $D_{tag} = \frac{N_c - N_w}{N_c + N_w}$  where  $N_c$  is the number of events correctly tagged and  $N_w$  is the number of events with a wrong tag. These wrong tags arise from mixing of the tagging  $b$  hadron, muons from decays  $b \rightarrow c \rightarrow \mu$ , additional  $c$  pairs and various particles decaying into muons. The wrong tag fraction  $\omega = N_w/(N_c + N_w)$  is the ratio of wrongly tagged events to all tagged events. As the generation of the simulated data does not include  $B$  meson oscillations, mixing of the tagging side hadron is introduced artificially using the integrated mixing probabilities  $\chi_d$  and  $\chi_s$  [8]:

$$\chi_d = \frac{\Gamma(B_d^0 \rightarrow \bar{B}_d^0 \rightarrow \mu^+ X)}{\Gamma(B_d^0 \rightarrow \mu^\pm X)} = 0.188 \pm 0.003 \quad \chi_s = \frac{\Gamma(B_s^0 \rightarrow \bar{B}_s^0 \rightarrow \mu^+ X)}{\Gamma(B_s^0 \rightarrow \mu^\pm X)} = 0.49924 \pm 0.00003$$

### 4.2 Application to Signal Samples

In Fig. 5 the transverse momentum of the signal  $B_s^0$  mesons is compared for the two  $B_s^0$  decay channels, the vertical lines show the mean values of the two distributions. This difference arises from the different kinematical configuration due to the condition on all charged final state particles  $p_T > 0.5$  GeV at Monte

Carlo generation. As  $B_s^0 \rightarrow D_s^- a_1^+$  has a total number of six final state particles, the mean transverse momentum of the signal  $B_s^0$  is higher compared to  $B_s^0 \rightarrow D_s^- \pi^+$  with a total number of four final state particles. The difference in the  $B_s^0$  transverse momentum spectrum is also expected at offline reconstruction level due to the different  $p_T$  selection cuts for the  $\pi$  and the  $a_1$  combinations (see Section 5.1). This leads in the case of the  $B_s^0 \rightarrow D_s^- \pi^+$  sample to an overall wrong tag fraction of  $\omega = 20.29 \pm 0.14 \%$  and in the case of the  $B_s^0 \rightarrow D_s^- a_1^+$  channel to a wrong tag fraction  $\omega = 21.05 \pm 0.11 \%$ , which is higher compared to the  $B_s^0 \rightarrow D_s^- \pi^+$  channel (see all events in Table 11 in Section 5.3).

Figure 5: Normalised distributions of signal  $B_s^0$  transverse momentum  $p_T$  of the two channels  $B_s^0 \rightarrow D_s^- \pi^+$  and  $B_s^0 \rightarrow D_s^- a_1^+$ . The vertical lines represent the mean values of the distributions, in the case of  $B_s^0 \rightarrow D_s^- \pi^+$  the mean is  $14.80 \pm 0.03$  GeV, in the case of  $B_s^0 \rightarrow D_s^- a_1^+$   $17.68 \pm 0.03$  GeV. The observed difference is due to the different particle selections.

In Fig. 6 the wrong tag fractions and the sources of these wrong tags are compared for both  $B_s^0$  decays channels. The wrong tag fraction is shown as a function of the tagging muon's transverse momentum  $p_T(\mu)$ , in Fig. 6(a) for  $B_s^0 \rightarrow D_s^- \pi^+$  and in Fig. 6(b) for  $B_s^0 \rightarrow D_s^- a_1^+$ . In the regime  $p_T(\mu) < 11$  GeV the  $B_s^0 \rightarrow D_s^- a_1^+$  wrong tag fraction is higher. As mentioned above this difference arises from the different track selections of the two decay channels. In both channels the two main sources of wrong tags are mixing of neutral  $B$  mesons on the tagging side and muons from cascade decays  $b \rightarrow c \rightarrow \mu$ . As the overall wrong tag fraction is decreasing with the muon  $p_T$ , also the part with a wrong tag due to the cascade  $b \rightarrow c \rightarrow \mu$  is decreasing at the same rate. A further source of mistags are additional  $c\bar{c}$ -pairs. The wrong tag fraction of this part stays about constant with increasing  $p_T(\mu)$ . A small part of the wrong tag fraction originates from  $J/\psi$ ,  $\phi$ ,  $\rho$ ,  $\eta$  or  $\tau$  particles decaying into muons. Additional sources like muons from kaons and pions or hadrons misidentified as muons can be neglected [12].

A  $b\bar{b}$  pair produced in proton proton collisions has a transverse momentum equal to zero at first order. Going through fragmentation and hadronisation, the  $p_T$  of the signal  $B_s^0$  meson and the opposite side  $b$  hadron are still correlated, and therefore a muon coming from a semileptonic decay of the  $b$  hadron also is correlated with the signal  $B_s^0$ . Hence a muon from a cascade  $b \rightarrow c \rightarrow \mu$  is more likely to pass the LVL1 muon trigger when  $B_s^0$  meson has a higher  $p_T$ , leading to the increase in wrong tag fraction with  $p_T(B_s^0)$ . This behaviour is shown in the Fig. 6(c) and 6(d).

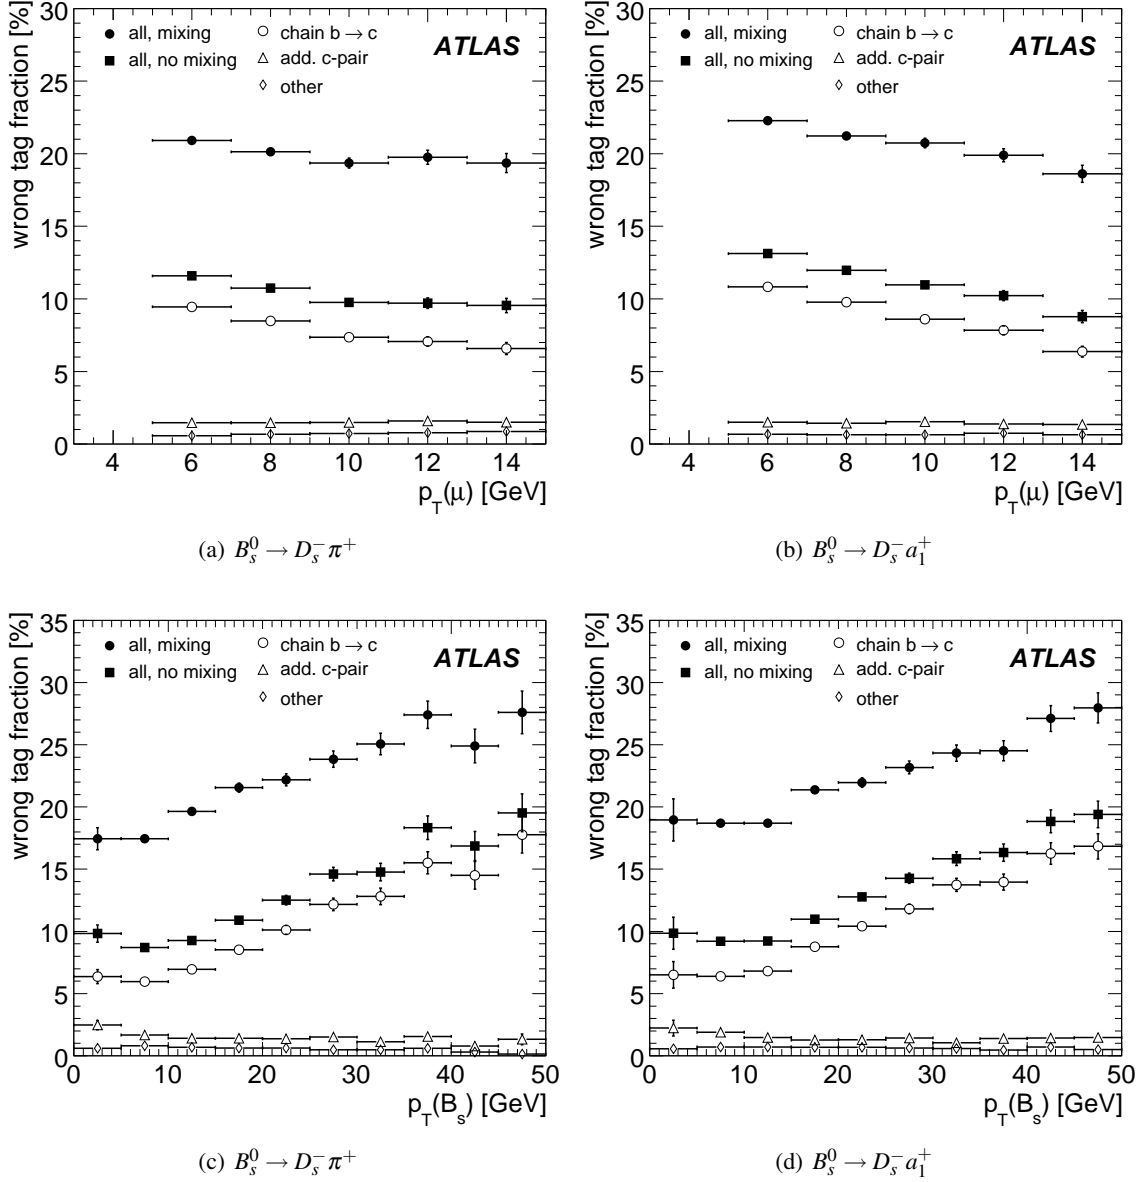

Figure 6: Wrong tag fraction as functions of tagging muons transverse momentum  $p_T(\mu)$  in (a) and (b) and wrong tag fractions as functions of signal Monte Carlo  $B_s^0$  transverse momentum  $p_T(B_s^0)$  in (c) and (d). The wrong tag fraction is shown with mixing of the tagging side  $b$  hadron and without mixing. Without mixing, the different sources of wrong tags are shown. The main contribution is coming from  $b \rightarrow c \rightarrow \mu$  followed by additional  $c$  pairs. Additional sources shown are muons coming from  $J/\psi$ ,  $\phi$ ,  $\rho$ ,  $\eta$  and  $\tau$ .

### 4.3 Systematic Uncertainties of Soft Muon Tagging

The calibration of the soft muon tagger will be done with events from the exclusive decay channel  $B^+ \rightarrow J/\psi(\mu^+\mu^-)K^+$ . The high branching ratio and the simple event topology allows the measurement of this channel during the initial luminosity phase at the LHC. Without mixing on the signal side, these events can be used to estimate the systematic uncertainties of soft muon tagging.

For an integrated luminosity of  $1 \text{ fb}^{-1}$  160 000 events of the decay channel  $B^+ \rightarrow J/\psi(\mu^+\mu^-)K^+$  are expected [15] at ATLAS. About 13.5 % events are estimated to have an additional third muon for flavour tagging. Requiring a minimum transverse momentum of 6 GeV for this additional muon, the number of events will be reduced by a factor of three. Assuming that the wrong tag fraction in this channel behaves like in the hadronic  $B_s^0$  decay channels, the expected statistical error of the wrong tag fraction would be of the order of 0.1 % for  $1 \text{ fb}^{-1}$  integrated luminosity.

## 5 Event Selection

For the following analysis selecting  $B_s$  candidates the default trigger choices are to require MU06 and JT04 trigger elements at LVL1 and to perform a search for the  $D_s \rightarrow \phi(K^+K^-)\pi$  decay within a jet RoI at LVL2. Resulting event numbers and plots are given for  $10 \text{ fb}^{-1}$  unless indicated otherwise.

### 5.1 Signal Event Reconstruction

For the reconstruction of the  $B_s$  vertex only tracks with a pseudo-rapidity  $|\eta| < 2.5$  are used proceeding via the following steps. The  $\phi$  decay vertex is first reconstructed by considering all pairs of oppositely-charged tracks with  $p_T > 1.5 \text{ GeV}$  for both tracks. Kinematic cuts on the angles between the two tracks,  $\Delta\phi_{KK} < 10^\circ$  and  $\Delta\theta_{KK} < 10^\circ$ , are imposed, where  $\phi$  denotes the azimuthal angle and  $\theta$  the polar angle. The two-track vertex is then fitted assigning the kaon mass to both tracks. Combinations passing a fit-probability cut [16] of 1% ( $\simeq \chi^2/\text{dof} = 7/1$ ) with the invariant mass within three standard deviations of the nominal  $\phi$  mass are selected as  $\phi$  candidates. The plots in Fig. 7 show the invariant mass distribution for all  $m_{KK}$  combinations overlaid with the  $\phi$  candidates matching a generated  $\phi$  from the signal decay (grey filled area) fitted with a single Gaussian function. For the  $B_s^0 \rightarrow D_s^- \pi^+$  channel the mass resolution is  $\sigma_\phi = (4.30 \pm 0.03) \text{ MeV}$  and for the  $B_s^0 \rightarrow D_s^- a_1^+$  channel  $\sigma_\phi = (4.28 \pm 0.03) \text{ MeV}$ . This mass window for accepted  $\phi$  candidates is shown by the vertical lines. No trigger selections are applied for the mass plots shown in Fig. 7 to Fig. 9.

From the remaining tracks, a third track with  $p_T > 1.5 \text{ GeV}$  is added to all accepted  $\phi$  candidates. The pion mass is assigned to the third track and a three-track vertex is fitted. Three-track vertex candidates which have a fit probability greater than 1% ( $\simeq \chi^2/\text{dof} = 12/3$ ) and an invariant mass within three standard deviations of the nominal  $D_s$  mass are selected as  $D_s$  candidates. The plots in Fig. 8 show the invariant mass distribution for all  $m_{KK\pi}$  combinations overlaid with the  $D_s$  candidates matching a generated  $D_s$  from the signal decay (grey filled area) fitted with a single Gaussian function. For the  $B_s^0 \rightarrow D_s^- \pi^+$  channel the mass resolution is  $\sigma_{D_s} = 17.81 \pm 0.13 \text{ MeV}$  and for the  $B_s^0 \rightarrow D_s^- a_1^+$  channel  $\sigma_{D_s} = 17.92 \pm 0.13 \text{ MeV}$ . The  $3\sigma_{D_s}$  mass range for accepted  $D_s$  candidates is shown by the vertical lines.

For the  $B_s^0 \rightarrow D_s^- a_1^+$  channel a search is performed for  $a_1^\pm$  candidates using three-particle combinations of charged tracks for events with a reconstructed  $D_s$  meson. In a first step  $\rho^0$  mesons are reconstructed from all combinations of two tracks with opposite charges and with  $p_T > 0.5 \text{ GeV}$ , each particle in the combination being assigned a pion mass. A kinematic cut  $\Delta R_{\pi\pi} = \sqrt{\Delta\phi_{\pi\pi}^2 + \Delta\eta_{\pi\pi}^2} < 0.650$  is used to reduce the combinatorial background. The two selected tracks are then fitted as originating from the same vertex; from the combinations passing a fit probability cut of 1% ( $\simeq \chi^2/\text{dof} = 7/1$ ), those with an invariant mass within 400 MeV of the nominal  $\rho^0$  mass are selected as  $\rho^0$  candidates. Next a third track with  $p_T > 0.5 \text{ GeV}$  from the remaining charged tracks is added to the  $\rho^0$  candidate, assuming the

pion hypothesis for the extra track. A kinematic cut  $\Delta R_{\rho\pi} < 0.585$  is applied. The three tracks are fitted to a common vertex without any mass constraints. Combinations with a fit probability greater than 1% ( $\simeq \chi^2/\text{dof} = 12/3$ ) and with an invariant mass within 325 MeV of the nominal  $a_1$  mass are selected as  $a_1^\pm$  candidates.

The  $B_s^0$  candidates are reconstructed combining the  $D_s^\pm$  candidates with  $a_1^\pm$  candidates with opposite charge and different tracks. A six-track vertex fit is performed with mass constraints for the tracks from  $\phi$  and  $D_s$ ; due to the large  $a_1$  natural width the three tracks from the  $a_1$  are not constrained to the  $a_1$  mass. The total momentum of the  $B_s^0$  vertex is required to point to the primary vertex and the momentum of the  $D_s$  vertex to the  $B_s^0$  vertex. Only six-track combinations with a vertex fit probability greater than 1% ( $\simeq \chi^2/\text{dof} = 27/12$ ) are considered as  $B_s^0$  candidates.

For the  $B_s^0 \rightarrow D_s^- \pi^+$  channel for each reconstructed  $D_s$  meson a fourth track from the remaining tracks in the event is added. This track is required to have opposite charge with respect to the pion track from the  $D_s$  and  $p_T > 1$  GeV. The four-track decay vertex is fitted including  $\phi$  and  $D_s$  mass constraints, and requiring that the total momentum of the  $B_s^0$  vertex points to the primary vertex and the momentum of  $D_s$  vertex points to the  $B_s^0$  vertex. In order to be selected as  $B_s^0$  candidates, the four-track combinations are required to have a vertex fit probability greater than 1% ( $\simeq \chi^2/\text{dof} = 20/8$ ).

For both channels,  $B_s^0 \rightarrow D_s^- \pi^+$  and  $B_s^0 \rightarrow D_s^- a_1^+$ , the signed separation between the reconstructed  $B_s^0$  vertex and the primary vertex is required to be positive (the momentum should not point backward to the parent vertex). To improve the purity of the sample, further cuts are imposed: the proper decay time of the  $B_s^0$  has to be greater than 0.4 ps, the  $B_s^0$  impact parameter (shortest distance of the reconstructed  $B_s^0$  trajectory from the primary vertex in the transverse plane to the reconstructed  $B_s^0$  decay vertex) is required to be smaller than 55  $\mu\text{m}$  and  $p_T$  of the  $B_s^0$  must be larger than 10 GeV. The plot in Fig. 9(a) shows the invariant mass distribution for all  $m_{KK\pi\pi}$   $B_s$  candidates matching a generated  $B_s$  from the signal decay for the  $B_s^0 \rightarrow D_s^- \pi^+$  channel fitted with a single Gaussian function and giving a mass resolution of  $\sigma_{B_s} = 52.80 \pm 0.68$  MeV. For the  $B_s^0 \rightarrow D_s^- a_1^+$  channel Fig. 9(b) shows the invariant mass distribution for all  $m_{KK\pi\pi\pi\pi}$   $B_s$  candidates matching a generated  $B_s$  and giving a mass resolution of  $\sigma_{B_s} = 40.82 \pm 0.53$  MeV. The difference in the  $B_s^0$  mass resolutions is caused by the  $p_T$  spectrum of the  $\pi$  in the  $B_s^0 \rightarrow D_s^- \pi^+$  decay being harder than the  $p_T$  spectra of the three pions in the  $B_s^0 \rightarrow D_s^- a_1^+$  decay, as the pion momentum resolution is worse for higher  $p_T$ . A final mass cut of two standard deviations on the  $B_s^0$  candidates is applied for further analysis (see vertical lines in Fig. 9). For some events more than one  $B_s^0$  candidate is reconstructed and in that case the candidate with the lowest  $\chi^2/\text{dof}$  from the vertex fit is selected for further analysis.

No relevant effects induced by the trigger selections on fit variables of the mass plots or the kinematic distributions of the  $B_s$  candidates are found (discussed in Section 6.3). All differences are within the fit errors.

## 5.2 Background Channels

Two main sources of background are considered: irreducible background coming from a decay channel that closely mimics the  $B_s^0$  signal and combinatorial background coming from random combination of tracks.

### 5.2.1 Exclusive Background Channels

The exclusive samples listed in Table 1 are used as irreducible background sources. See Table 12 in Section 6 for the numbers of reconstructed candidates after applying the same selection cuts as for the signal samples. The histograms in Fig. 10 show the invariant mass spectrum of reconstructed  $B_s^0$  candidates for the  $B_s^0 \rightarrow D_s^- \pi^+$  and  $B_s^0 \rightarrow D_s^- a_1^+$  channel respectively (no trigger selection cut applied). The different contributions are scaled with the cross-section given in Table 1.

Figure 7: Reconstructed mass  $m_{KK}$  for all combinations within the signal sample (black line) and  $KK$  candidates corresponding to a  $\phi$  particle from the signal decay in the Monte Carlo truth information (grey filled). The standard deviation obtained from a fit within two standard deviations of a Gaussian function (dashed) to the distribution defines the three standard deviation cut range (vertical dashed). No trigger conditions are applied.

Figure 8: Reconstructed mass  $m_{KK\pi}$  for all combinations within the signal sample (black line) and  $KK\pi$  candidates corresponding to a  $D_s$  particle from the signal decay in the Monte Carlo truth information (grey filled). The standard deviation obtained from a fit within two standard deviations of a Gaussian function (dashed) to the distribution defines the three standard deviation cut range (vertical dashed). No trigger conditions are applied.

Figure 9:  $m_{KK\pi\pi}$  (a) and  $m_{KK\pi\pi\pi\pi}$  (b) reconstructed mass and fit of a Gaussian function to the distribution. Each  $KK\pi\pi$  ( $KK\pi\pi\pi\pi$ ) candidate displayed corresponds to a  $B_s$  particle in the Monte Carlo truth information. The two standard deviation cut range is shown by the vertical dashed lines. No trigger chain applied.

Figure 10:  $m_{KK\pi\pi}$  (a) and  $m_{KK\pi\pi\pi\pi}$  (b) reconstructed mass for signal and background channels. In (b) the upper limit for the branching fraction of the channel  $B_d \rightarrow D_s a_1$  is used.

In the case of  $B_d^0 \rightarrow D_s^+ a_1^-$ , there is no measurement of the branching fraction available. The current upper limit is therefore used as a conservative estimate. The similarity to the  $B_d^0 \rightarrow D_s^+ \pi^-$  channel indicates that the  $B_d^0 \rightarrow D_s^+ a_1^-$  cross section could be in the same order as the one of the  $B_d^0 \rightarrow D_s^+ \pi^-$  channel and therefore the  $B_d^0 \rightarrow D_s^+ a_1^-$  contribution in Fig. 10 (b) could be much smaller.

The  $B_s \rightarrow D_s^* \pi$  and  $B_s \rightarrow D_s^* a_1$  channels are treated as a background source, since the momentum and hence the lifetime estimation for this decay is flawed due to the missing photon from the decay of the  $D_s^*$ .

### 5.2.2 Combinatorial Background

The limited statistics of the combinatorial background samples (e.g. 242 150 events for  $b\bar{b} \rightarrow \mu 6X$ ) do not allow us to give a reasonable estimate for the signal to background ratio. This ratio as well as kinematic properties of the combinatorial background, like the shape of the proper time distribution will be studied once early data are available.

### 5.3 Tagging Results

Soft muon tagging is applied on all available simulated data of the two hadronic signal channels  $B_s^0 \rightarrow D_s^- \pi^+$  and  $B_s^0 \rightarrow D_s^- a_1^+$ . Table 11 shows the number of events, the tagging efficiency and the wrong tag fractions. The tagging efficiency corresponds to the fraction of events where muon candidates have been successfully reconstructed. The events with at least one muon are separated into events with a good tag and events with a wrong tag resulting in a wrong tag fraction.

Comparing the results for all simulated events between the two signal channels, the difference in the wrong tag fraction is of the order 1 % due to the different kinematical topology. As the RoI trigger applies a  $p_T$  cut of 1.4 GeV on all reconstructed tracks, low  $p_T$   $B_s^0$  mesons are rejected leading to an increased wrong tag fraction for the triggered events (see Fig. 6(c) and 6(d)). After event reconstruction overall wrong tag fractions of  $\omega = 22.30^{+0.56}_{-0.55}$  % for the channel  $B_s^0 \rightarrow D_s^- \pi^+$  and  $\omega = 23.31^{+0.56}_{-0.55}$  % for the channel  $B_s^0 \rightarrow D_s^- a_1^+$  are observed. Effects of mixing are included as described in Section 4.1.

Table 11: Tagging efficiencies and wrong tag fractions for the signal channels  $B_s^0 \rightarrow D_s^- \pi^+$  and  $B_s^0 \rightarrow D_s^- a_1^+$  are shown for three different stages: all simulated events, all triggered events passing the LVL1 muon trigger and the LVL2 RoI trigger, and finally the numbers for the reconstructed events. The errors are statistical only.

Process	Type of Events	Number of Events	Tagging Efficiency [%]	Wrong Tag Fraction [%]
$B_s^0 \rightarrow D_s^- \pi^+$	all events	88450	$96.08 \pm 0.07$	$20.29 \pm 0.14$
	triggered	21613	$98.77 \pm 0.07$	$22.96 \pm 0.29$
	reconstructed	5687	$98.79^{+0.14}_{-0.15}$	$22.30^{+0.56}_{-0.55}$
$B_s^0 \rightarrow D_s^- a_1^+$	all events	98450	$95.93 \pm 0.06$	$21.05 \pm 0.13$
	triggered	27118	$98.55 \pm 0.07$	$23.91 \pm 0.26$
	reconstructed	5757	$98.47^{+0.16}_{-0.17}$	$23.31^{+0.56}_{-0.55}$

## 6 Determination of $\Delta m_s$

### 6.1 Methods for the Determination of $\Delta m_s$ and its Measurement Limits

For the determination of the  $B_s^0$  oscillation frequency the maximum likelihood method is used. The likelihood  $\mathcal{L}$  is a function of the proper time  $t$  and the mixing state  $\mu$ , parametrised by  $\Delta m_s$  and  $\Delta\Gamma_s$ , applied to five classes of events simultaneously: mixed and unmixed  $B_s^0$ , mixed and unmixed  $B_d^0$ , and background with lifetime but no mixing. The  $B_s^0$  and  $B_d^0$  classes have characteristic wrong tag fractions  $\omega$ , which are determined on event-by-event basis as described previously. By maximising the likelihood  $\mathcal{L}$  for a given event sample one can then extract the model parameters.

For obtaining the  $5\sigma$  discovery and 95% exclusion measurement limits on  $\Delta m_s$  the amplitude fit method is used because the maximum likelihood method was found to have some disadvantages in that case [5]. The estimation of the maximum value of  $\Delta m_s$  measurable with the ATLAS detector is using  $B_s^0$  candidates from the  $B_s^0 \rightarrow D_s^- \pi^+$  and  $B_s^0 \rightarrow D_s^- a_1^+$  hadronic channels. The numbers of reconstructed events after applying the trigger selection (L1\_MU06 and LVL2 RoI) and the  $B_s^0$  selection cuts as well as the expected numbers for an integrated luminosity of  $10 \text{ fb}^{-1}$  are given in Table 12 for all signal and background channels. The effective cross-sections for the various processes can be found in Table 1. Significant background comes from the  $\bar{B}_d^0 \rightarrow D_s^- \pi^+ / a_1^+$  and  $B_s^0 \rightarrow D_s^{*-} \pi^+ / a_1^+$  channels, and from the combinatorial background. Due to limited sample size the estimation of the combinatorial background is very approximate.

The relative fractions of the signal and the background contributions will be determined by a fit of mass shape templates to the reconstructed  $B_s^0$  mass distribution employing a wider mass window than used here for the final extraction of  $\Delta m_s$ , similar to the method used by CDF [1]. The mass shape templates will be determined from Monte Carlo mass distributions of the individual channels. Uncertainties in the knowledge of the shapes will be taken into account as part of the systematical uncertainty.

Table 12: Signal and background samples used for the study of  $B_s^0$ - $\bar{B}_s^0$  oscillations and number of events as obtained from the analysis as well as expected numbers for an integrated luminosity of  $10 \text{ fb}^{-1}$ .

Process	Simulated events	Rec. events	Rec. events for $10 \text{ fb}^{-1}$
$B_s^0 \rightarrow D_s^- \pi^+$	88 450	5 687	6 657
$B_d^0 \rightarrow D_s^+ \pi^-$	43 000	1 814	99
$B_d^0 \rightarrow D^- \pi^+$	41 000	23	35
$B_s^0 \rightarrow D_s^{*-} \pi^+$	40 500	495	1 116
$B_s^0 \rightarrow D_s^- a_1^+$	98 450	5 757	3 368
$B_d^0 \rightarrow D_s^+ a_1^-$	50 000	1 385	< 2 454
$B_d^0 \rightarrow D^- a_1^+$	50 000	49	36
$B_s^0 \rightarrow D_s^{*-} a_1^+$	100 000	870	1 052

### 6.2 Construction of the Likelihood Function

The probability density to observe an initial  $B_j^0$  meson ( $j = d, s$ ) decaying at time  $t_0$  after its creation as a  $\bar{B}_j^0$  meson is given by

$$p_j(t_0, \mu_0) = \frac{\Gamma_j^2 - (\Delta\Gamma_j/2)^2}{2\Gamma_j} e^{-\Gamma_j t_0} \left( \cosh \frac{\Delta\Gamma_j t_0}{2} + \mu_0 \cos(\Delta m_j t_0) \right) \quad (1)$$

where  $\Delta\Gamma_j = \Gamma_H^j - \Gamma_L^j$ ,  $\Gamma_j = (\Gamma_H^j + \Gamma_L^j)/2$  and  $\mu_0 = -1$ .

For the unmixed case (an initial  $B_j^0$  meson decaying as a  $B_j^0$  meson at time  $t_0$ ), the probability density is obtained by setting  $\mu_0 = +1$  in Eq. 1. Here the small effects of CP violation are neglected. Unlike  $\Delta\Gamma_d$ , which can be safely set to zero, the width difference  $\Delta\Gamma_s$  in the  $B_s^0$ - $\bar{B}_s^0$  system could be as much as 20% of the total width [17].

However, the above probability is modified by experimental effects. The probability as a function of  $\mu_0$  and the reconstructed proper time  $t$  is obtained as the convolution of  $p_j(t_0, \mu_0)$  with the proper time resolution  $\text{Res}_j(t | t_0)$ :

$$q_j(t, \mu_0) = \frac{1}{N} \int_0^\infty p_j(t_0, \mu_0) \text{Res}_j(t | t_0) dt_0 \quad (2)$$

with the normalisation factor

$$N = \int_{t_{\min}}^\infty (\int_0^\infty p_j(t', \mu_0) \text{Res}_j(t | t') dt') dt. \quad (3)$$

Here  $t_{\min} = 0.4$  ps is the cut on the  $B_s^0$  reconstructed proper decay time. Plots in Fig. 11 show the proper time resolutions, which are parametrised with the sum of two Gaussian functions around the same mean value. The widths from the fit are  $\sigma_1 = (68.4 \pm 3.3)$  fs for the core fraction of 53.2% and  $\sigma_2 = (157.2 \pm 5.7)$  fs for the rest of the tail part of the distribution for the  $B_s^0 \rightarrow D_s^- \pi^+$  channel. The values for the  $B_s^0 \rightarrow D_s^- a_1^+$  channel are  $\sigma_1 = (72.5 \pm 4.3)$  fs for the core fraction of (58.0  $\pm$  6.8) % and  $\sigma_2 = (144.7 \pm 7.3)$  fs for the tail part.

Assuming a fraction  $\omega_j$  of wrong tags occurring at production and/or decay, the probability becomes

$$\tilde{q}_j(t, \mu) = (1 - \omega_j) q_j(t, \mu) + \omega_j q_j(t, -\mu) \quad (4)$$

where  $\mu_0$  has been replaced by  $\mu$  in order to indicate that now we are talking about the experimental observation of same or opposite flavour tags. For each signal channel, the background is composed of oscillating  $B_d^0$  mesons, with probability given by Eq. 4, and of non-oscillating combinatorial background, with probability given by Eq. 5, which results from Eq. 1 and Eq. 4 by setting  $\Delta m = 0$  and  $\Delta\Gamma = 0$ :

$$p_{\text{cb}}(t, \mu) = \frac{\Gamma_{\text{cb}}}{2} e^{-\Gamma_{\text{cb}} t} [1 + \mu (1 - 2\omega_{\text{cb}})] \quad (5)$$

For a fraction  $f_{kj}$  of the  $j$  component ( $j = s, d$ , and combinatorial background cb) in the total sample of type  $k$ , one obtains the probability density function

$$\text{pdf}_k(t, \mu) = \sum_{j=s,d,\text{cb}} f_{kj} \tilde{q}_j(t, \mu). \quad (6)$$

The index  $k = 1$  denotes the  $B_s^0 \rightarrow D_s^- \pi^+$  channel and  $k = 2$  the  $B_s^0 \rightarrow D_s^- a_1^+$  channel. The likelihood of the total event sample is written as

$$\mathcal{L}(\Delta m_s, \Delta\Gamma_s) = \prod_{k=1}^{N_{\text{ch}}} \prod_{i=1}^{N_{\text{ev}}^k} \text{pdf}_k(t_i, \mu_i) \quad (7)$$

where  $N_{\text{ev}}^k$  is the total number of events of type  $k$ , and  $N_{\text{ch}} = 2$ . Each  $\text{pdf}_k$  is properly normalised to unity.

Figure 12 shows how the experimental effects, as parametrised in Eqs. 2, 4, and 6, modify the distribution of the proper time  $t$  of a Monte Carlo data sample.

Figure 11: The resolution  $\sigma_t$  of the proper time of simulated  $B_s^0$  fitted with two Gaussian functions (dashed lines). Both Gaussian functions use a common mean value.

Figure 12: A sequence of plots showing how a true  $B_s^0$  oscillation signal with  $\Delta m_s^{\text{gen}} = 17.77 \text{ ps}^{-1}$  (a) is diluted first by the effect of a finite proper time resolution (b) and then by adding background events and including the effect of wrong tags (c). The plots contain samples of events equivalent to  $10 \text{ fb}^{-1}$  of integrated luminosity. They were generated using the Monte Carlo method described in Section 6.3. Only the case of mixed events is shown. For illustration a  $\chi^2$ -fit of the function  $C \exp(-t/\tau)(1 - D \cos(\Delta m_s t))$  is overlaid to the solid histogram in (c), where  $D$  can be interpreted as the combined dilution factor:  $D \approx 0.1$  here. Note that this is different from the unbinned maximum likelihood fit to the total event sample of mixed and unmixed events which is actually used to derive results in this study. The dashed histogram in (c) describes the contribution from all background sources.

### 6.3 Monte Carlo Data Sample

For the amplitude fit method a simplified Monte Carlo method is applied to generate a  $B_s^0$  sample using the following input parameters: for each signal channel  $k$  the number of reconstructed signal events  $N_{\text{sig}}^{(k)}$  for an integrated luminosity of  $10 \text{ fb}^{-1}$  and the number of background events  $N_{B_{d,s}^0}^{(k)}$  from  $B_{d,s}^0$  decays is given in Table 12. For the combinatorial background the ratio  $N_{\text{sig}}^{(k)}/N_{\text{cb}}^{(k)}$  is taken to be 1. The wrong tag fraction is assumed to be the same for both  $B_s^0$  and  $B_d^0$  mesons in a specific signal channel ( $\omega_s = \omega_d$ ), however, the values are slightly different for the two signal channels (see Table 11).

A Monte Carlo sample with  $N_{\text{sig}} = N_{\text{sig}}^{(1)} + N_{\text{sig}}^{(2)}$  signal events oscillating with a given frequency  $\Delta m_s$  (e.g.  $\Delta m_s = 100 \text{ ps}^{-1}$ , which is far off the expected value for  $\Delta m_s$ ), together with  $N_{B_{d,s}^0} = N_{B_{d,s}^0}^{(1)} + N_{B_{d,s}^0}^{(2)}$  background events oscillating with frequency  $\Delta m_{d,s}$  and  $N_{\text{cb}} = N_{\text{cb}}^{(1)} + N_{\text{cb}}^{(2)}$  combinatorial events (no oscillations) is generated according to Eq. 1.

The uncertainty on the measurement of the transverse decay length,  $\sigma_{d_{xy}}$  (see Fig. 13), and the true value of the  $g$ -factor  $g_0$  ( $g := m/p_T$ ) as seen in Fig. 14(a), are generated randomly according to the distributions obtained from the simulated samples, fitted with appropriate combinations of Gaussian and exponential functions. For the  $B_s^0 \rightarrow D_s^- a_1^+$  channel the true  $p_T^0$  distribution shown in Fig. 14(b) is fitted with a combination of a parabola function in the low  $p_T^0$  region and a sum of two exponential functions in the high  $p_T^0$  region. The  $g_0$  values are obtained by converting generated  $p_T^0$  values at random.

From the computed true decay length,  $d_{xy}^0 = t_0/g_0$ , the corresponding reconstructed decay length is generated as  $d_{xy} = d_{xy}^0 + \sigma_{d_{xy}} \cdot (\mu_{d_{xy}} + S_{d_{xy}} \Omega)$ .  $t_0$  is the proper time of the generated  $B_s$ .  $S_{d_{xy}}$  is the width and  $\mu_{d_{xy}}$  the mean value of the Gaussian shape of the pull of the transverse decay length  $\frac{d_{xy} - d_{xy}^0}{\sigma_{d_{xy}}}$  shown in Fig. 15. The fitted values are  $S_{d_{xy}} = 1.099 \pm 0.011$  and  $\mu_{d_{xy}} = (8.76 \pm 1.47) \cdot 10^{-2}$  for the  $B_s^0 \rightarrow D_s^- \pi^+$  channel respectively  $S_{d_{xy}} = 1.113 \pm 0.011$  and  $\mu_{d_{xy}} = (5.40 \pm 1.48) \cdot 10^{-2}$  for the  $B_s^0 \rightarrow D_s^- a_1^+$  channel. The reconstructed  $g$ -factor is generated as  $g = g_0 + g_0 \mu_g + g_0 S_g \Omega'$ . The distribution of the fractional  $g$ -factor  $\frac{g - g_0}{g_0}$  as shown in Fig. 16 is fitted with a Gaussian resulting in a width of  $S_g = (0.89 \pm 0.01) \cdot 10^{-2}$  and a mean value of  $\mu_g = (0.27 \pm 0.12) \cdot 10^{-3}$  for the  $B_s^0 \rightarrow D_s^- \pi^+$  channel respectively  $S_g = (0.82 \pm 0.01) \cdot 10^{-2}$  and  $\mu_g = (0.56 \pm 0.11) \cdot 10^{-3}$  for the  $B_s^0 \rightarrow D_s^- a_1^+$  channel. Both  $\Omega$  and  $\Omega'$  are random numbers distributed according to the normal distribution. From the transverse decay length and  $g$ -factor, the reconstructed proper time is then computed as  $t = g d_{xy}$ . The probability for the event to be mixed or unmixed is determined from the  $t_0$  and  $\Delta m_s$  (or  $\Delta m_d$ ) values using the expression  $(1 - \cos(\Delta m_j t_0) / \cosh(\Delta \Gamma_j t_0 / 2)) / 2$  which is left from Eq. 1 after the exponential part has been separated.

For a fraction of the events, selected at random, the state is interchanged between mixed and unmixed, according to the wrong tag fraction  $\omega_{\text{tag}}$ . Half of the combinatorial events are added to the mixed events and half to the unmixed events.

For the exclusive  $B_{d,s}^0$  background channels as well as the combinatorial background, the reconstructed proper time is generated assuming that it has the same distribution as the one for signal  $B_s^0$  mesons coming from the  $D_s^- \pi^+$  and  $D_s^- a_1^+$  sample respectively, no mixing included.

The  $\Delta m_s$  measurement limits are obtained applying the amplitude fit method [5] to the sample generated as described in the previous section. According to this method a new parameter, the  $B_s^0$  oscillation amplitude  $\mathcal{A}$ , is introduced in the likelihood function by replacing the term ' $\mu_0 \cos \Delta m_s t_0$ ' with ' $\mu_0 \mathcal{A} \cos \Delta m_s t_0$ ' in the  $B_s^0$  probability density function given by Eq. 1. The new likelihood function, similar to Eq. 7, again includes all experimental effects. For each value of  $\Delta m_s$ , this likelihood function is minimized with respect to  $\mathcal{A}$ , keeping all other parameters fixed, and a value  $\mathcal{A} \pm \sigma_{\mathcal{A}}^{\text{stat}}$  is obtained. One expects, within the estimated uncertainty,  $\mathcal{A} = 1$  for  $\Delta m_s$  close to its true value, and  $\mathcal{A} = 0$  for  $\Delta m_s$

Figure 16: The fractional resolution of the  $g$ -factor  $\frac{g - g_0}{g_0}$  of simulated  $B_s^0$  fitted with a single Gaussian function including trigger selection.

Figure 17: The  $B_s^0$  oscillation amplitude (a) and the measurement significance (b) as a function of  $\Delta m_s$  for an integrated luminosity of 10 fb<sup>-1</sup> for a specific Monte Carlo experiment with  $\Delta m_s^{\text{gen}} = 100$  ps<sup>-1</sup>.

far from the true value. A five standard deviation measurement limit is defined as the value of  $\Delta m_s$  for which  $1/\sigma_{\mathcal{A}} = 5$ , and a sensitivity at 95% C.L. as the value of  $\Delta m_s$  for which  $1/\sigma_{\mathcal{A}} = 1.645$ . Limits are computed with the statistical uncertainty  $\sigma_{\mathcal{A}}^{\text{stat}}$ . A detailed investigation on the systematic uncertainties  $\sigma_{\mathcal{A}}^{\text{syst}}$ , which affects the measurement of the  $B_s^0$  oscillation, is presented in [18].

#### 6.4 Extraction of the $\Delta m_s$ Sensitivity

For the nominal set of parameters (as defined in the previous sections),  $\Delta \Gamma_s = 0$  and an integrated luminosity of 10 fb<sup>-1</sup>, the amplitude  $\pm 1\sigma_{\mathcal{A}}^{\text{stat}}$  is plotted as a function of  $\Delta m_s$  in Fig. 17(a). The 95% C.L. sensitivity to measure  $\Delta m_s$  is found to be 29.6 ps<sup>-1</sup>. This value is given by the intersection of the dashed line, corresponding to  $1.645 \sigma_{\mathcal{A}}^{\text{stat}}$ , with the horizontal line at  $\mathcal{A} = 1$ .

From Fig. 17(b), which shows the significance of the measurement  $S(\Delta m_s) = 1/\sigma_{\mathcal{A}}$  as a function of  $\Delta m_s$ , the 5 $\sigma$  measurement limit is found to 20.5 ps<sup>-1</sup>.

The dependence of the  $\Delta m_s$  measurement limits on the integrated luminosity is shown in Fig. 18(a), with the numerical values given in Table 13.

Table 13: The dependence of  $\Delta m_s$  measurement limits on the integrated luminosity  $\mathcal{L}$ .

$\mathcal{L}$ [fb <sup>-1</sup> ]	5 $\sigma$ limit [ps <sup>-1</sup> ]	95% C.L. sensitivity [ps <sup>-1</sup> ]
3	14.5	25.0
5	17.0	27.0
10	20.5	29.6
20	23.7	32.0
30	25.3	33.2
40	26.4	34.1

The dependence of the  $\Delta m_s$  measurement limits on  $\Delta \Gamma_s/\Gamma_s$  is determined for an integrated luminosity

Figure 18: The dependence of  $\Delta m_s$  measurement limits (a) on the integrated luminosity and (b) on  $\Delta\Gamma_s/\Gamma_s$  for an integrated luminosity of  $10 \text{ fb}^{-1}$ . The dashed horizontal line in (a) denotes the CDF measurement.

of  $10 \text{ fb}^{-1}$ , other parameters having their nominal value. The  $\Delta\Gamma_s/\Gamma_s$  is used as a fixed parameter in the amplitude fit method. As shown in Fig. 18(b) no sizeable effect is seen up to  $\Delta\Gamma_s/\Gamma_s \sim 30\%$ .

### 6.5 Extraction of the $\Delta m_s$ Measurement Precision

Whereas the  $\Delta m_s$  measurement limits are obtained by using the amplitude method (see previous section), in case of the presence of an oscillation signal in the data the value of the oscillation frequency  $\Delta m_s$  and its precision are determined by minimising the likelihood (given by Eq. 7) with respect to  $\Delta m_s$ . In this fit  $\Delta\Gamma_s$  is fixed to 0, because a study has shown that the systematic uncertainties resulting from varying  $\Delta\Gamma_s/\Gamma_s$  in the range 0 to 0.2 (suggested by the present uncertainty) are practically negligible.

An example of the likelihood function is given in Fig. 19(a), in which the  $\Delta m_s^{\text{gen}}$  in the Monte Carlo sample has been set to the value measured by CDF for illustration. From this type of graphs the precision of the measurement of  $\Delta m_s$  is extracted and plotted in Fig. 19(b) as a function of the integrated luminosity for three values of  $\Delta m_s^{\text{gen}}$ .

### 6.6 Discussion of Results

In this note it is shown that with an integrated luminosity of  $10 \text{ fb}^{-1}$  ATLAS is able to verify the CDF measurement of  $\Delta m_s = (17.77 \pm 0.10(\text{stat}) \pm 0.07(\text{sys})) \text{ ps}^{-1}$  at the five standard deviation level. For these parameters the statistical error on  $\Delta m_s$  is calculated to be about  $0.065 \text{ ps}^{-1}$ .

In a preceding study [18] it was found that over a wide range of values for  $\Delta m_s$  and integrated luminosity the systematic uncertainty on the measured value of  $\Delta m_s$  was smaller by at least a factor of 10 compared to the statistical uncertainty. The list of contributions to that systematic error estimation included the wrong tag fraction with a relative error of 5% compared to 2.5% found in this study. For the reasons mentioned above, the evaluation of systematic effects has not been repeated here. The study of the effect of varying  $\Delta\Gamma_s$  (as explained in the previous section) is new, but the contribution to the systematic uncertainty is also very small.

Figure 19: (a) The negative natural logarithm of the likelihood for a specific Monte Carlo data sample for an integrated luminosity of  $10 \text{ fb}^{-1}$  and a true value of  $\Delta m_s^{\text{gen}} = 17.77 \text{ ps}^{-1}$ . The inset shows a zoom around the minimum. (b) The statistical error  $\sigma_{\text{stat}}(\Delta m_s)$  as a function of the integrated luminosity for values of  $\Delta m_s^{\text{gen}}$  of 15, 17.77 and  $20 \text{ ps}^{-1}$ . For comparison: the CDF statistical error on their  $\Delta m_s$  measurement is  $0.10 \text{ ps}^{-1}$ .

Systematic uncertainties on the overall trigger efficiencies mainly effect the statistics available for the analysis. However, an important systematic effect for the  $\Delta m_s$  measurement would be introduced in case different trigger efficiencies for positively and negatively charged muons are observed. In order to constrain this effect, dimuon events from a calibration channel like  $B^+ \rightarrow J/\psi K^+$  with  $J/\psi \rightarrow \mu^+ \mu^-$  which are triggered by a single muon trigger could be used.

Clearly LHCb can measure  $\Delta m_s$  more precisely than ATLAS ( $\sigma_{\text{stat}}(\Delta m_s) \sim 0.01 \text{ ps}^{-1}$  with  $2 \text{ fb}^{-1}$  of data [19]), but the  $\Delta m_s$  measurement with ATLAS is needed for the simultaneous fit of all parameters of the weak sector of the  $B_s^0$ - $\bar{B}_s^0$  system (weak mixing phase  $\phi_s$ ,  $\Delta m_s$ ,  $\Gamma_s$  and  $\Delta\Gamma_s$ ). This will be performed by a combined analysis of the channels described in this note and the  $B_s^0 \rightarrow J/\psi \phi$  channel [20]. The ATLAS measurement is an independent cross-check of the measurements performed by other experiments.

## 7 Summary and Conclusions

We have studied the capabilities of the ATLAS detector to measure  $B_s^0$  oscillations in  $pp$  collisions at 14 TeV using the purely hadronic decay channels  $B_s^0 \rightarrow D_s^- (\phi \pi^-) \pi^+$  and  $B_s^0 \rightarrow D_s^- (\phi \pi^-) a_1^+$ . For an integrated luminosity of  $10 \text{ fb}^{-1}$  a  $\Delta m_s$  sensitivity limit of  $29.6 \text{ ps}^{-1}$  and a five standard deviation measurement limit of  $20.5 \text{ ps}^{-1}$  is obtained from a likelihood fit employing the amplitude fit method. This result depends only weakly on the lifetime difference  $\Delta\Gamma_s$ . The trigger is based on a single muon trigger with adjustable muon  $p_T$  thresholds between 4 and 10 GeV on all trigger levels and an active search for  $D_s \rightarrow \phi \pi$  decays by the High Level Trigger. For  $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  we will be able to afford a muon trigger with the loosest  $p_T$  threshold combined with a FullScan  $D_s \rightarrow \phi \pi$  search. For  $10^{32} \text{ cm}^{-2} \text{ s}^{-1}$ , we will need to increase the muon  $p_T$  threshold to 6 GeV and possibly employ the RoI-based LVL2 trigger. In both cases, the trigger rates can be kept at an acceptable level. For higher luminosities, we need to implement additional constraints in the HLT in order to reduce the event output rates further.

The offline event reconstruction searches for the hadronic decay of the  $B_s^0$  and requires a muon with a minimum  $p_T$  of 6 GeV for each event. While the flavour of the  $B_s^0$  at decay time is determined from the charge of the  $D_s$  particle, the identification of the initial  $B_s^0$  flavour at production time is extracted from the charge of the soft muon in the event, taking effects of  $B_s^0$  mixing into account. An overall tagging efficiency of  $98.8 \pm 0.2\%$  and  $98.5 \pm 0.2\%$  as well as average wrong tag fractions of  $22.3 \pm 0.6\%$  and  $23.3 \pm 0.6\%$  for the  $B_s^0 \rightarrow D_s^- \pi^+$  and the  $B_s^0 \rightarrow D_s^- a_1^+$  channels, respectively, are obtained.

About 100000 Monte Carlo events of each sample have been produced without  $B_s^0$  oscillations. Monte Carlo events for several exclusive  $B_s^0$  and  $B_d^0$  background channels as well as for inclusive background like  $b\bar{b} \rightarrow \mu X$  and  $c\bar{c} \rightarrow \mu X$  have been used. The hadronic decay of the signal side  $B_s^0$  is reconstructed constraining the masses of intermediate particles in the decay chain. A  $B_s^0$  mass resolution of  $52.8 \pm 0.7$  MeV and  $40.8 \pm 0.5$  MeV is obtained and after the application of all analysis cuts, 6657 and 3368 events are expected for an integrated luminosity of  $10 \text{ fb}^{-1}$  for the  $B_s^0 \rightarrow D_s^- \pi^+$  and the  $B_s^0 \rightarrow D_s^- a_1^+$  decay channels, respectively. We have considered several exclusive background channels, contributing to the background inside the  $B_s^0$  mass window. The  $B_d^0 \rightarrow D^- \pi^+ / a_1^+$  channels hardly contribute (percent level of the signal), but the  $B_s^0 \rightarrow D_s^{*-} \pi^+ / a_1^+$  make a considerable contribution of about 16% ( $B_s^0 \rightarrow D_s^- \pi^+$ ) and 31% ( $B_s^0 \rightarrow D_s^- a_1^+$ ). While the  $B_d^0 \rightarrow D_s^- \pi^+$  channel is expected to contribute with about 1.5% relative to the  $B_s^0 \rightarrow D_s^- \pi^+$  signal, we can only estimate the  $B_d^0 \rightarrow D_s^- a_1^+$  contribution to be less than about 70% of the  $B_s^0 \rightarrow D_s^- a_1^+$  signal, given that this decay channel has not yet been observed.

In future, the  $B_s^0 \rightarrow D_s^{*-} \pi^+ / a_1^+$  channels may be considered signal rather than background. An estimate of the combinatorial background is severely limited by the available Monte Carlo event statistics. We plan to use early data to obtain a realistic estimate. For an integrated luminosity of  $100 \text{ pb}^{-1}$  at  $10^{32} \text{ cm}^{-2} \text{ s}^{-1}$  we only expect about 90 events in the  $B_s^0 \rightarrow D_s^- \pi^+$  and  $B_s^0 \rightarrow D_s^- a_1^+$  channels, while the  $B^+ \rightarrow J/\psi(\mu\mu)K^+$  decay channel, which has a large branching ratio, may be used to calibrate the soft muon tagging with early data. On LVL2 the processing time for the  $D_s \rightarrow \phi\pi$  trigger may be reduced by restricting the track reconstruction to Regions of Interest (RoI), seeded by a LVL1 jet energy trigger. This typically leads to a reduction of the trigger efficiency by a few percent. At an instantaneous luminosity of  $2 \cdot 10^{33} \text{ cm}^{-2} \text{ s}^{-1}$  several options will be considered to achieve acceptable Event Filter output rates. Besides further constraining the mass windows of the  $D_s \rightarrow \phi\pi$  trigger, other improvements are obtained by checking for a good reconstruction quality of the  $D_s$  vertex or the implementation of a trigger element in the Event Filter which searches for the full  $B_s^0$  decay chain. However, there is an uncertainty of a factor two in the overall  $b\bar{b}$  cross-section at the centre-of-mass energy of 14 TeV and therefore the trigger rates may vary.

Due to the achieved sensitivity limit to measure the  $B_s^0$  oscillations we expect to be able to verify the CDF measurement of  $\Delta m_s = 17.77 \pm 0.10 (\text{stat}) \pm 0.07 (\text{sys}) \text{ ps}^{-1}$  at the five standard deviation level with a statistical error on  $\Delta m_s$  of about  $0.065 \text{ ps}^{-1}$ . This will provide a reasonable precision which allows us to combine the measurement described in this note with the analysis of the  $B_s^0 \rightarrow J/\psi\phi$  channel [20] in a simultaneous fit for all parameters of the weak sector of the  $B_s^0$ - $\bar{B}_s^0$  system.

# Higgs Boson

# Introduction on Higgs Boson Searches

## Abstract

The investigation of the dynamics responsible for electroweak symmetry breaking is one of the prime tasks of experiments at present and future colliders. Experiments at the CERN Large Hadron Collider (LHC) will be able to discover a Standard Model Higgs boson over the full mass range as well as Higgs bosons in extended models. In this introductory paper the Higgs boson production cross-section and decay branching ratios according to the Standard Model, and its Minimal Supersymmetric extension, are presented and discussed.

## 1 Introduction

The Large Hadron Collider at CERN, almost ready to start colliding proton beams at  $\sqrt{s}=14$  TeV, will play an important role in the investigation of fundamental questions of particle physics. While the Standard Model of electroweak [1] and strong [2] interactions is in excellent agreement with the numerous experimental measurements, the dynamics responsible for electroweak symmetry breaking are still unknown. Within the Standard Model, the Higgs mechanism [3] is invoked to break the electroweak symmetry. A doublet of complex scalar fields is introduced, of which a single neutral scalar particle, the Higgs boson, remains after symmetry breaking [4]. Many extensions of this minimal version of the Higgs sector have been proposed, mostly discussed a scenario with two complex Higgs doublets as realized in the Minimal Supersymmetric Standard Model (MSSM) [5].

Within the Standard Model, the Higgs boson is the only particle that has not been discovered so far. The direct search at the  $e^+e^-$  collider LEP has led to a lower bound on its mass of 114.4 GeV [6]. Indirectly, high precision electroweak data constrain the mass of the Higgs boson via their sensitivity to loop corrections. Assuming the overall validity of the Standard Model, a global fit [7] to all electroweak data leads to the 95% C.L.  $m_H < 144$  GeV. The 95 % C.L. lower limit obtained from LEP is not used in the determination of this limit. Including it increases the limit to 182 GeV [7].

On the basis of the present theoretical knowledge, the Higgs sector in the Standard Model remains largely unconstrained. While there is no direct prediction for the mass of the Higgs boson, an upper limit of  $\sim 1$  TeV can be inferred from unitarity arguments [8].

Further constraints can be derived under the assumption that the Standard Model is valid only up to a cutoff energy scale  $\Lambda$ , beyond which new physics becomes relevant. Requiring that the electroweak vacuum is stable and that the Standard Model remains perturbative allows to set upper and lower bounds on the Higgs boson mass [9, 10]. For a cutoff scale of the order of the Planck mass, the Higgs boson mass is required to be in the range  $130 < M_H < 180$  GeV. If new physics appears at lower mass scales, the bound becomes weaker, *e.g.*, for  $\Lambda = 1$  TeV the Higgs boson mass is constrained to be in the range  $50 < M_H < 800$  GeV.

Direct searches for the Standard Model Higgs boson at the Tevatron include looking for its production via gluon fusion and subsequent decay to  $WW^{(*)}$ . The observed 95% C.L. limit by CDF (with an integrated luminosity of  $2.4 \text{ fb}^{-1}$  analysed) is 0.85 pb for  $M_H = 160$  GeV, which is about 1.6 times the Standard Model prediction [11]. Similarly the DØ Collaboration excludes at 95% C.L. the production of this boson with a cross-section about 2.4 times the one predicted by the Standard Model ( $\sigma_{SM}^{WW}$ ). Searches at low mass are done studying Higgs bosons produced in association with the  $W$  and  $Z$ , and looking for  $H \rightarrow b\bar{b}$  with leptonic  $W$  and  $Z$  decays ( $e, \mu$ ). CDF sets a 95% C.L. limit to  $8.2 \times \sigma_{SM}^{b\bar{b}}$ , while the one from DØ is  $11 \times \sigma_{SM}^{b\bar{b}}$ , for  $M_H = 115$  GeV. Preliminary results on the combination of the results from these two experiments lead to a 95% C.L. limit on the Higgs boson production cross-section to about  $5.1 \times \sigma_{SM}$  for  $M_H = 115$  GeV, and  $1.1 \times \sigma_{SM}$  for  $M_H = 160$  GeV [11].

The Minimal Supersymmetric Standard Model contains two complex Higgs doublets, leading to five physical Higgs bosons after electroweak symmetry breaking: three neutral (two CP-even  $h$  and  $H$ , and one CP-odd  $A$ ) and a pair of charged Higgs bosons  $H^\pm$ . At tree level, the Higgs sector of the MSSM is fully specified by two parameters, generally chosen to be  $m_A$ , the mass of the CP-odd Higgs boson, and  $\tan\beta$ , the ratio of the vacuum expectation values of the two Higgs doublets. Radiative corrections modify the tree-level relations significantly. This is of particular interest for the mass of the lightest CP-even Higgs boson, which at tree level is constrained to be below the mass of the  $Z$  boson. Loop corrections are sensitive to the mass of the top quark, to the mass of the scalar particles and in particular to mixing in the stop sector. The largest values for the mass of the Higgs boson  $h$  are reached for large mixing, characterized by large values of the mixing parameter  $X_t := A_t - \mu \cot\beta$ , where  $A_t$  is the trilinear coupling and  $\mu$  is the Higgs mass parameter. If the full one-loop and the dominant two-loop contributions are included [12, 13], the upper bound on the mass of the light Higgs boson  $h$  is expected to be around 135 GeV ( $m_h$ -max scenario). While the light neutral Higgs boson may be difficult to distinguish from its Standard Model counterpart, the other heavier Higgs bosons are a distinctive signal of physics beyond the Standard Model. The masses of the heavier Higgs bosons  $H$ ,  $A$  and  $H^\pm$  are often almost degenerate.

Direct searches at LEP have given lower bounds of 92.9 (93.3) GeV and 93.4 (93.3) GeV on the masses of the lightest CP-even Higgs boson  $h$  and the CP-odd Higgs boson  $A$  within the  $m_h$ -max (no-mixing) scenario. [14] In those scenarios, the mixing parameter in the stop sector is set to values of  $X_t = 2$  TeV and  $X_t = 0$ , respectively. Given the LEP results, the  $\tan\beta$  regions of  $0.9 < \tan\beta < 1.5$  and  $0.4 < \tan\beta < 5.6$  are excluded at 95% confidence level for the  $m_h$ -max and the no-mixing scenarios, respectively [14]. However, it should be noted that the exclusions in  $\tan\beta$  depend critically on the exact value of the top-quark mass. In the LEP analysis  $m_t = 179.3$  GeV has been assumed. With decreasing top mass the theoretical upper bound on  $m_h$  decreases and hence the exclusions in  $\tan\beta$  increase, while for  $m_t$  of about 183 GeV, or higher, the exclusions in  $\tan\beta$  vanish.

Direct searches at the Tevatron have been performed looking to the tau-pair and b-pair production. With an integrated luminosity of  $1.8 \text{ fb}^{-1}$  no excess of events has been observed, and exclusion limits on production cross-section times branching fraction to tau pairs for a Higgs boson mass in the range from 90 to 250 GeV have been set. The expected reach of this search, assuming MSSM Higgs production, extends below  $\tan\beta = 40$  for  $M_A$  in the mass range  $M_A = 120$  to 160 GeV [15].

The charged Higgs boson mass is related to  $m_A$  via the tree-level relation  $m_{H^\pm}^2 = m_W^2 + m_A^2$  and it is less sensitive to radiative corrections [16]. Direct searches for charged Higgs bosons in the decay modes  $H^\pm \rightarrow \tau\nu$  and  $H^\pm \rightarrow cs$  have been carried out at LEP, yielding a lower bound of 78.6 GeV on  $m_{H^\pm}$  independent of the  $H^\pm \rightarrow \tau\nu$  branching ratio [17]. At the Tevatron, the CDF and DØ experiments have performed direct and indirect searches for the charged Higgs boson through the process  $p\bar{p} \rightarrow t\bar{t}$  with at least one top quark decaying via  $t \rightarrow H^\pm b$ . These searches have excluded the small and large  $\tan\beta$  regions for  $H^\pm$  masses up to  $\sim 160$  GeV [18]. Other experimental bounds on the charged Higgs boson mass can be derived using processes where the charged Higgs boson enters as a virtual particle. For example, the measurement of the  $b \rightarrow s\gamma$  decay rate allows indirect limits to be set on the charged Higgs boson mass [19] which, however, are strongly model dependent [20].

The high collision energy of the LHC will allow the search for Higgs bosons to be extended into unexplored mass regions. The experiments have a large discovery potential for Higgs bosons in both the Standard Model and in the MSSM over the full parameter range. Should the Higgs boson be light, *i.e.* have a mass in the range favoured by the precision electroweak measurements, the experiments at the Tevatron might also get indications of the existence of a Higgs boson.

In this chapter, the potential for Higgs boson searches at the Large Hadron Collider with the ATLAS experiment is reviewed, focussing on the investigation of the Higgs sectors in the Standard Model and in the MSSM.

Table 1: Set of parameters used in the evaluation of the Higgs boson cross-sections (see text).

$M_{uds} = 190 \text{ MeV}$	$M_c = 1.40 \text{ GeV}$	$M_b = 4.60 \text{ GeV}$
$M_t = 172 \text{ GeV}$	$M_Z = 91.187 \text{ GeV}$	$M_W = 80.41 \text{ GeV}$
$G_F = 1.16639 \times 10^{-5} \text{ GeV}^{-2}$	$N_F = 5$	$\Lambda_{QCD}^{LO} = 165 \text{ MeV}$
$\Lambda_{QCD}^{NLO} = 226 \text{ MeV}$	$\alpha_s^{LO}(M_Z) = 0.130$	$\alpha_s^{NLO}(M_Z) = 0.118$

 Table 2: Cross-sections for Higgs boson production via gluon fusion at LO and NLO in the mass range  $100 \leq M_H \leq 1000 \text{ GeV}$ . The first column gives the Higgs boson mass, the second the LO order cross-section, the third and fourth column gives the NLO electroweak (EW) and QCD corrections respectively (see text), the last column presents the overall NLO cross-section.

## 2 Production cross-sections and branching fractions for a Standard Model Higgs boson

### 2.1 Production cross-sections

This section reports on the Standard Model Higgs boson production cross-section via gluon fusion, Vector Boson Fusion (VBF), and the associated production with a Vector Boson ( $WH$  and  $ZH$ ), to leading order (LO) and to next to leading order (NLO). The associated production with  $t\bar{t}$  is also discussed.

The calculation is performed using the CTEQ6L1 and CTEQ6M Parton Distribution Functions (PDF) at LO and NLO respectively [21]. Single and two-loop calculations of the running strong coupling constant  $\alpha_s$  are used for the LO and NLO computation respectively. Table 1 shows the values of the Standard Model parameters used in the computations.

The cross-section of the gluon fusion process is evaluated using the program HIGLU [22]. The calculation is performed with exact NLO matrix element. The renormalization and factorization scales are set to the Higgs boson mass. The values of  $\alpha_s$  are calculated according to the values of  $\Lambda_{QCD}$  given in Table 1 with 5 flavors. This approach may overestimate the LO cross-section; however this effect is expected to be negligible compared to the effect from the scale uncertainty.

Table 2 reports the cross-sections for Higgs boson production via gluon fusion at LO and NLO in

Table 3: Cross-sections for Higgs boson production via Vector Boson Fusion at LO and NLO in the mass range  $100 \leq M_H \leq 1000, \text{GeV}$ . The first column gives the Higgs boson mass, the second the LO order cross-section, the third and fourth column gives respectively the NLO electroweak (EW) and QCD corrections (see text), the fifth column presents the overall NLO cross-section.

190	0.303	0.25	-0.09	0.349
200	0.252	0.25	-0.09	0.292

the mass ranges  $100 \leq M_H \leq 1000 \text{ GeV}$ . The NLO cross-section is obtained from the LO one as follows:  $\sigma_{NLO} = \sigma_{LO} \times (1 + \delta_{QCD} + \delta_{EW})$ .

The cross-section of VBF Higgs boson production is estimated with the package VV2H F [22]. The results are reported in Table 3 as a function of the Higgs boson mass in the range  $100 \text{ GeV} \leq M_H \leq 1000 \text{ GeV}$ . The renormalization and factorization scales are set to the Higgs boson mass.

The cross-sections for  $WH$ ,  $ZH$  and  $t\bar{t}H$  production are one to two orders of magnitude below the gluon and vector boson fusion cross-sections. The values are given in Tables 4, 5, and 6 respectively.

The cross-section for the Higgs boson produced in association with  $t\bar{t}$  is estimated with the package HHQ [22]. The renormalization and factorization scales are set to  $(M_H + 2M_t)/2$ . The QCD corrections to this process are known [23, 24] and yield a K-factor of about 1.25. However it should be stressed that the main backgrounds in this analysis ( $t\bar{t}b\bar{b}$  and  $t\bar{t}jj$ ) are known to LO only. Table 6 reports the cross-section of Higgs boson production associated to  $t\bar{t}$  in the mass range  $100 \text{ GeV} \leq M_H \leq 200 \text{ GeV}$ .

The package V2HV is used to estimate the Higgs boson production cross-section in association with the  $W$  and  $Z$  bosons [22]. The renormalization and factorization scales are set to the sum of the invariant masses of the weak boson and of the Higgs boson. Tables 4 and 5 report the cross-sections of these processes in the mass range  $100 \text{ GeV} \leq M_H \leq 200 \text{ GeV}$ .

Table 5: cross-sections for the Higgs boson associated production with Z bosons at LO and NLO in the mass range  $100 \leq M_H \leq 200$  GeV.

## 2.2 Decays branching ratios

Higgs boson branching ratios are evaluated with the program HDECAY [25]. Here, the default settings defined by the authors are used (see Ref. [25]), except for the parameters specified in Table 1.

Tables 7 and 8 report the most relevant Higgs boson branching ratios for  $100 \leq M_H \leq 1000$  GeV:  $H \rightarrow b\bar{b}, \tau^+\tau^-, \gamma\gamma, ZZ^{(*)}, WW^{(*)}$  and  $t\bar{t}$ .

Figure 1 (left) shows the branching fractions and the production cross-section (right) of the Standard Model Higgs boson as a function of its mass (Figures taken from Reference [26]).

## 2.3 Standard Model Higgs boson search in ATLAS

The Standard Model Higgs boson is searched for at the LHC in various decay channels, the choice of which depends by the signal rates and the signal to background ratios in the various mass regions.

The Standard Model Higgs boson channels considered in this volume are:

- $pp \rightarrow H \rightarrow \gamma\gamma$
- $pp \rightarrow H \rightarrow ZZ^{(*)} \rightarrow 4l(l = e, \mu)$
- $pp \rightarrow qqH \rightarrow qq\tau^+\tau^-$
- $pp \rightarrow H \rightarrow W^+W^- \rightarrow l\nu l\nu, l\nu qq$

Table 7: Relevant Higgs boson branching ratios for the mass range  $100 \leq M_H \leq 200$  GeV.

$M_H(\text{GeV})$	$\Gamma_H(\text{GeV})$	$H \rightarrow b\bar{b}$	$H \rightarrow \tau^+\tau^-$	$H \rightarrow \gamma\gamma$	$H \rightarrow WW(*)$	$H \rightarrow ZZ(*)$

### 3 Higgs Bosons in the Minimal Supersymmetric Extension to the Standard Model

As discussed in the Introduction, in the Minimal Supersymmetric Standard Model two Higgs doublets are required, resulting in three neutral and two charged observable Higgs bosons. The production of neutral Higgs bosons and their decays are different from those in the Standard Model. While decays into  $ZZ$  or  $WW$  are dominant in the Standard Model for Higgs boson masses above  $M_H > 2 M_W$ , for high values of  $\tan\beta$  these decay modes are either suppressed in case of the  $h$  and  $H$  or even absent in the case of the  $A$ . Instead, the coupling of the Higgs bosons to third generation fermions are strongly enhanced for large regions of the MSSM parameter space.

Figure 1: Left: Branching ratios for the relevant decay modes of the Standard Model Higgs boson as a function of its mass. Right: cross-sections for the five production channels of the Standard Model Higgs boson at the LHC at 14 TeV.

### 3.1 Production and decays of neutral Higgs bosons

The Higgs boson production proceeds via two different mechanisms, the direct and the  $b$  quark associated production, as described below. In the following  $\phi$  stands for either of the three neutral Higgs bosons:  $A$ ,  $H$ , and  $h$ . Further details can be found in [27].

**Direct Production:** The diagram for this process is depicted in Fig. 2(a). It dominates in the range of low  $\tan\beta$  and its rates are significantly larger than for the Standard Model. For the range of higher  $\tan\beta$  it is still dominant for low  $m_A$ . The cross-section for this process has been calculated at NLO accuracy [22] and the numerical values used here are listed under  $\sigma_{h/H/A}^{\text{direct}}$  in Table 9.

**Associated Production:** Different approaches have been followed by theorists to calculate the cross-section for Higgs boson production in association with  $b$  quarks, each of them assuming one of the diagrams depicted in Fig. 2(b-d) as their leading order (LO) contribution. The implications connected with this choice are briefly discussed below.

- $gg \rightarrow b\bar{b}\phi$ :

The cross-section for this process has been calculated at NLO accuracy for the case of both  $b$  quarks at high transverse momentum [28, 29], where this calculation is considered to be reliable.

Figure 2: Feynman diagrams contributing to the MSSM Higgs boson production. Diagram a) is called ‘direct production’, diagrams b) to e) contribute to the  $b$  quark associated production. In the above diagrams  $\phi$  represents either of the neutral Higgs bosons in the MSSM,  $h$ ,  $H$ , or  $A$ .

For the cases where only one or zero  $b$  quarks with high  $p_T$  are required in the final state, the cross-section has been calculated at NLO accuracy by integrating over the momentum of one or both  $b$  quarks, respectively [28, 30, 31]. In these cases the predictions are considered less reliable due to the occurrence of potentially large collinear logarithms of the form  $\log(Q/m_b)$  from the gluon splitting process, where  $Q$  is the factorization scale which is expected to be much larger than  $m_b$ .

- $b\bar{b} \rightarrow \phi$ :  
The potentially large collinear logarithms can be dealt with by absorbing them into the parton density function (PDF) of the  $b$  quark and thus resumming them to all orders of perturbation theory. The intrinsically still present  $b$  quarks from the gluon splitting process are given zero transverse momentum at leading order. At higher order they can acquire transverse momentum. E.g. the process  $bg \rightarrow b\phi$  is a NLO contribution leading to an observable  $b$  quark. The total cross-section for this process has been calculated at NLO [32, 33] and NNLO accuracy [34] and is considered to be reliable when it is not required (but also not vetoed) to observe a  $b$  quark.
- $bg \rightarrow b\phi$ :  
This process is a mixture of the two processes discussed above in a sense that one  $b$  quark is coming from the matrix element description and the other from the  $b$  PDF. This process has been calculated at NLO accuracy [35] and is considered to be reliable if one observes only one  $b$  quark with high  $p_T$  in the final state. In principle in this case one should also veto any additional  $b$  quark which is experimentally challenging due to the limited  $b$ -tagging efficiency.
- $qq \rightarrow b\bar{b}\phi$ :  
Compared to  $gg \rightarrow b\bar{b}\phi$  this process only contributes at the 1%-level at LHC energies and is therefore only mentioned for completeness.

A comparison of the predicted cross-sections for both the inclusive and exclusive approach is shown in Figure 3. The blue band corresponds to the NNLO calculation of  $b\bar{b} \rightarrow \phi$ , where the width of the band corresponds to the residual scale uncertainties when varying the default renormalization ( $\mu_r = m_H$ ) and factorization ( $\mu_f = m_H/4$ ) scales. The red band shows the corresponding NLO calculation of  $gg \rightarrow b\bar{b}\phi$ . The scale uncertainty for  $gg \rightarrow b\bar{b}\phi$  is of the order 20 to 30%, while the scale uncertainty for  $b\bar{b} \rightarrow \phi$  is much smaller, in particular at high Higgs boson masses. This might be due to the remaining collinear logarithms in the  $gg \rightarrow b\bar{b}\phi$  calculation. However, contributions from e.g. PDF-uncertainties, in particular for the  $b$  PDF have not been included here. Both methods agree within uncertainties. At larger Higgs boson masses, the prediction from  $b\bar{b} \rightarrow \phi$  is slightly higher than that from  $gg \rightarrow b\bar{b}\phi$ . One of the effects that might explain this is the inclusion of closed-top-loops in the  $gg \rightarrow b\bar{b}\phi$  calculation, absent in the  $b\bar{b} \rightarrow \phi$  case. In conclusion, both predictions may be used to normalize an inclusive signal sample, where no cuts have been applied on the momenta of the  $b$  quarks at generator level.

Due to the finite integrated luminosity assumed to be available for the analyses discussed in this note, the inclusive normalization is chosen. The cross-section were calculated using FeynHiggs-2.6.2 [36] yielding the cross-section for a Standard Model Higgs boson. The cross-sections in the MSSM were then obtained by scaling them by the ratio of partial widths into  $b\bar{b}$ :

$$\sigma_{\text{MSSM}}^{\phi}(m_A, \tan\beta) = \sigma_{\text{SM}}(m_{\phi}) \cdot \frac{\Gamma_{b\bar{b}\phi}^{\text{MSSM}}(m_A, \tan\beta)}{\Gamma_{b\bar{b}\phi}^{\text{SM}}(m_{\phi})}. \quad (1)$$

The production cross-sections for all Higgs boson masses considered here and their branching fraction into a  $\tau^+\tau^-$  and  $\mu^+\mu^-$  final states in the  $m_h^{\text{max}}$  scenario are summarized in Table 9 for  $\tan\beta = 20$ .

Figure 3: The inclusive cross-sections for the processes  $b\bar{b} \rightarrow \phi$  (blue hatched region) and  $gg \rightarrow b\bar{b}\phi$  (red hatched region) are shown on the right-hand side; the exclusive cross-sections for  $bg \rightarrow b\phi$  (blue hatched region) and  $gg \rightarrow b\bar{b}\phi$  (red hatched region) are shown on the right-hand side. The width of the bands corresponds to the theoretical uncertainty due to the choice of renormalization and factorization scales.

### 3.2 Production and decays of charged Higgs bosons

The search strategies for charged Higgs bosons depend on the charged Higgs boson mass, which dictates both the production and the available decay modes. Below the top quark mass the main production mode is through top quark decays,  $t \rightarrow H^+ b$ , and in this range the  $H^+ \rightarrow \tau^+ \nu$  decay mode is dominant. Once above the top quark threshold, production mainly takes place through  $gb$  fusion ( $g\bar{b} \rightarrow \bar{t}H^+$ ). For such high charged Higgs boson masses, the decay into a top and a  $b$  quark dominates,  $H^+ \rightarrow t\bar{b}$ , but  $H^+ \rightarrow \tau^+ \nu$  can still be sizeable and offers a much cleaner signature. The process  $gg \rightarrow \bar{t}bH^+$  is important for charged Higgs boson production with  $m_{H^+}$  around the top mass. Since the LHC will be the first collider  $t\bar{t}$  factory, “light” charged Higgs bosons may be copiously produced through the process  $q\bar{q}, gg \rightarrow t\bar{t} \rightarrow \bar{t}bH^+$  [37]. While this is the dominant production mode, there are other processes which also contribute to the light charged Higgs boson production, like single top events or diagrams with the same final state as mentioned above ( $tbH^+$ ), but which do not proceed through  $t\bar{t}$  production.  $H^+$  events through single top production are not considered in this volume.

The charged Higgs boson production cross-section is evaluated for two different MSSM scenarios. They are chosen such that in Scenario A the decay of  $H^+$  into SUSY particles is suppressed, and in Scenario B (also known as the “ $m_h$ -max” scenario) the mass of the lightest Higgs boson  $h^0$  is maximised.

Table 9: Mass, cross-section for direct production, cross section for  $b$ -associated production, and branching fractions into  $\tau^+ \tau^-$  and  $\mu^+ \mu^-$  final states for Higgs bosons in the  $m_h^{\max}$  scenario and for  $\tan \beta = 20$ . All values were obtained using FeynHiggs-2.6.2 and HIGLU.

Mass / GeV			$\sigma_{h/H/A}^{\text{direct}}/\text{fb}$			$\sigma_{h/H/A}^{\text{associated}}/\text{fb}$			$\mathcal{B}(h/H/A \rightarrow \tau^+ \tau^-)/\%$			$\mathcal{B}(h/H/A \rightarrow \mu^+ \mu^-)/\%$		
A	H	h	A	H	h	A	H	h	A	H	h	A	H	h

For the two scenarios the following set of parameters have been used:

Scenario A:

- $m_t = 175$  GeV
- $M_{\text{SUSY}} = 500$  GeV
- $A_t = 1000$  GeV
- $\mu = 200$  GeV
- $M_2 = 1000$  GeV
- $M_3 = 1000$  GeV

Scenario B (“ $m_h$ -max”):

- $m_t = 170$  GeV
- $M_{\text{SUSY}} = 1000$  GeV
- $X_t = 2000$  GeV, where  $A_t = X_t + \mu / \tan \beta$
- $\mu = 200$  GeV
- $M_2 = 200$  GeV
- $M_3 = 800$  GeV

$M_{\text{SUSY}}$  denotes the soft SUSY-breaking mass parameter in the sfermion sector,  $m_t X_t$  is the off-diagonal entry in the stop mass matrix,  $\mu$  the Higgsino mixing parameter, and  $M_2$  and  $M_3$  the soft SUSY-breaking mass parameters in the SU(2) gaugino and the gluino sector, respectively. In the following, numerical NLO cross-sections for the low-mass  $H^+$  region are calculated with FeynHiggs (version 2.6.2 [36]). Heavy  $H^+$  NLO cross-sections are obtained with Ref. [38] and corrected with the dominant supersymmetry loop corrections (reflecting the altered relation between the bottom quark mass and its Yukawa coupling,  $\Delta m_b$ ) as proposed in Ref. [39].

Figure 4 shows the results for the  $tbH^+$  final state as a function of  $\tan \beta$  for the MSSM scenarios A and B. The production cross-section has a minimum at  $\tan \beta \approx 7$ . This is caused by a minimum in the  $H^+ tb$  Yukawa coupling and renders the so-called intermediate  $\tan \beta$  region ( $4 < \tan \beta < 10$ ) which is experimentally hard to reach.

Figure 4: Expected charged Higgs boson production cross-section in the MSSM for scenarios A and B for light [36] and heavy charged Higgs bosons [38].

Below the top quark mass, the charged Higgs boson predominantly decays into a  $\tau$  lepton and a neutrino, and for values of  $\tan \beta > 5$  this branching ratio is close to 100%, as shown in Figures 5 and 6. Decay modes involving  $c\bar{s}$  and  $Wh$  are also present, but depending on the value of  $\tan \beta$  they are one or two orders of magnitude smaller than  $\tau\nu$ . The decay of the W boson originating from the associated top quark adds variety to the possible charged Higgs boson signatures, but it also provides handles for signal reconstruction and, even more important, for background rejection.

Once above the top quark mass threshold, the  $H^+ \rightarrow t\bar{b}$  decay mode shows a rapid growth and soon becomes an important decay mode as shown in Figure 5. Contrary to the light charged Higgs boson,

Figure 5: Charged Higgs boson branching ratios as a function of mass for the  $m_h$ -max scenario for  $\tan\beta = 2$  and  $\tan\beta = 35$  and three selected decay modes.

for which the  $H^+ \rightarrow \tau^+ \nu$  decay mode is an almost exclusive decay mode, the heavy charged Higgs  $H^+$  boson does not solely decay into  $t\bar{b}$ , but a significant fraction is allowed to decay into other decay modes like  $\tau^+ \nu$ ,  $W^+ h$ ,  $c\bar{s}$  or SUSY particles where kinematically allowed.

The calculations are performed with FeynHiggs [36], as it allows to calculate both the  $\text{BR}(t \rightarrow H^+ b)$  and the  $H^+$  decay branching in a consistent way, and includes important corrections to the tree level values. Figure 6 shows the calculated branching ratios for two different charged Higgs boson masses, one light (130 GeV) and one heavy (600 GeV), as a function of  $\tan\beta$ .

Figure 6: Expected charged Higgs boson branching ratios in the MSSM for scenarios A and B for the example of a light ( $m_{H^+} = 130$  GeV) and a heavy ( $m_{H^+} = 600$  GeV) charged Higgs boson [36].

# Prospects for the Discovery of the Standard Model Higgs Boson Using the $H \rightarrow \gamma\gamma$ Decay

## Abstract

The discovery potential for the Standard Model Higgs boson through the  $H \rightarrow \gamma\gamma$  decay in the ATLAS detector is reported. Various performance aspects of the Higgs boson mass reconstruction and the photon identification are discussed. Trigger issues are also considered. The potential of an inclusive  $H \rightarrow \gamma\gamma$  search and Higgs boson searches in association with one or two high  $p_T$  jets are evaluated. Studies of the associated  $WH$ ,  $ZH$  and  $t\bar{t}H$  production processes are also presented. Finally, the discovery potential is assessed using an unbinned multivariate maximum-likelihood fit. These studies are performed for experimental conditions expected for an instantaneous luminosity of  $\approx 10^{33} \text{ cm}^{-2} \text{ s}^{-1}$ .

## 1 Introduction

In the mass range  $110 < m_H < 140$  GeV the Higgs boson is expected to decay into two photons with a branching fraction large enough to render the search feasible at the LHC [1]. The inclusive search for the Higgs boson in the diphoton decay channel has been studied in ATLAS for many years and constitutes one of the benchmarks for the detector performance [2–4]. In this paper the sensitivity of ATLAS to this channel is re-evaluated with an updated detector description and software. The impact of higher order QCD and electroweak corrections on the discovery potential is also evaluated.

The Higgs boson can be produced in association with hadronic jets of high transverse momentum,  $p_T$ . Gluons from initial-state radiation in the  $gg \rightarrow H$  and  $q\bar{q} \rightarrow q\bar{q}H$  Vector Boson Fusion (VBF) processes are the largest contributors to Higgs boson production in association with high  $p_T$  hadronic jets. The search for a Higgs boson using the diphoton decay mode in association with one and two jets at the LHC has been suggested [5–7] and a previous analysis reported on feasibility studies for these final states using a fast detector simulation [8, 9]. This paper presents an update of these studies based on a more complete description of the detector simulation.

In addition to the diphoton invariant mass, other discriminating variables are incorporated into the analysis and combined by means of an unbinned maximum-likelihood fit. Photon reconstruction properties and the event topology are used to separate the data sample into categories that are fit simultaneously.

In the search for a Standard Model Higgs boson, the associated production with  $W$ ,  $Z$ , or  $t\bar{t}$  can serve to complement the inclusive Higgs boson and Higgs boson + jets channels and help to determine the Higgs boson coupling to the Standard Model gauge bosons and the Yukawa coupling to the top quark [10]. These measurements would provide consistency checks of the Standard Model. They could also be interpreted in terms of Minimal Supersymmetric Standard Model couplings at high  $\tan\beta$  (for  $m_H \sim 120$  GeV) and high  $m_A$ . Deviations from Standard Model rates could imply new physics such as gauge-Higgs unification [11, 12] or the presence of resonances in models of little Higgs [13, 14], Left-Right symmetry [15] or technicolour [16]. The feasibility of diphoton searches in association with weak vector bosons is evaluated using a full detector simulation. This involves searches for diphotons in association with either just missing transverse energy,  $E_T^{\text{miss}}$ , or  $E_T^{\text{miss}}$  and a charged lepton (electron or muon), and updates earlier studies performed with a fast detector simulation [17, 18].

## 2 Monte Carlo event generation

The Monte Carlo (MC) event generation required for this paper is split into two main groups. The first group corresponds to MC samples produced with a full detector simulation based on GEANT4 [19]. These are used for the evaluation of detailed detector effects relevant to the analyses. The second group of MC samples are processed with a fast detector simulation [20] and are used primarily for the evaluation of the analysis sensitivity. For example, the Higgs boson mass resolution, photon identification efficiency and photon-jet rejection are evaluated with a full detector simulation. The resulting photon efficiency and photon-jet rejection are parameterised as a function of the photon  $p_T$  and these parameterisations are then applied to the fast detector simulation.

### 2.1 Signal processes

Signal events are generated using PYTHIA [21]: this package implements Leading Order (LO) Matrix Element calculations for all the signal processes considered here. The gluon fusion process is also simulated with the MC@NLO [22, 23] package. This package provides QCD Next-to-Leading-Order (NLO) Matrix Elements [24–27] in addition to a good description of multiple soft-gluon emission at next-to-next-to-leading logarithmic level (NNLL) [28–30]. This is relevant to evaluating the discriminating power of the diphoton  $p_T$  and other relevant variables. All signal processes used here are processed through a full detector simulation. Signal events produced via the VBF mechanism are also modeled with HERWIG [31]. All the generated samples for signal processes used here are normalized to the NLO cross-sections [32] taking into account only QCD corrections.

### 2.2 Background processes

Background processes can be split into two main groups: backgrounds coming from the production of two isolated photons, which are usually referred to as irreducible, and reducible backgrounds coming from events with at least one fake photon. Fake photons are mostly due to the presence of a leading  $\pi^0$  resulting from the fragmentation of a quark or a gluon. Table 1 gives a summary of the MC packages and the cross-sections (in pb) for the irreducible and reducible backgrounds used here.

In this paper QCD corrections to both signal and background are considered in the inclusive analysis. The irreducible background is mainly due to the  $q\bar{q}, qg \rightarrow \gamma\gamma x$  processes at up to order  $\alpha^2\alpha_s$  (namely the Born and Bremsstrahlung contributions) and the  $gg \rightarrow \gamma\gamma$  up to order  $\alpha^2\alpha_s^3$  (referred to as the box contribution). Contributions from photons produced collinear to quarks are also taken into account at NLO. The DIPHOX [33] and ResBos [34–36] programs are used to assess the irreducible background computation. DIPHOX includes all the processes to order  $\alpha^2\alpha_s$ , including the Bremsstrahlung contribution with the quasi collinear fragmentation of quarks and gluons which are computed at NLO. DIPHOX does not include resummation effects. ResBos includes the Born and box contributions at NLO as well as the bremsstrahlung contribution (but the fragmentation contribution is only at LO). ResBos includes resummation effects to NNLL.

In these computations, a parton level isolation cut of 15 GeV in a cone of  $\Delta R = 0.4$  is used. This is checked against the real photon identification cuts using PYTHIA fully simulated events. DIPHOX and ResBos predictions for the total irreducible background agree to better than 10% [37].

Table 1 shows the cross-sections used to normalize the MC generation in the inclusive analysis. The cross-sections for  $q\bar{q}, qg \rightarrow \gamma\gamma x$  and  $gg \rightarrow \gamma\gamma$  quoted in Table 1 were computed with ResBos for  $80 < m_{\gamma\gamma} < 150$  GeV, where  $m_{\gamma\gamma}$  is the invariant mass of the diphoton system, and  $p_{T\gamma} > 25$  GeV, where  $p_{T\gamma}$  is the transverse momentum of the photons. Photons are required to lie in the central region of the detector,  $|\eta| < 2.5$ . The factorization and renormalization scales are set dynamically as the invariant mass of the diphoton system.

Table 1: Details of the cross-section calculation and event generation for the irreducible and reducible photonic backgrounds used in the  $H \rightarrow \gamma\gamma$  analysis. The first three columns display the cross-section calculators, kinematic cuts and resulting cross-sections (in pb). The last two columns show the MC packages used for event generation and the number of events generated with a full and fast detector simulations, respectively.

Process	$\sigma$ calculator	Cuts	$\sigma$ (pb)	Full simulation # of events	Fast simulation # of events
$q\bar{q}, qg \rightarrow \gamma\gamma x$	ResBos/ DIPHOX	$80 < m_{\gamma\gamma} < 150$ GeV $p_{T\gamma} > 25$ GeV, $ \eta  < 2.5$	20.9	PYTHIA/ALPGEN 200000/1300000	ALPGEN 1670000
$gg \rightarrow \gamma\gamma$	ResBos	$80 < m_{\gamma\gamma} < 150$ GeV $p_{T\gamma} > 25$ GeV, $ \eta  < 2.5$	8.0	PYTHIA 200000	PYTHIA 850000
$\gamma j$	JETPHOX	$p_{T\gamma} > 25$ GeV	$180 \cdot 10^3$	PYTHIA 3000000	ALPGEN 36700000
$jj$	NLOJET++	$p_T > 25$ GeV	$477 \cdot 10^6$	PYTHIA 10000000	ALPGEN 37000000

In order to evaluate irreducible backgrounds for signal-significance computations and to include the effect of high- $p_T$  jets, the ALPGEN MC generator is used [38, 39].<sup>1</sup> This includes  $2 \rightarrow N$  tree-level Matrix Elements, where  $N = 2 - 5$ . The minimum parton  $p_T$  and maximum pseudorapidity are set to 20 GeV and  $|\eta| < 5$ , respectively. A prescription for the merging of matrix elements and parton showers is used [41]. The  $p_T$  threshold for the merging of the parton shower and the Matrix Elements is set to 20 GeV and  $\Delta R = 0.7$ .

The total cross-section of the ALPGEN samples of  $\gamma\gamma$ +jets events is normalized to the cross-section given in Table 1. The diphoton invariant mass and transverse momentum spectra are re-weighted to the corresponding spectra obtained with ResBos for the Born and Bremsstrahlung contributions. This is motivated by the fact that ResBos provides a NNLL description of the resummation effects that significantly affects the  $p_T$  spectrum of the diphoton system up to about 40 or 50 GeV.

The box contribution is simulated with the PYTHIA package using the leading order one loop Matrix Elements with full and fast detector simulations. The cross-section of this sample is normalized to the cross-section given in Table 1. The diphoton invariant mass and momentum spectra are re-weighted to the corresponding spectra obtained with ResBos.

The total inclusive cross-section for the  $\gamma j$  process is obtained using the package JETPHOX [42]. This package simulates direct and fragmentation single photon production. The distribution of the photon  $p_T$  that is obtained is compared with that for direct production predicted using the PYTHIA package. It is observed that the differential cross-section obtained with JETPHOX is a factor of 2.1 larger than that obtained with PYTHIA, with a weak  $p_T$  dependence. Table 1 shows the cross-section for inclusive  $\gamma j$  production for  $p_{T\gamma} > 25$  GeV.

The inclusive dijet cross-section is computed with the help of the NLOJET++ package [43,44], which takes into account QCD NLO corrections. The dijet cross-section obtained with this program is found to be a factor of 1.3 larger than that obtained with PYTHIA. Table 1 shows the cross-section for inclusive dijet production for  $p_T > 25$  GeV.

For purposes of signal significance computation the ALPGEN MC package is used to generate sam-

<sup>1</sup>This generation does not include the box contribution nor the electroweak  $\gamma\gamma jj$  process. The latter is generated with the MadGraph package [40] and it is used in the Higgs boson searches in association with hadronic jets only (see Sections 5.2 and 5.3).

Table 2: Event generators and cross-sections for backgrounds used in the analyses of associated production. Photons are required to be in  $|\eta| < 2.7$  and to have  $p_T > 20$  GeV. For the  $W^\pm(\rightarrow e^\pm \nu)\gamma$  process the electron is required to pass the same cuts as the photons. The diphoton invariant mass should be in the interval  $90 < m_{\gamma\gamma} < 150$  GeV, when appropriate. For the  $b\bar{b}\gamma\gamma$  process the  $p_T$  of the b quark is required to be greater than 20 GeV.

Process	Generator	Cross-section	Number of events
$Z(\rightarrow \ell\ell)\gamma\gamma$	MadGraph	2.4 fb	17500
$Z(\rightarrow \nu\nu)\gamma\gamma$	MadGraph	4.9 fb	17500
$W^+(\rightarrow \ell\nu)\gamma\gamma$	MadGraph	3.3 fb	28200
$W^-(\rightarrow \ell\nu)\gamma\gamma$	MadGraph	3.1 fb	31500
$W^\pm(\rightarrow e^\pm \nu)\gamma$	PYTHIA	5.9 pb	218350
$c\bar{c}\gamma\gamma$	MadGraph	257 fb	5000
$b\bar{b}\gamma\gamma$	MadGraph	24.41 fb	5000
$t\bar{t}\gamma\gamma$	MadGraph	1.97 fb	4900

ples of  $\gamma$ +jets and multi-jets with a fast detector simulation. ALPGEN includes  $2 \rightarrow N$  tree-level Matrix Elements, where  $N = 2 - 5$ . The minimum parton  $p_T$  and pseudorapidity range are set to 20 GeV and  $|\eta| < 6$ , respectively. The same matching conditions as in the  $\gamma\gamma$ +jets sample are used. The samples generated with ALPGEN are normalized to cross-sections given in Table 1.

A small background contribution is expected from Drell-Yan  $e^+e^-$  faking a photon pair. For this purpose 420k events were generated using the PYTHIA package with a full detector simulation. The generator cross-section after requiring one lepton with  $p_T > 10$  GeV and  $|\eta| < 2.7$  is 1.23 nb.

Specific backgrounds contributing to the Higgs boson plus lepton and Higgs boson plus missing transverse energy channels are also produced.  $W/Z$  + diphoton backgrounds can produce the same topology as the signal. To evaluate the contributions from these backgrounds, the MadGraph [40] generator, which includes the  $Z$  and  $W$  bosons produced in association with two photons with tree-level diagrams has been used. The cross-sections for these processes, including the leptonic branching ratios, are shown in Table 2, requiring that the photons have  $p_T > 20$  GeV and  $|\eta| < 2.7$ , and that the invariant mass of the two photons be between 90 and 150 GeV.

The  $c\bar{c}\gamma\gamma$ ,  $b\bar{b}\gamma\gamma$  and  $t\bar{t}\gamma\gamma$  cross-sections shown in Table 2 do not include the branching ratios of leptonic decays. For the  $b\bar{b}\gamma\gamma$  process the transverse momentum of the b quark is required to be greater than 20 GeV. In the  $t\bar{t}\gamma\gamma$  events, also produced by MadGraph, the photons only come from the top quarks. The contribution from events in which photons arise from the decay products of the  $t\bar{t}$  system was roughly evaluated. Events were generated with PYTHIA using the Matrix Elements for the  $t\bar{t}$  process. The production of two additional high  $p_T$  photons coming from the final state radiation of the top quark decay products was evaluated. It was found that the  $t\bar{t}\gamma\gamma$  background needs to be multiplied by a factor 7.5 to account for this effect: this factor was applied for the analysis of the associated channel. It is probably conservative because the photons radiated by the quarks should not be isolated and would be removed by the analysis cuts.

There is a contribution to the background from events with a  $W$  boson and a photon, where the  $W$  boson decays into an electron and a neutrino. In some events, the electron can be mis-reconstructed as a photon. The PYTHIA generator is used for this background and the cross-section, including the leptonic branching ratio, is given in Table 2 after requiring  $p_T > 20$  GeV and  $|\eta| < 2.7$  for both the photon and the electron. For all the processes in Table 2 a full detector simulation was used and QED radiative corrections to the  $Z/W$  decays were treated with PHOTOS [45].

### 3 Photon selection and $\gamma\gamma$ reconstruction

#### 3.1 Photon reconstruction and calibration

Photons in the calorimeter are reconstructed from clusters of different sizes: in the barrel region ( $|\eta| < 1.37$ ) a  $\Delta\eta \times \Delta\phi = 3 \times 7$  cluster (in units of middle sampling calorimeter cells) is used for converted photons to recover as much as possible the energy that might be lost due to the opening of the two electrons in the magnetic field. A  $3 \times 5$  cluster is used for unconverted photons. In the endcap region ( $1.52 < |\eta| < 2.37$ ) a  $5 \times 5$  cluster has been used for both converted and unconverted photons. The chosen cluster sizes are a compromise between maximal energy containment and minimization of the noise. In the simulation, all the effects that contribute to the calorimeter resolution constant term, which by design should be kept below 0.7%, are taken into account by smearing the reconstructed cells energies. The energy of the photons in the electromagnetic (EM) calorimeter has been reconstructed using appropriate weights for the presampler and back compartments of the calorimeter to correct for the energy lost in the material in front of the calorimeter, for the longitudinal leakage and for the energy losses outside the cluster. Different weights for unconverted photons and electrons are used, as derived from the nominal detector geometry (see Ref. [46] for details). Clusters are then corrected for a series of effects. The variations of the energy with respect to the impact point inside each cell are corrected for. These effects are due to the fact that the shower is not fully contained inside the cluster (the effect is larger for small cluster sizes) and to the calorimeter material structure in  $\phi$ . The photon candidate position is defined as the barycenter of the associated cluster: the fact that the cells have a finite granularity introduces a bias in the measured position which is corrected for as a function of the particle impact point within the central cell (more details in Ref. [46]).

#### 3.2 Photon identification

Powerful photon identification is required to reduce the background from jets faking photons (from  $jj$  events and  $\gamma j$  events) below the irreducible background. The photon identification relies on the fine segmentation of the electromagnetic calorimeter, especially the first layer, allowing an event-by-event rejection of “isolated”  $\pi^0$ s, which are the main source of fake photons from jets. The details of the shower-shape variables and the cuts can be found in Ref. [47]. The shower-shape variables include the leakage in the first compartment of the hadronic calorimeter, variables characterizing the lateral size of the shower in the second layer of the EM calorimeter, and variables related to the transverse size in the first layer of the EM calorimeter, together with a search for a second maximum in  $\eta$  in the energy deposited in the strips of the first layer. The average efficiency of the calorimeter cuts for photons from Higgs boson decays with  $p_T > 25$  GeV has been found to be 83% when pile-up corresponding to  $10^{33} \text{cm}^{-2} \text{s}^{-1}$  instantaneous luminosity is added. A track isolation cut is also applied to reduce further the fake background: the sum of the  $p_T$  of tracks in a  $\Delta R = 0.3$  cone around the cluster position is computed for tracks with  $p_T > 1$  GeV and a cut at 4 GeV is applied. For tracks with  $\Delta R < 0.1$  of the cluster position additional cuts are applied to remove conversion tracks from the sum. The efficiency of this cut for photons fulfilling all other identification cuts is 98% [47]. The cuts have been optimized using photons from Higgs boson decays as a signal sample and an inclusive jet sample for the fake rate study. The optimisation of the cuts has been done mostly in the  $E_T$  range 25 – 35 GeV and the same cuts are applied to converted and unconverted photons. Table 3 shows the rejection factors for inclusive jets (normalized to jets found from the simulated particles without detector effects using a cone of size  $\Delta R = 0.4$ ), as measured from the inclusive jet sample. The rejection is also given separately for quark and gluon jets. The difference in rejection comes from the different fragmentation. After all cuts, the dominant background comes from “single”  $\pi^0$ s. The uncertainty on the rejection (uncertainty on the fragmentation, modeling of the detector response) is close to a factor of two [47].

Table 3: Jet rejections expected for the inclusive jet sample for  $E_T > 25$  GeV. The results are shown before and after track isolation cuts for all jets and separately for quark and gluon jets. The errors are statistical only.

	All	quark-jet	gluon-jet
Rejection (before isolation)	$5070 \pm 120$	$1770 \pm 50$	$15000 \pm 700$
Rejection (after isolation)	$8160 \pm 250$	$2760 \pm 100$	$27500 \pm 2000$

### 3.3 Conversion reconstruction

Considering Higgs boson decays with photons within  $|\eta| < 2.5$ , about 57% of the selected events have at least one true conversion with a radius smaller than 80 cm. Converted photons may start showering before the beginning of the calorimeter thereby degrading the energy resolution. In addition, the energy deposition in the calorimeter from a converted photon is geometrically broader in  $\phi$  than that from an unconverted photon due to the magnetic field in the Inner Detector cavity. On the other hand when a photon from a Higgs boson decay converts, the measurement of the conversion radius can be used to improve the accuracy on the measurement of the photon direction (see Section 3.4).

Conversions are reconstructed by a vertexing algorithm using the reconstructed particle tracks, as explained in more detail in Ref. [48]. An electromagnetic cluster with an associated track which is one of the two tracks of a conversion, is classified as a *double track conversion*. When a photon converts and only one reconstructed track is associated to the corresponding cluster this photon may be mis-identified as an electron: in order to increase the conversion reconstruction efficiency when an electromagnetic cluster has an associated track with no B-layer hit and the associated track does not belong to a reconstructed double track conversion, this object is classified as a *single track conversion*. Including single track conversions in the analysis increases by  $\approx 6\%$  the signal efficiency while the overall background is increased by approximately the same factor. The conversion reconstruction efficiency as a function of the conversion radius is shown in Fig. 1: with the reconstruction software version used for this analysis, the overall efficiency is  $\approx 66.4\%$  for conversions with a radius below 40 cm. The different contributions from single-track and double-track conversion reconstruction are also shown.

Figure 1: Efficiency of single-track and double-track conversion reconstruction as a function of the conversion radius.

For a given electromagnetic cluster, more than one associated reconstructed conversion can be found:

multiple conversions are due to secondary conversions or fake conversions. Fake conversions arise from two tracks that do not come from a conversion or with only one of the two tracks coming from a conversion. In the case of multiple conversions, the conversion with the smallest radius is selected: the reconstructed conversion is then correctly associated to a converted photon from a Higgs boson decay in 97.6% of simulated signal cases.

The jet contribution to the total background can be evaluated from the analysis of converted photons (see Ref. [48] for more details and updated results). The presence of tracks associated to the conversion provides a measurement of the transverse momentum of the converted photon in the tracker and consequently an evaluation of the ratio  $p_T/E_T$ , where  $E_T$  is the transverse energy of the calorimeter cluster. This variable should be distributed between 0 and 1. As shown in Fig. 2, converted photons have values of  $p_T/E_T$  which populate the region around 1 with a large non Gaussian tail to lower values due to bremsstrahlung of the electrons. In contrast, the distribution expected for a converted photon from a  $\pi^0$  with the same transverse energy peaks at much lower values since the cluster collects the full energy of both photons from  $\pi^0$  decay. It is particularly instructive to note that Fig. 2 also shows that the expected distributions for  $p_T/E_T$  for jets passing all the photon identification cuts is very similar to that obtained from single  $\pi^0$ 's with the same transverse energy: this indicates that the residual background from jets is dominated by single  $\pi^0$ 's. The shapes in Fig. 2 for converted photons coming from a jet and converted photons from the direct process can be parametrized and used to discriminate between the two components in a data sample of conversion events, allowing an evaluation of the  $\gamma j$  and  $j j$  percentage in the background.

Figure 2:  $p_T/E_T$  ratio for conversions where both tracks were reconstructed in different event samples.

### 3.4 Primary vertex reconstruction

Among the reconstructed photons passing the identification cuts, the two with highest  $p_T$  are assumed to come from the Higgs boson decay. The azimuthal angle  $\phi$  is determined by the cluster barycenter in the second layer of the EM calorimeter. The pseudorapidity  $\eta$  relies on the knowledge of the position  $z_H$  at which the Higgs boson is produced and decays.

Exploiting the multi-layer structure of the EM calorimeter, an estimate of the direction of each photon can be achieved by fitting a straight line in the  $(R, z)$  plane through the cluster barycenters detected in the presampler and in the first and second samplings of the EM calorimeter. The intercept of these lines with the ATLAS beam axis provides two independent measurements of the hard scattering vertex,  $z_{\gamma 1}$  and  $z_{\gamma 2}$  with their uncertainties. They are combined in a weighted average with the nominal interaction vertex

at  $z_0 = 0$  which has a spread of  $\pm 56$  mm to yield a calorimeter estimate,  $z_H^{\text{calo}}$ , of the primary vertex. The performance expected for  $H \rightarrow \gamma\gamma$  events is displayed in Table 4 and Fig. 3 (left plot). The accuracy (RMS) of the primary vertex position reconstruction is 13 mm, 17 mm, 41 mm, when both photons are in the barrel, one in the barrel and one in the endcap, and both in the endcap. In the simulation of the events used for this analysis a 4mm shift of the electromagnetic calorimeter along the z-axis was introduced (see Ref. [49] for more details) with respect to the nominal position. This effect has been taken into account at the reconstruction level, recalculating the pseudorapidity of the cells in each calorimeter layer with respect to the interaction point taking as a radial position reference the geometrical center (in the radial direction) of the cell. To compute the photon direction, the pointing algorithm makes use of the radial position of the barycenter of the shower instead of the geometrical center of the cell biasing the distribution of the reconstructed primary vertex position obtained from calorimeter pointing with respect to the true position as shown in Fig. 3, left plot (see Ref. [50] for more details). When a conversion is reconstructed, its coordinates are added as an extra point to the straight line fit, thus improving the Higgs boson vertex position accuracy; the distribution exhibits large tails with an RMS of 8 mm and a narrow Gaussian core with a width of 0.15 mm.

By adding the reconstructed primary vertex to the linear fit, the best Higgs boson position accuracy is achieved, with a Gaussian width of 0.07 mm (see Table 4 and Fig. 3, plot on the right). In the case of pile-up, more than one primary vertex may be reconstructed by the inner detectors. The discrimination of the hard-scattering vertex from pile-up vertices is done using a likelihood that is a combination of the calorimeter information and the sum of the squares of the  $p_T$ s of the tracks originating from the vertex (named  $P_T^2$  in the following). So

$$\mathcal{L} = \mathcal{L}_{P_T^2} \times \mathcal{L}_{\text{calo}} \quad (1)$$

where

$$\mathcal{L}_{P_T^2} = p_H(p_T^2) / p_{MB}(p_T^2) \quad (2)$$

$$\mathcal{L}_{\text{calo}} = e^{-\frac{1}{2} \frac{z^2}{56^2}} \times e^{-\frac{1}{2} \frac{(z - z_{\text{calo}})^2}{\sigma_{\text{calo}}^2}} / e^{-\frac{1}{2} \frac{z^2}{56^2}} = e^{-\frac{1}{2} \frac{(z - z_{\text{calo}})^2}{\sigma_{\text{calo}}^2}} \quad (3)$$

The first component of the likelihood,  $\mathcal{L}_{P_T^2}$ , is, for a certain value of  $P_T^2$ , the probability for the Higgs boson vertex to have this  $P_T^2$  divided by the same probability for a minimum bias vertex. The second component is the product of the probabilities that a measured vertex is that of the Higgs boson vertex divided by the probability that the measured vertex position is that of a minimum bias vertex. The vertex misidentification due to pile-up is displayed by the columns labeled ‘tail’ in Table 4. When the vertex associated to the Higgs boson production is correctly identified among the others, the impact of the direction measurement on the invariant mass resolution becomes negligible with respect to that of the energy measurement.

### 3.5 Invariant mass and signal acceptances

The invariant mass of diphoton pairs has been reconstructed for different signal samples using the tools described in the previous Sections: the 2g17i trigger selection (see Section 4 for more details) is applied and two identified photons are required to be reconstructed with  $p_T > 40$  GeV and  $p_T > 25$  GeV within the fiducial region of  $0 < |\eta| < 1.37$  and  $1.52 < |\eta| < 2.37$ . Fig. 4 presents the invariant mass distributions of  $\gamma\gamma$  pairs from Higgs boson decay with  $m_H = 120$  GeV. The shaded histograms correspond to events with at least one true converted photon with a conversion radius smaller than 80 cm. The converted photons are currently calibrated at the electron scale and the unconverted ones at the photon scale: in the case of the geometry with additional material in front of the calorimeter, the observed difference

Table 4: Performance of the Higgs boson longitudinal vertex position reconstruction, using calorimeter pointing only ( $z_H^{\text{calo}}$ ) and the reconstructed primary vertex ( $z_H^{\text{calo+vtx}}$ ): averages ( $\langle \rangle$ ) and RMS are displayed in mm. ‘tail’ shows the percentage of events which are outside the histogramme window ( $\pm 100$  mm and  $\pm 1$  mm for  $z_H^{\text{calo}}$  and  $z_H^{\text{calo+vtx}}$  respectively).

Luminosity	$z_H^{\text{calo}} - z_H^{\text{true}}$ (mm)			$z_H^{\text{calo+vtx}} - z_H^{\text{true}}$ (mm)		
	$\langle \rangle$	RMS	tail(%)	$\langle \rangle$	RMS	tail(%)
No pileup	2.3	17.3	0.09	-0.008	0.10	1.2
$10^{33}$	3.3	17.4	0.09	-0.010	0.10	13.0
$2 \cdot 10^{33}$	2.4	17.1	0.18	-0.007	0.10	18.3

Figure 3: Difference between the reconstructed primary vertex position and the true position obtained from calorimetric pointing and conversion track information (when available) without/with the reconstructed primary vertex (left/right plot), for events without pile-up (black plots) and with pile-up evaluated for  $10^{33}$  and  $2 \cdot 10^{33} \text{ cm}^{-2} \text{ s}^{-1}$  (red, green plots). The narrow peak on top of the broader one is due to events in which at least one photon has a reconstructed conversion vertex. In the right plots, the non-Gaussian shape is due to the overlap of barrel-barrel, barrel-endcap and endcap-endcap topologies, which have different resolutions.

between the peak of the distribution of events with no conversions and the one with at least one reconstructed conversion is around 1 %. In the future a specific calibration will be implemented for converted photons using the same prescription as that used for electrons and unconverted photons.

To be consistent with previous studies ([4], [3]) the mass resolution obtained for the photon pairs has been determined from an asymmetric Gaussian fit ( $[-2 \sigma, +3 \sigma]$ ) of the invariant mass peak. The asymmetric window is used to reduce the impact of the residual low energy tails in the reported width. Table 5 shows the results for different Higgs boson masses with and without pileup at  $10^{33} \text{ cm}^{-2} \text{ s}^{-1}$  in the case of simulations with additional dead material in front of the calorimeter (see Ref. [49] for more details). Since the energy calibration coefficients have been calculated using the nominal geometry, the presence of additional dead material in front of the calorimeter affects the determination of the value of the invariant mass, moving the peak mean down by a few per mille. In addition it increases the amount of low energy tails: the percentage of events with a reconstructed invariant mass more than  $3\sigma$  from the mean increases from 3.5 % for the nominal geometry to 6.8 % for the distorted geometry.

Figure 4: Invariant mass distributions for photons pairs from Higgs boson decays with  $m_H = 120$  GeV after trigger and identification cuts; on the left the invariant mass distribution obtained using the nominal geometry simulation is reported while on the right plot the same invariant mass distribution is reported when additional dead material is included in the simulation. The shaded histograms correspond to events with at least one converted photon.

The acceptances after trigger selection (see Section 4 for more details) and analysis cuts together with the mass resolutions for the different values of  $m_H$  are reported in Table 5. The mass window for the evaluation of the signal significance (denoted *mass bin*) is defined as  $\pm 1.4\sigma$  around the central value. As can be seen in Table 5 the fraction of signal events in the mass bin is 26 % for  $m_H = 120$  GeV slightly increasing with the Higgs boson mass. The relative mass resolution  $\sigma_m/m$  is close to 1.2 % degrading by a few percent relative when the pileup is added.

Table 5: Efficiencies after trigger, identification and inclusive analysis cuts (see Section 5.1). Reconstructed invariant mass peak positions and resolutions for different Higgs boson masses with and without  $10^{33} \text{ cm}^{-2}\text{s}^{-1}$  pileup are also reported. Distorted geometry has been used in all cases.

	$m_H = 120$ GeV		$m_H = 130$ GeV		$m_H = 140$ GeV	
	No pileup	Pileup	No pileup	pileup	No pileup	Pileup

### 3.6 Background analysis on fully simulated samples

Large samples of  $\gamma\gamma$  and  $\gamma j$  events as well as Drell-Yan  $Z \rightarrow e^+e^-$  were generated with PYTHIA and fully simulated. The differential cross-section at LO as a function of the diphoton invariant mass for  $\gamma j$  and  $e^+e^-$  events after the analysis procedure described in previous sections is reported in Fig. 5. For the  $jj$  background contribution evaluation not enough statistic was available in full simulation and it has been estimated only from fast simulated events using photon efficiency and the jet rejection parametrizations obtained from full simulation.

Figure 5: Diphoton candidates invariant mass distribution for  $\gamma j$  (left) and Drell-Yan  $e^+e^-$  (right) events after photon identification and analysis cuts with and without trigger selection.

The goodness of the photon efficiency and jet rejection parametrizations used in Section 5 on fast simulated events to estimate the background contributions has been tested on the  $\gamma j$  sample in full simulation: the distribution of the cross-section as a function of the diphoton candidates invariant mass has found to be in agreement within 15 % in the 110-150 GeV mass range with the distribution from the fast simulated sample after photon efficiency and jet rejection parametrization used in Section 5.

### 3.7 Jet tagging in simulation

Section 5 presents two analyses which rely on tagging hadronic jets. Jet tagging is particularly relevant to Higgs boson searches in association with two high  $p_T$  jets since such an analysis is intended to isolate Higgs boson production via VBF.

In the VBF production process, it is expected that the two quark-initiated jets are observed in opposite hemispheres and with a large separation in pseudorapidity. Tagging these jets further suppresses the background processes. Furthermore, since there is no colour exchange between the two quarks, the Higgs boson should be observed in a large rapidity gap, where additional activity from QCD jets is small. A central jet veto (CJV) which suppresses the background processes is therefore used in the event selection,

The relative efficiencies for jet tagging are summarized in Table 6. The following four conditions are applied:

- two simulated quarks with  $p_T > 40$  GeV and  $p_T > 20$  GeV ( $|\eta| < 5$ ) and in opposite hemispheres,
- two reconstructed jets with  $p_T > 40$  GeV and  $p_T > 20$  GeV ( $|\eta| < 5$ ),
- the two reconstructed jets are in opposite hemispheres,
- differences in  $\eta$  between the simulated quarks and the reconstructed jets are smaller than 0.4 (this is referred to as matching).

The present tagging method selects correct tagging jets in 75.7% of the events. Under a pileup condition of  $10^{33}\text{cm}^{-2}\text{s}^{-1}$ , a degradation of less than 5% is observed. The difference between HERWIG and PYTHIA is about 6%.

## 4 Performance of the photon trigger on $H \rightarrow \gamma\gamma$ events.

There are two trigger selections which are foreseen for the  $H \rightarrow \gamma\gamma$  analyses: 2g17i and g55. The 2g17i trigger selects events with at least two isolated photons and is efficient for photon  $p_T$  above 20 GeV. The

Table 6: Relative efficiencies of the tagging method for VBF  $H \rightarrow \gamma\gamma$  with  $m_H = 120$  GeV (see text).

Selection	HERWIG (no pileup)	HERWIG (Pileup $10^{33}$ )	PYTHIA (no pileup)
step 1 (quark level)	$0.618 \pm 0.002$	$0.613 \pm 0.003$	$0.632 \pm 0.002$
step 2 (rec level)	$0.914 \pm 0.002$	$0.911 \pm 0.002$	$0.943 \pm 0.001$
step 3 (rec level)	$0.801 \pm 0.002$	$0.774 \pm 0.003$	$0.771 \pm 0.002$
step 4 (matching)	$0.757 \pm 0.003$	$0.726 \pm 0.003$	$0.713 \pm 0.003$

g55 trigger selects events with at least one photon and is efficient for photon  $p_T$  above 60 GeV. No isolation is required in the g55 trigger. In the analyses presented in Section 5 only the 2g17i menu has been considered to avoid possible biases in the invariant mass reconstruction: a more detailed description of the photon selection at the High Level Trigger is available [51]. The photon reconstruction at the trigger level relies only on calorimetric information. To calculate  $E_T$  and shower shapes variables the High Level Trigger uses algorithms similar to those used for offline analysis using information from the first and second sampling of the calorimeter. For photon trigger menus the isolation is only applied at L1 trigger.

The trigger efficiency has been evaluated for Higgs boson events having two offline reconstructed photons passing the following kinematic cuts: two photons with  $p_{T\gamma} > 25$  GeV and  $p_{T\gamma} > 40$  GeV respectively both in the region  $0 < |\eta| < 1.37$  and  $1.52 < |\eta| < 2.37$ , passing the identification cuts described in Section 3.2.

Table 7: Efficiency for the 2g17i menu item to trigger on  $H \rightarrow \gamma\gamma$  events with  $m_H = 120$  GeV, normalized with respect to the offline selections.

Trigger Level	2g17i Trigger efficiency
L1	$96.3 \pm 0.3$
L2 Calo	$95.0 \pm 0.4$
EF Calo	$93.6 \pm 0.4$

Table 7 shows in the first column the efficiency of the 2g17i menu item to select  $H \rightarrow \gamma\gamma$  events after each trigger level.

The 2g17i trigger menu item is expected to be  $\sim 94\%$  efficient for triggering on Higgs boson decays with two reconstructed photons. The efficiency loss is mainly due to the calorimeter isolation at L1 which is not applied in the offline photon selection.

Trigger rates for 2g17i are studied in the context of the ATLAS trigger development. This trigger is found to be usable (unprescaled) up to luminosities of  $10^{33} \text{ cm}^{-2} \text{ s}^{-1}$  [51].

## 5 Event selection

In this Section the analysis details of the various event selections are described. The event selection for the inclusive analysis is given in Section 5.1 and for the Higgs boson search in association with jets are given in Sections 5.2 and 5.3. Finally, the event selections for diphoton searches in association with missing transverse momentum and charged leptons are given in Sections 5.4 and 5.5. Here the various event selections are presented as disjoint analyses. In Section 7 the statistical power of these channels is combined and their impact on the Higgs boson discovery potential is evaluated.

### 5.1 Inclusive analysis

The inclusive analysis refers to the search for a resonance in events with two photons that pass certain quality criteria. The analysis reported here follows closely the event selection of past studies [3,4]. The detector performance and optimization studies succinctly presented in Sections 3 and 4 are geared toward maximizing the discovery potential of the inclusive analysis.

The following cuts are applied:

- Ia** At least two photon candidates (see Section 3.2) in the central detector region defined as  $|\eta| < 2.37$  excluding the transition region between barrel and endcap calorimeters,  $1.37 < |\eta| < 1.52$  (*crack* in the following). At this level it is required that the event passes the trigger selection (see Section 4).
- Ib** Transverse momentum cuts of 40, 25 GeV on the leading and sub-leading photon candidates, respectively.

The fiducial cuts in **Ia** are motivated by the quality of the off-line photon identification and the fake photon rate (see Section 3.2). The values of the cuts on the transverse momentum of the photon candidates (cut **Ib**) are not varied and are obtained from previous optimization studies [3].

Figure 6: Diphoton invariant mass spectrum after the application of cuts of the inclusive analysis. Results are presented in terms of the cross-sections in fb. The contribution from various signal and background processes are presented in stacked histograms (see text).

Figure 6 shows the expected diphoton mass spectrum after the application of cuts **Ia** and **Ib**. The hashed histogram in the bottom corresponds to the contributions from events with one and two fake photons. The second hashed histogram corresponds to the irreducible backgrounds (see Section 2.2). The background contributions are obtained with MC samples with a fast detector simulation normalized to the cross-sections specified in Section 2.2. The fast detector simulation is corrected in order to reproduce the aspects of the detector performance critical to the analysis, which are obtained with a full detector simulation (see Sections 3 and 4). The expected contribution from a Higgs boson signal for  $m_H = 120$  GeV, obtained with a full detector simulation, is also shown in Fig. 6.

Table 8: Expected cross-sections (in fb) for different signal ( $m_H = 120$  GeV) and background processes within a mass window of  $m_{\gamma\gamma} \pm 1.4$  of the mass resolution in the no pileup case reported in Table 5. Cuts **Ia** and **Ib** were applied.

Signal Process	Cross-section (fb)	Background Process	Cross-section (fb)
$gg \rightarrow H$	21	$\gamma\gamma$	562
VBF $H$	2.7	Reducible $\gamma j$	318
$t\bar{t}H$	0.35	Reducible $j\bar{j}$	49
$VH$	1.3	$Z \rightarrow e^+e^-$	18

Table 9: Summary of the relative systematic uncertainties on the  $\gamma\gamma$  and  $\gamma j$  processes.

Potential sources	$\gamma\gamma$	$\gamma j$
Scale dependence	14%	20%
Fragmentation	5%	1%
PDF	6%	7%
Total	16%	21%

Table 8 shows the expected cross-sections (in fb) for background and signal in a mass window of  $\pm 1.4$  of the mass resolution in the no pileup case reported in Table 5 around 120 GeV after the application of cuts **Ia** and **Ib**. Table 8 indicates that the relative contribution from events with at least one fake photon constitutes 39% of the total background, about a factor of two larger than evaluated in Ref. [4]. This increase is mostly attributed to three factors. Firstly, a different method for the parametrization of the fake photon background is used here. Secondly, the budget of inactive material in front of the first layer of the calorimeter has increased with respect to the one used in previous studies. Finally, the contribution from fragmentation in the  $\gamma j$  process (see Section 2.2) is allowed for here for the first time.

### 5.1.1 Theoretical uncertainties on background prediction

In this Section the theoretical uncertainties of the predictions for prompt single and double photon production used in the inclusive analysis are evaluated.

The irreducible background rate is evaluated using ResBos [34–36], which implements a full matrix element calculation at NLO and the resummed formalism. It thus yields an accurate description of the low  $p_{T\gamma\gamma}$  region, as corroborated by recent Tevatron results [52]. In the high diphoton transverse momentum,  $p_{T\gamma\gamma}$ , domain the precision of its prediction needs to be assessed. To account for the incompleteness of the fixed order calculation two approaches are used: both the renormalisation and factorisation scales ( $\mu_{R,F}$ ) are varied, from  $0.5 \times m_{\gamma\gamma}$  to  $2 \times m_{\gamma\gamma}$ , first assuming  $\mu_R = \mu_F$  then independently.

ResBos does not provide the most accurate description of the fragmentation of partons into photons. In particular, it implements the single-photon fragmentation only at LO. An improved estimation of this contribution is given by the DIPHOX program [33] which implements single and double-photon fragmentation at NLO. The predictions of the fragmentation and direct contributions of the two aforementioned calculations agree to within 6%.

The systematic uncertainty related to the parton distribution functions is studied in Ref. [53] and estimated to be of the order of 6%. Systematic uncertainties related to the irreducible background evaluation are summarised in Table 9 they amount to an overall relative uncertainty of 16%.

A similar study has been performed with JETPHOX in order to evaluate theoretical uncertainties of the  $\gamma\gamma$  process. The second column of Table 9 reports the results from this study.<sup>2</sup>

## 5.2 Higgs boson plus one jet analysis

In this Section and in Section 5.3 two event selections are presented that take into account the presence and properties of high  $p_T$  hadronic jets in association with the photon pair. This analysis follows earlier studies in ATLAS using a fast detector simulation [8].

Parton level studies have indicated that searches for the Higgs boson in association with at least one high  $p_T$  jet may have a strong discovery potential [5]. This analysis exploits mainly the fact that the gluon radiation pattern of the two leading Higgs boson production mechanisms differs strongly from the one expected for the reducible and irreducible backgrounds. The leading jet in the  $gg \rightarrow H j$  and  $VBF$  mechanisms tends to be harder and be more separated from the diphoton system than in background events. The invariant mass of the two photons and the jet system discriminates well the signal from the background.

The following event selection is chosen after the application of cut **Ia**:

**IIa** Transverse momentum cuts of 45 and 25 GeV on the leading and sub-leading photon candidates, respectively.

**IIb** Presence of at least one hadronic jet with  $p_T > 20$  GeV in  $|\eta| < 5$ .

**IIc** A cut on the invariant mass of the diphoton and the leading jet,  $m_{\gamma\gamma j} > 350$  GeV.

The lower bound on the jet  $p_T$  is dictated by the ability to calibrate hadronic jets in ATLAS [54]. The large hadronic activity due to the underlying events and multiple proton-proton interactions at the LHC, in conjunction to the significant amount of inactive material before the calorimeter, may make it difficult to lower the  $p_T$  threshold. The variable  $m_{\gamma\gamma j}$  is the main discriminator used here to improve the signal-to-background ratio. Other discriminating variables could be used to further enhance the analysis sensitivity [5].

Figure 7 displays the resulting diphoton invariant mass spectrum after the application of cuts **Ia** and **IIa-IIc**.

Table 10: Expected cross-sections (in fb) for the Higgs boson plus one jet Analysis. Results are given after the application of cuts **Ia** and **IIa-IIc** (see Section 5.2). In the last row the expected cross-sections within a mass window of  $m_{\gamma\gamma}$  of  $\pm 2$  GeV around 120 GeV are given.

Cut	$gg \rightarrow H$ $\sigma$ (fb)	$VBFH$ $\sigma$ (fb)	$VH$ $\sigma$ (fb)	$ttH$ $\sigma$ (fb)	Total $\sigma$ (fb)
<b>Ia-IIa</b>	28	3.6	1.7	0.49	34
<b>IIb</b>	13	3.5	1.5	0.49	19
<b>IIc</b>	3.2	1.9	0.22	0.17	5.5
Mass Window	2.3	1.4	0.17	0.13	4.0

Tables 10 and 11 display the expected cross-sections for signal and background events in the range  $110 < m_{\gamma\gamma} < 150$  GeV after the application of cuts **Ia** and **IIa-IIc**. Table 10 illustrates that the leading

<sup>2</sup>It is important to note that the uncertainty of the contribution of the reducible background is dominated by the uncertainty in the determination of the fake photon rejection. This uncertainty may be significantly larger than the uncertainties quoted in Table 9.

Figure 7: Diphoton invariant mass spectrum in fb obtained with the Higgs boson plus one jet analysis (see Section 5.2). The same procedure as in Fig. 6 in Section 5.1 is used to obtain the histograms in Fig. 7. The same codes for signal and backgrounds are used as in Fig. 6.

Table 11: Expected cross-sections (in fb) of background for the Higgs boson plus one jet Analysis. Results are given after the application of cuts **Ia** and **IIa-IIc** (see Section 5.2). In the last row the expected cross-sections within a mass window of  $m_{\gamma\gamma}$  of  $\pm 2$  GeV around 120 GeV are given.

Cut	$\gamma\gamma$ $\sigma$ (fb)	Reducible $\gamma j$ $\sigma$ (fb)	Reducible $jj$ $\sigma$ (fb)	EW $\gamma\gamma jj$ $\sigma$ (fb)	Total $\sigma$ (fb)
<b>Ia-IIa</b>	9698	8498	937	99	19233
<b>IIb</b>	4786	4438	444	99	9768
<b>IIc</b>	501	824	89	71	1485
Mass Window	28	17	2.0	1.5	49

Higgs boson production mechanism after the application of cuts remains the  $gg \rightarrow H j$  process, closely followed by the VBF mechanism. It is important to note that the  $gg \rightarrow H j$  process has been evaluated at LO ignoring the large QCD NLO corrections.

### 5.3 Higgs boson plus two jets analysis

This Section considers an event selection comprising two photons in association with two high  $p_T$  jets, or tagging jets. In this analysis the tagging jets are defined as the two leading jets in the event. The VBF Higgs boson process at LO produces two high  $p_T$  and relatively forward jets in opposite hemispheres (backward-forward). The pseudorapidity gap and invariant mass of these jets tend to be significantly larger than those expected for background processes. The NLO description of the VBF process does not significantly distort this picture.<sup>3</sup>

<sup>3</sup>About 10% of the VBF events display the feature that a radiated gluon coming from one of the quark lines happens to become a tagging jet. In this class of events the pseudorapidity gap and the invariant mass of the tagging jets appears similar to

A number of variables are chosen that are sensitive to the different kinematics displayed by the signal and background processes [9]. The following is the optimized event selection after the application of cut **Ia**:

- IIIa** Transverse momentum cuts of 50 and 25 GeV on the leading and sub-leading photon candidates, respectively.
- IIIb** Presence of at least two hadronic jets in  $|\eta| < 5$  with  $p_T > 40, 20$  GeV for the leading and sub-leading jet, respectively. The tagging jets must be in opposite hemispheres,  $\eta_{j1} \cdot \eta_{j2} < 0$ , where  $\eta_{j1}$  and  $\eta_{j2}$  correspond to the pseudorapidity of the leading and sub-leading jets, respectively. Finally, it is required that the pseudorapidity gap between the tagging jets be large,  $\Delta\eta_{jj} > 3.6$ .
- IIIc** Photons are required to have pseudorapidity between those of the tagging jets.
- IIId** Invariant mass of the tagging jets,  $m_{jj} > 500$  GeV.
- IIIe** Veto on events with a third jet with  $p_T > 20$  GeV and  $|\eta| < 3.2$

Figure 8: Diphoton invariant mass spectrum obtained with the Higgs boson plus two jet analysis (see Section 5.3).

Figure 8 displays the resulting diphoton invariant mass spectrum after the application of cuts **Ia** and **IIIa-IIIe**.

Tables 12 and 13 display the expected cross-sections for a Higgs boson signal with  $m_H = 120$  GeV and background events in the mass range  $\pm 2$  GeV around 120 GeV after the application of cuts **Ia** and **IIIa-IIIe**. Table 12 shows that the dominant Higgs boson production mechanism surviving the events selection is the VBF mechanism. Unfortunately, the QCD NLO corrections to the main backgrounds included in Table 13 are not known and therefore these results suffer from large theoretical uncertainties.

The event selections presented in this and the previous Sections have a certain degree of overlap. This is particularly relevant for the VBF Higgs boson production mechanism. In Section 7 the signal significance of a combined analysis is presented that takes into account the event overlap.

that displayed by a typical QCD background process. This effect is well reproduced by the HERWIG generator.

Table 12: Expected cross-sections (in fb) for the Higgs boson plus two jet analysis. Results are given after the application of cuts **Ia** and **IIIa-IIIe** (see Section 5.3). In the last row the expected cross-sections within a mass window of  $m_{\gamma\gamma}$  of  $\pm 2$  GeV around 120 GeV are given.

#### 5.4 Higgs boson plus missing transverse energy and isolated leptons

The main signal production mechanism contributing to a category of events with two photons, missing transverse energy and isolated leptons will be from  $WH \rightarrow \ell\nu\gamma\gamma$  and  $t\bar{t}H$ . The basic selection requires the presence of two energetic photons, missing transverse momentum, and one high energetic lepton. The main backgrounds for this channel are  $t\bar{t}\gamma\gamma$ ,  $W\gamma\gamma$  where the  $W$  decays to  $\ell\nu$  and  $W\gamma \rightarrow e\nu\gamma$  where the other photon is radiated by the electron or is a fake photon from an additional jet.<sup>4</sup> This latter background is multiplied by a factor 2 to include the  $W\gamma \rightarrow \mu\nu\gamma$  contribution. Another important background turns out to be  $\gamma\gamma$  and  $\gamma j$ , when fake electrons or muons are reconstructed. ALPGEN was used to produce the diphoton background including a full simulation of the detector. The cross section was multiplied by a factor 1.4 to account approximately for the box diagram (40% of the contribution, see Table 1). For reducible backgrounds (68% contribution, see Table 8), the cross-section of the diphoton background is scaled by a factor 1.68. It is difficult to evaluate the accuracy of this approximation but this diphoton process is not the leading background. A multivariate analysis based on various kinematical variables would require very large Monte Carlo samples for the backgrounds. Here, a simple set of basic event selection criteria is chosen:

**IVa** The first selection criterion sets minima on the transverse momenta of the two reconstructed pho-

<sup>4</sup>Note that there is some double counting when both  $W\gamma$  and  $W\gamma\gamma$  are included.

tons. The cut requires the  $p_T$  of the most energetic photon to be higher than 60 GeV and the  $p_T$  of the second more energetic photon to be above 30 GeV. Events where one of the two photons is reconstructed in the crack region are rejected. The cross-sections in the first line of the table 14 are given in the mass range between 110 and 150 GeV.

- IVb** Requiring a cut that the transverse momentum of the most energetic isolated lepton (electron or muon) be higher than 30 GeV suppresses efficiently the diphoton and  $W\gamma$  backgrounds. Only the electrons passing a tight electron identification cut are selected.
- IVc** The diphoton background can further be strongly suppressed by requiring missing transverse energy higher than 30 GeV.
- IVd** When an electron is reconstructed, events are removed in with either of the invariant masses of the electron and each of the photons is close to the  $Z$  mass (between 80 and 100 GeV): this cut removes the events coming from the  $(Z/\gamma^*) + \gamma \rightarrow e^+e^-\gamma$  when an electron is reconstructed as a photon.

Table 14: Expected cross-sections (in fb) for the Higgs boson with missing transverse energy and lepton analysis for  $m_H = 120$  GeV. Results are given after the application of cuts **IVa-IVc** (see Section 5.4) in the mass range  $110 < m_{\gamma\gamma} < 150$  GeV. In the last row the expected cross-sections within a mass window of  $m_{\gamma\gamma}$  of  $\pm 2$  GeV around 120 GeV are given.

Cut	$W^\pm H \rightarrow \ell\nu\gamma\gamma$ $\sigma$ (fb)	$t\bar{t}H \rightarrow x\gamma\gamma$ $\sigma$ (fb)	$W^\pm\gamma\gamma \rightarrow \ell\nu\gamma\gamma$ $\sigma$ (fb)	$t\bar{t}\gamma\gamma$ $\sigma$ (fb)	$b\bar{b}\gamma\gamma$ $\sigma$ (fb)	$W^\pm\gamma \rightarrow e\nu\gamma$ $\sigma$ (fb)	$(Z/\gamma^*) + \gamma \rightarrow e^+e^-\gamma$ $\sigma$ (fb)	$\gamma\gamma$ $\sigma$ (fb)
<b>IVa</b>	0.328	0.467	0.509	2.53	3.78	18.0	10.28	2558
<b>IVb</b>	0.122	0.103	0.149	0.582	0.0098	0.406	2.60	0.644
<b>IVc</b>	0.091	0.086	0.097	0.474	0	0.263	0.076	0.091
<b>IVd</b>	0.084	0.077	0.090	0.419	0	0.143	0	0.091
Mass Win.	0.064	0.062	0.0092	0.042	0	0.014	0	0.010

Table 14 summarizes the expected cross-sections for the principal signal and backgrounds after the various cuts used in the analysis. The uncertainty in the background level, due to Monte Carlo statistics only, is estimated to be 10%. However, the background contribution in this analysis can have larger sources of systematic uncertainties. The resulting Higgs boson mass peak and background are shown in Fig. 9 after all cuts have been applied. The reconstructed mass resolution is 1.47 GeV.

## 5.5 Higgs boson plus missing transverse energy

This analysis is intended to select principally the  $ZH \rightarrow \nu\nu\gamma\gamma$  events. In order to have an analysis independent from that of Section 5.4, only events which do not have a reconstructed lepton with  $p_T > 30$  GeV have been considered here. It should be noted that cases where the lepton is of low  $p_T$  or did not pass the tight selection criterion are included. Thus the  $WH$  signal contributes significantly. The main features are the presence of two energetic photons from the Higgs boson and a large transverse missing energy. The dominant backgrounds for this channel are the  $t\bar{t}\gamma\gamma$ ,  $Z\gamma\gamma$  and  $W\gamma \rightarrow e\nu\gamma$  channels where, in the latter case, the electron can be mis-reconstructed as a photon or the second photon is either radiated by the electron or is a fake photon. Here, the diphoton background is multiplied by the same factors as in Section 5.4 and the  $t\bar{t}\gamma\gamma$  by the factor 7.5 as explained in Section 2.2.

Figure 9: Expected distribution of the invariant mass of the two photons for the signals and main backgrounds after applying the analysis cuts for events having one lepton reconstructed in the final state. Due to a lack of MC statistics for the diphoton and the  $W\gamma$  backgrounds, their expected distribution is approximated by showing an average of the number of events passing the analysis cuts in the  $m_{\gamma\gamma}$  mass range shown.

- Va** As in Section 5.4, a cut on the transverse momentum of the most energetic photon above 60 GeV and a cut on the second more energetic photon  $p_T$  of 30 GeV are applied to suppress the diphoton background. Events where one of the two photons is reconstructed in the crack region are then removed.
- Vb** The selection is then based mostly on the requirement of high missing transverse momentum. A cut of  $E_T^{\text{miss}} > 80$  GeV suppresses almost completely the  $\gamma\gamma$  background while reducing the  $W\gamma$  background by a factor 20 and the  $ZH \rightarrow \nu\nu\gamma\gamma$  signal by a factor 2.
- Vc** In order to further suppress the  $W\gamma$  background, where the electron is often reconstructed as a converted photon, events where either of the photons appears to have converted are rejected.
- Vd** At this point, because of potentially significant background from QCD events, difficult to evaluate, a cut requiring that the scalar sum of the  $p_T$  of the jets in the event be larger than 150 GeV is imposed. It suppresses the contribution from the  $t\bar{t}\gamma\gamma$  and  $b\bar{b}\gamma\gamma$  backgrounds, as well as of the  $t\bar{t}H$  signal.

Table 15 summarizes the expected cross-sections after the different cuts applied for this analysis for signal and backgrounds. The expected mass distributions of diphotons from the associated  $W/Z$  plus Higgs boson and from the backgrounds are shown in Fig. 10, after the application of all cuts. To account for the  $W\gamma \rightarrow \mu\nu\gamma$ , the  $W\gamma \rightarrow e\nu\gamma$  background has been multiplied by two in the figure although some double counting is introduced. The uncertainty in the background level, due to Monte Carlo statistics only, is estimated to be 15%. The reconstructed mass resolution is 1.31 GeV. This result is expected to be sensitive to uncertainties in the simulation and reconstruction of  $E_T^{\text{miss}}$  tails.

Table 15: Expected cross-sections (in fb) for the Higgs boson with missing transverse energy analysis. Results are given after the application of cuts **Va-Vd** (see Section 5.5) in the mass range  $110 < m_{\gamma\gamma} < 150$  GeV. In the last row the expected cross-sections within a mass window of  $m_{\gamma\gamma}$  of  $\pm 1.8$  GeV around 120 GeV are given.

## 6 Maximum-likelihood fit

An unbinned extended multivariate maximum-likelihood fit to extract the  $H \rightarrow \gamma\gamma$  signal and background event yields is performed. With respect to the cut analysis presented in Section 5, the fit takes advantage of further discrimination information from the kinematic and topological properties of  $H \rightarrow \gamma\gamma$  decays. In addition to the diphoton invariant mass,  $m_{\gamma\gamma}$ , the transverse momentum of the Higgs boson,  $P_{T,H}$ , and the magnitude of the photon decay angle in the Higgs boson rest frame with respect to the Higgs boson lab flight direction,  $|\cos\theta^*|$ , are included. To reduce the model dependence, the most relevant parameters describing the probability density functions (PDF) for the dominant background are freely varied and determined simultaneously with the event yields by the fit. Only the parametric shapes of the PDFs are obtained from Monte Carlo simulation. Sufficient background statistics in the sidebands must be retained to ensure that the floating shape parameters do not increase the statistical errors on the signal

yield. The  $m_{\gamma\gamma}$  resolution depends on the diphotons' pseudorapidities, with core Gaussian widths varying between 1.2 and 3 GeV. Disjoint pseudorapidity regions (denoted *categories*), are defined such that the  $m_{\gamma\gamma}$  resolution is similar for events belonging to the same category, and maximally different for events of different categories. The  $m_{\gamma\gamma}$  resolution also depends on whether or not photons have converted at an early stage in the material in front of the calorimeter (see Section 3.3).  $H \rightarrow \gamma\gamma$  events can have zero, one or two reconstructed conversions, which are split into corresponding categories. Following Section 5 disjoint categories are also introduced for events accompanied by zero, one and two or more jets, where the last category contains predominantly VBF events. The use of categories separates sub-populations of events with different properties and hence improves the accuracy of the likelihood model.

The signal and background samples used to build the likelihood model are selected with the criteria described in Section 5. The full detector simulation is used for signal processes, while the background processes are generated with the fast simulation. The trigger and photon identification efficiencies, and the misidentification in background events are parametrised using the full detector simulation. The probability of a photon to convert into an  $e^+e^-$  pair with one or two tracks being reconstructed, and the energy resolution of the converted photon are parametrised using the full detector simulation.

### 6.1 Likelihood model

The probability density function,  $P_i^c$ , for an event  $i$  in category  $c$  is the weighted sum of the probability densities of all components, namely  $P_i^c = N_H f_H^c P_{H,i}^c + \sum_{j=1}^{n_{\text{bkg}}} N_{B_j}^c P_{B_j,i}^c$ , where  $N_H$  is the number of  $H \rightarrow \gamma\gamma$  signal events determined by the fit,<sup>5</sup>  $f_H^c$  is the fraction of signal events in category  $c$  ( $c = 1, \dots, n_{\text{cat}}$ , note that  $\sum_c f_H^c = 1$ ) taken from simulation, and  $N_{B_j}^c$  is the number of background events of type  $j$  ( $j = 1, \dots, n_{\text{bkg}}$ ) found in category  $c$ , which is determined from the fit. The signal and background PDFs  $P_{U,i}^c$ , with  $U = H, B_j$ , are the products  $P_{U,i}^c = \prod_{k=1}^{n_{\text{var}}} p_U^c(x_{k,i})$  of the PDFs  $p_U^c(x_{k,i})$  of the discriminating variables  $x_{k,i}$ ,  $k = 1, \dots, n_{\text{var}}$ , used in the fit. The extended likelihood over all categories and events is given by  $\mathcal{L} = \prod_{c=1}^{n_{\text{cat}}} e^{-\bar{N}^c} \prod_{i=1}^{N^c} P_i^c$ , where  $\bar{N}^c$  ( $N^c$ ) is the total number of events expected (observed) in category  $c$  with  $c = 1, \dots, n_{\text{cat}}$ . The PDFs  $P_{U,i}^c$  depend on parameters (coefficients) that may be freely varying in the fit. The parametrisations and hence the adjustable parameters differ between categories in general, but can also span over several categories.

### 6.2 Fit variables

The  $H \rightarrow \gamma\gamma$  distribution of  $m_{\gamma\gamma}$  forms a Gaussian peak with tails to lower values from photon energy losses before the calorimeter. It is well modeled by a *Crystal Ball* (CB) function [55]

$$p_H(m_{\gamma\gamma}) = N \cdot \begin{cases} \exp(-t^2/2), & \text{for } t > -\alpha, \\ (n/|\alpha|)^n \cdot \exp(-|\alpha|^2/2) \cdot (n/|\alpha| - |\alpha| - t)^{-n}, & \text{otherwise,} \end{cases} \quad (4)$$

where  $t = (m_{\gamma\gamma} - m_H - \delta_{m_H})/\sigma(m_{\gamma\gamma})$ ,  $N$  is a normalisation parameter,  $m_H$  is the Higgs boson mass,  $\delta_{m_H}$  is a category dependent offset,  $\sigma$  represents the diphoton invariant mass resolution, and where  $n$  and  $\alpha$  parametrise the non-Gaussian tail. To catch outliers an additional broad tail Gaussian is added to Equation 4, which is, however, only relevant for events falling into the “bad”  $m_{\gamma\gamma}$  category (see Section 6.3). Within a sufficiently narrow mass window, the background distribution of  $m_{\gamma\gamma}$  forms an exponential tail described by a single slope parameter  $\xi$ .

Because of the large available statistics for simulated signal samples, shape uncertainties due to deficiencies in the functional description are negligible. Systematic effects are due to simulation inaccuracies and are discussed in Section 7. A high-fidelity description of the background PDFs is mandatory because

<sup>5</sup>Throughout this section the subscript  $S$  is identified with the  $H \rightarrow \gamma\gamma$  signal.

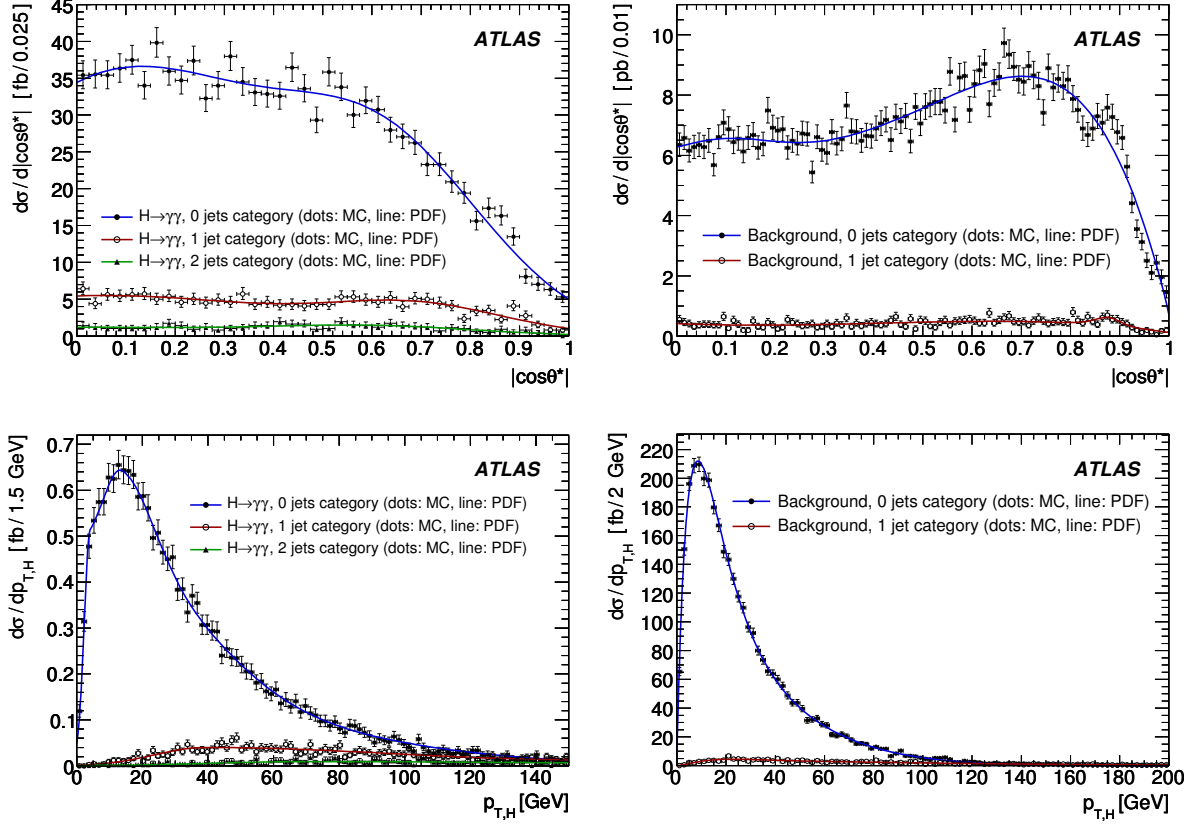

Figure 11: Signal (left) and background (right) distributions of the Higgs boson decay angle,  $|\cos\theta^*|$  (top), and the diphoton transverse momentum (bottom) for events with zero jets (full dots), one jet (open circles) and VBF topology (full triangles, not shown for background because of a too low relative cross-section). The corresponding PDF parametrisations are overlaid (see text).

the large majority of the events entering the fit are of that type. It is achieved by flexible parametrisations with a sufficient number of parameters determined by the fit, ensuring a stable fit result with respect to shape redefinitions.

The distribution of  $|\cos\theta^*|$  for a scalar Higgs boson is uniform. However, acceptance effects, primarily from the minimum  $p_T$  requirements for the photons (See Section 5.1), suppress  $|\cos\theta^*|$  values towards one, where the photons are collinear with the Higgs boson lab frame momentum. The empirical signal PDF is interpolated by a double Gaussian function. The phase space for background events from  $t$ -channel graphs and quark or gluon fragmentation at NLO is enhanced for photons collinear with the diphoton lab momentum, so that the background  $|\cos\theta^*|$  distribution exhibits some clustering towards large values. Acceptance suppression competes, however, with this enhancement thus reducing the discrimination power of the variable. It is found that the  $|\cos\theta^*|$  distributions differ significantly between the  $\gamma\gamma$ ,  $\gamma j$  and  $jj$  backgrounds, with stronger enhancements at large  $|\cos\theta^*|$  values for the backgrounds originating from jet misidentification. The inclusive shape of these backgrounds is parametrised by the sum of a positively defined third order polynomial and two Gaussian functions. The inclusive signal and background distributions of  $|\cos\theta^*|$  for events with and without jets are shown in Fig. 11.

The Higgs boson transverse momentum exhibits a strong rise at low values and a long exponential tail beyond the maximum. The distribution is fitted by a sum of two bifurcated Gaussian functions (distributions where below and above the center half Gaussian distributions with different widths are used) and one symmetric Gaussian. The diphoton transverse momentum distribution for background is

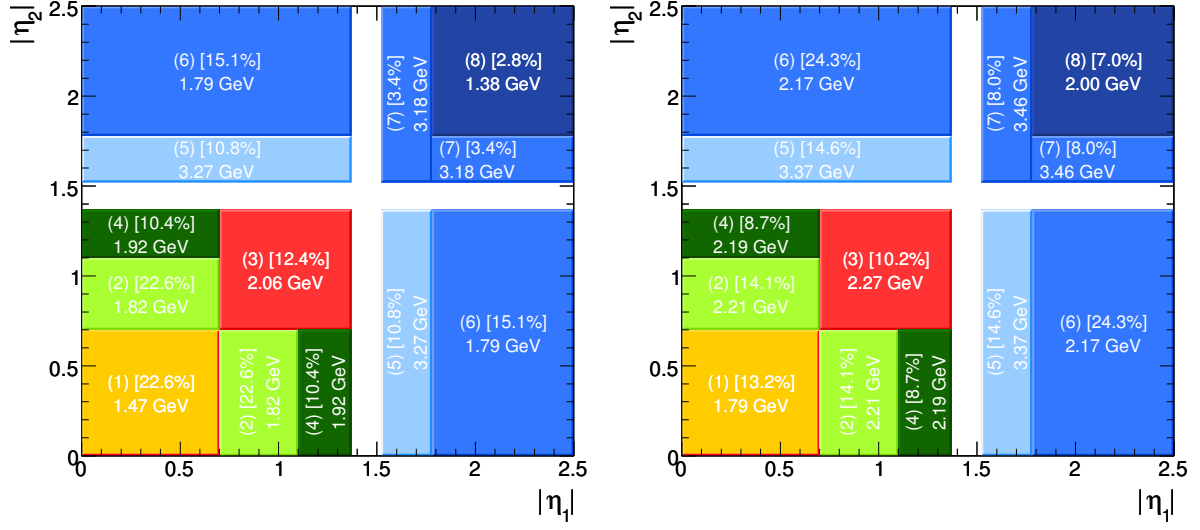

Figure 12: Regions of photon pseudorapidities with different invariant mass resolutions for unconverted photons (left) and at least one converted photon (right). The text per box denotes the region number, the percentage of events occurring in the region and the RMS of the diphoton invariant mass for  $H \rightarrow \gamma\gamma$  events. To simplify the likelihood model, events with photons in regions (1) and (8) are merged and represent category “good” (signal fraction 24%), events in regions (2), (3), (4) and (6) correspond to category “medium” (60%), and regions (5) and (7) are “bad” (15%).

softer than that for signal and can be described by the sum of three exponential polynomials (see Fig. 11).

### 6.3 Fit categories

Eight photon pseudorapidity regions with different diphoton invariant mass resolution for  $H \rightarrow \gamma\gamma$  events are identified. They are illustrated in Fig. 12 for unconverted photon pairs (left plot) and events with at least one photon conversion (right plot). The regions are chosen to be symmetric with respect to an interchange of the photons. The crack region is excluded from the photon selection. The  $m_{\gamma\gamma}$  RMS values vary between 1.3 GeV in the centre and large- $\eta$  regions to 3.1 GeV in the regions closely beyond the crack. To simplify the likelihood model, the eight regions are merged into three categories that are distinguished in the fit (see Fig. 12).

Two categories are introduced to separate events without and with at least one photon conversion to take account of the worse resolution of the latter events. Photon conversions reconstructed with one or two tracks are not explicitly distinguished. Additional categories are introduced for Higgs boson production with zero, one, and two or more accompanying jets, using the requirements described in Sections 5.2 and 5.3. No separate categories are introduced in the present analysis to distinguish Higgs boson production in association with a  $W$  and  $Z$  boson or a  $t\bar{t}$  quark pair; these are included in the previous selections. Separating them would add some power, but would increase the complexity.

### 6.4 Correlations

The likelihood product used to derive the event PDF  $P_U^c$  ignores correlations between the discriminating variables  $x_k$ . The classification in categories of events with distinct properties improves the accuracy of this assumption. The remaining (positive) linear correlation coefficients is lower than 7% (10%) for signal (background) events among the three fit variables tolerable.

Table 16:  $H \rightarrow \gamma\gamma$  discovery potential for a Higgs boson mass of 120 GeV, various likelihood setups and a simulated integrated luminosity of  $10\text{fb}^{-1}$ . The left column gives the discriminating variables used in the fit, the second column the categories, the third (fifth) column the average  $\Delta\ln\mathcal{L}$  and its statistical uncertainty as derived from the toy MC samples, and the fourth (sixth) column quotes the estimated Gaussian signal significance in units of one standard deviation. Due to the background dominance, the variance of the significance in the toy experiments is approximately one. The fits have been performed with fixed Higgs boson mass (Higgs boson mass floating within  $[112, 128]$  GeV). The significance for floating Higgs boson mass has been obtained with toy MC simulation (the  $\Delta\ln\mathcal{L}$  cannot be directly interpreted in terms of significance and is given for completeness only). Due to the large number of required toy MC fits it has not been computed for the most involved fit with highest expected significance.

Fit variables	Categories	Higgs boson mass fixed		Higgs boson mass floating	
		$\langle\Delta\ln\mathcal{L}\rangle$	Significance [ $\sigma$ ]	$\langle\Delta\ln\mathcal{L}\rangle$	Significance [ $\sigma$ ]
$m_{\gamma\gamma}$	–	$2.67 \pm 0.04$	$2.31 \pm 0.02$	$3.54 \pm 0.05$	$1.44 \pm 0.02$
$m_{\gamma\gamma}$	$\eta$	$3.18 \pm 0.05$	$2.52 \pm 0.02$	–	–
$m_{\gamma\gamma}$	$\eta$ , Conversions	$3.32 \pm 0.05$	$2.58 \pm 0.02$	–	–
$m_{\gamma\gamma}$	$\eta$ , Conversions, Jets	$5.99 \pm 0.07$	$3.46 \pm 0.02$	$6.66 \pm 0.07$	$2.64 \pm 0.02$
$m_{\gamma\gamma},  \cos\theta^* $	$\eta$ , Conversions, Jets	$7.33 \pm 0.08$	$3.83 \pm 0.02$	–	–
$m_{\gamma\gamma}, P_{T,H}$	$\eta$ , Conversions, Jets	$7.03 \pm 0.08$	$3.75 \pm 0.02$	–	–
$m_{\gamma\gamma}, P_{T,H},  \cos\theta^* $	$\eta$ , Conversions, Jets	$8.49 \pm 0.08$	$4.12 \pm 0.02$	$9.25 \pm 0.09$	–

## 6.5 Fit performance

Studies are performed involving large samples of toy MC simulation to assess the discovery potential for fits using likelihood models of increasing complexity.<sup>6</sup> The abundance of signal and background events used in these fits is tuned to the NLO expectation for  $10\text{fb}^{-1}$  of integrated luminosity, taking into account the trigger and reconstruction acceptance.

The results for fits with fixed and floating Higgs boson mass (the latter only done for the  $m_{\gamma\gamma}$ -only and the full fits) are summarised in Table 16. For each toy MC sample we perform two fits, one with floating signal yield and another with zero signal to test the background-only hypothesis. The log-likelihood difference,  $\Delta\ln\mathcal{L}$ , found in these fits, estimates the false discovery probability (p-value). The  $\langle\Delta\ln\mathcal{L}\rangle$  values given in Table 16 are obtained from Gaussian fits to well-behaved pull distributions. For fixed Higgs boson mass, the signal significance in terms of  $\sigma$  can be approximated by the quantity  $\sqrt{-2\Delta\ln\mathcal{L}}$ . For floating Higgs boson mass, the extra degree of freedom in the fit yields a higher value of  $\langle\Delta\ln\mathcal{L}\rangle$ . However in this case the p-value and significance must be evaluated with toy MC simulation of background-only samples. As expected, the obtained significances are lower than in the fixed mass case, in spite of the higher  $\langle\Delta\ln\mathcal{L}\rangle$  values.

## 7 Discovery potential

This Section reports on the potential for the discovery of a Higgs boson in the mass range  $120 < m_H < 140$  GeV using the event counting computation and the maximum likelihood fit formalism (see Sec-

<sup>6</sup>Although required for real data the evaluation of goodness-of-fit estimators is not discussed here, because the generated toy data is intrinsically consistent with the underlying model.

tion 6). The signal significance is evaluated for each of the analyses presented in Section 5. The discovery reach is given for a combined analysis including the utilization of additional discriminating variables. The last signifies the maximum discovery potential for a Standard Model Higgs boson in the mass range specified above.

Table 17: Expected cross-sections (in fb) of signal (S) and background (B) for the different analyses presented in Section 5 within a mass window of  $\pm 1.4\sigma_{\gamma\gamma}$  as a function of the Higgs boson mass (in GeV).

$m_H$	Inclusive		$H + 1\text{jet}$		$H + 2\text{jets}$		$H+E_T^{\text{miss}} + \ell$		$H+E_T^{\text{miss}}$	
	S	B	S	B	S	B	S	B	S	B
120	25.4	947	4.0	49	0.97	1.95	0.134	0.077	0.075	0.037
130	24.1	755	4.3	47	0.96	1.72	0.112	0.076	0.063	0.037
140	19.3	610	3.9	46	0.81	1.72	0.079	0.076	0.045	0.036

Table 17 shows the signal and background effective cross-sections for the different analyses presented in Section 5 as a function of the Higgs boson mass.<sup>7</sup> Table 18 displays the corresponding expected signal significances for  $10\text{fb}^{-1}$  of integrated luminosity. The first sub-column under each analysis shows the signal significance based on event counting,  $\sigma(S, B)$ , where  $S$  and  $B$  correspond to the number of signal and background events in a mass window of  $\pm 1.4\sigma_{\gamma\gamma}$  around  $m_H$ , respectively, and where  $\sigma_{\gamma\gamma}$  is the mass resolution (in the no pileup case reported in Table 5).<sup>8</sup> The values of  $\sigma(S, B)$  reported in Table 18 can be compared with earlier studies performed by the ATLAS collaboration [2–4, 8, 9]. The inclusion of pileup decreases the event counting signal significance by at most 10%.

The signal significances reported in the second and third sub-column under each analysis,  $\sigma_{1D}^{\text{Fix}}$  and  $\sigma_{1D}^{\text{Float}}$ , are obtained by means of a one dimensional fit using the diphoton invariant mass as a discriminating variable by letting the Higgs boson mass fixed and floated, respectively.<sup>9</sup> Each analysis is treated independently from each other. In these fits the Higgs boson mass is let free in the range  $110 < m_H < 140$  GeV (except for  $m_H = 140$  GeV for which the range was set to  $120 < m_H < 150$  GeV) to take into account for the coverage of the analysis.<sup>10</sup> The results in Table 18 do not take into account the event overlap among the three analyses. The last column reports the event counting signal significance of the three analyses combined, taking into account the event overlap.

Table 18 illustrates that the inclusive search for a diphoton resonance is the most sensitive one for a search of a Standard Model Higgs boson. As reported in Section 2, the inclusive analysis is evaluated using QCD corrections for both signal and background processes. This is not the case for the  $H + 1\text{jet}$  and other analyses. The discovery potential of  $H + 1\text{jet}$  analysis could be further enhanced if QCD NLO corrections were applied on both signal and reducible backgrounds [56, 57].

Table 19 shows two fit-based signal significances compared to  $\sigma_{1D}^{\text{Fix}}$  and  $\sigma_{1D}^{\text{Float}}$  reported in Table 18. The values of  $\sigma_{C13D}^{\text{Fix}}$  and  $\sigma_{C13D}^{\text{Float}}$  correspond to the signal significance computed by means of a three dimensional fit, including  $m_{\gamma\gamma}$ ,  $P_{T,H}$  and  $|\cos\theta^*|$  (see Section 6.2) by means of fixing and floating the mass, respectively. At this stage the event classification according to  $|\eta|$  regions is used (see Section 6.3).<sup>11</sup>

<sup>7</sup>The contribution from Drell-Yan is computed for the inclusive analysis only.

<sup>8</sup>The event counting significance for the inclusive and  $H + 1\text{jet}$  analyses are approximated by  $S/\sqrt{B}$ . For the rest of the analyses a Poisson-based computation is used due to the small expected number of background events for  $10\text{fb}^{-1}$  of integrated luminosity.

<sup>9</sup>For the sake of simplicity, the fit-based signal significance does not include the Drell-Yan contribution.

<sup>10</sup>The range of the fit to the background is set to  $110 < m_H < 150$  GeV.

<sup>11</sup>For the final results presented in this section, a simplified fitting model as well as a more conservative classification are used with respect to those considered for Table 16. In particular the diphoton category with two jets is not split into  $\eta$  categories

Table 18: Signal significances (expressed in terms of Gaussian sigmas) for a Standard Model Higgs boson as a function of the mass (in GeV) using the different analyses reported in Sections 5.1-5.3 for  $10\text{fb}^{-1}$  of integrated luminosity. Results are reported in terms of the signal significance based on event counting,  $\sigma(S,B)$ , and a fit-based signal significance,  $\sigma_{1D}^{Fix}$  and  $\sigma_{1D}^{Float}$  (see text).

$m_H$	Inclusive (with K-factors)			$H + 1\text{jet}$ (no K-factors)			$H + 2\text{jet}$ (no K-factors)			Combined
	$\sigma(S,B)$	$\sigma_{1D}^{Fix}$	$\sigma_{1D}^{Float}$	$\sigma(S,B)$	$\sigma_{1D}^{Fix}$	$\sigma_{1D}^{Float}$	$\sigma(S,B)$	$\sigma_{1D}^{Fix}$	$\sigma_{1D}^{Float}$	
120	2.6	2.4	1.5	1.8	1.8	1.3	1.9	2.0	1.1	3.3
130	2.8	2.7	1.8	2.0	2.1	1.6	2.1	2.1	1.2	3.5
140	2.5	2.2	1.3	1.8	1.7	1.2	1.7	2.0	1.0	3.0

Table 19: Signal significances (expressed in terms of Gaussian  $\sigma$ s) for a Standard Model Higgs boson as a function of the mass for  $10\text{fb}^{-1}$  of integrated luminosity. Different fit-based approaches are used. The significances,  $\sigma_{1D}^{Fix}$ ,  $\sigma_{C13D}^{Fix}$  and  $\sigma_{C23D}^{Fix}$  correspond to a one dimensional fit, to a three dimensional fit using the first type of event classification and to a three dimensional fit (see Section 6.2) using all classifications considered in Section 6.3, respectively using a fix Higgs boson mass (see text). The significances  $\sigma_{1D}^{Float}$ ,  $\sigma_{C13D}^{Float}$  and  $\sigma_{C23D}^{Float}$ , correspond to fit based results obtained with a floating Higgs boson mass.

$m_H$ [GeV]	$\sigma_{1D}^{Fix}$	$\sigma_{1D}^{Float}$	$\sigma_{C13D}^{Fix}$	$\sigma_{C13D}^{Float}$	$\sigma_{C23D}^{Fix}$	$\sigma_{C23D}^{Float}$
120	2.4	1.5	3.1	2.1	3.6	2.8
130	2.7	1.8	3.4	2.4	4.2	3.4
140	2.2	1.3	3.2	2.2	4.0	3.2

The values of  $\sigma_{C23D}^{Fix}$  and  $\sigma_{C23D}^{Float}$  correspond to the maximum achievable sensitivity of all the analyses reported in Section 5 combined. In addition to the procedure followed to obtain  $\sigma_{C13D}^{Fix}$  and  $\sigma_{C13D}^{Float}$ , a classification of events according to the presence of hadronic jets is used.

Figure 13 displays a summary of the expected signal significance for the inclusive and final combined analysis for  $10\text{fb}^{-1}$  of integrated luminosity as a function of the Higgs boson mass. The solid circles correspond to the sensitivity of the inclusive analysis reported in Section 5.1 using event counting with background and signal rates assumed. The solid triangles linked with solid and dashed lines correspond to the sensitivity of the inclusive analysis by means of one dimensional fits, with a fixed and floating Higgs boson mass, respectively. The solid squares linked with solid and dashed lines correspond to the values of  $\sigma_{C13D}^{Fix}$  and  $\sigma_{C13D}^{Float}$  given in Table 19, respectively.

The stability of the fits are checked against changes in the composition of the background. The values of  $\sigma_{1D}^{Fix}$  for the inclusive analysis are recomputed by increasing and decreasing the reducible background by a factor of two. The fits are redone with the same functional forms as in the nominal analysis and the results are consistent with the expectations obtained by using  $S/\sqrt{B}$ .

The degradation of the Higgs boson discovery sensitivity due to systematic uncertainties is considered. Various sources of systematic errors are evaluated. The Higgs boson mass resolution has significant impact on the sensitivity. A large degradation of the Higgs boson mass resolution is chosen by the addition of a 1 % constant term in the photon energy resolution. The impact of Higgs boson mass resolution is evaluated for the inclusive analysis by means of one-dimensional fits with a fixed Higgs boson mass.

and the conversion categories are not used.

Figure 13: Expected signal significance for a Higgs boson using the  $H \rightarrow \gamma\gamma$  decay for  $10\text{fb}^{-1}$  of integrated luminosity as a function of the mass. The solid circles correspond to the sensitivity of the inclusive analysis reported in Section 5.1 using event counting. The open circles display the event counting significance when the Higgs boson plus jet analyses (see Sections 5.2 and 5.3) are included. The solid triangles linked with solid and dashed lines correspond to the sensitivity of the inclusive analysis by means of one dimensional fits, with a fixed and floating Higgs boson mass, respectively. The solid squares linked with solid and dashed lines correspond to the maximum sensitivity that can be attained with a combined analysis (see text and Table 19).

If the resolution is increased both in toy Monte Carlo experiments and in the fitting function a decrease of 8% in the signal sensitivity is observed. If, however, the resolution is only degraded in toy Monte Carlo experiments, so that the fitting model does not accommodate the Higgs boson mass resolution degradation, then the effect is a 12% reduction in sensitivity.

The systematic uncertainty due to  $P_{T,H}$  has been estimated by using PYTHIA signal events, reweighted to NLO using ResBos, and fitted with the nominal model based on MC@NLO event simulation. This inconsistency between generation and fit reduces the significance of the full fit (including all categories and the variables  $m_{\gamma\gamma}$ ,  $P_{T,H}$ , and  $|\cos\theta^*|$ , see Table 16) by 5%.

The sensitivity of the associated production channels has been studied separately for the diphoton +  $E_T^{\text{miss}}$  + lepton and for the diphoton +  $E_T^{\text{miss}}$  analyses (see Sections 5.4-5.5). With  $30\text{fb}^{-1}$  these channels have the potential to contribute to the overall discovery signal of a SM Higgs boson, but we choose not to report the value of the signal significance because the systematic uncertainties on the background normalization are large given the present status of simulations.

## 8 Conclusions

The feasibility of the search for a Standard Model Higgs boson in the  $H \rightarrow \gamma\gamma$  decay with the ATLAS detector at the LHC has been presented. The detector performance issues relevant to the search have been evaluated using a full detector simulation. Triggering effects and the impact of pile-up are also reported. A signal significance based on event counting of 2.6 (4.6) can be obtained with  $10$  ( $30$ )  $\text{fb}^{-1}$  of integrated luminosity for  $m_H = 120$  GeV in the case of inclusive analysis. Despite the slight degradation with respect to previous studies, the feasibility of the search for a Standard Model Higgs boson in the  $H \rightarrow \gamma\gamma$  decay is confirmed. In addition to the inclusive analysis the search for diphotons in association

with jets is considered. The addition of these channels enhances the event counting signal significance to 3.3 (5.7) with 10 (30)  $\text{fb}^{-1}$  of integrated luminosity for  $m_H = 120$  GeV. The expected sensitivity can be enhanced by means of an unbinned maximum-likelihood fit dividing the data sample into categories depending on the event topology and exploiting a number of discriminating variables: the increase in the discovery potential increases up to 3.6 (2.8) in the case of fixed (floating) mass fit for 10  $\text{fb}^{-1}$  of integrated luminosity.

The search for  $H \rightarrow \gamma\gamma$  in association with  $Z/W$  or  $t\bar{t}$  has been addressed, indicating that a good signal-to-background ratio can be achieved. However, the uncertainty on the background contribution in these analyses is large given the present status of simulations.

# Search for the Standard Model $H \rightarrow ZZ^* \rightarrow 4\ell$

## Abstract

The Standard Model Higgs boson discovery potential through its observation in the 4-lepton (electron and muon) final state using the ATLAS detector is investigated. Fully simulated signal and background samples were produced with the latest simulation of the ATLAS detector. The samples were subsequently digitized and reconstructed using the ATLAS offline software. The analysis performance dependence on kinematic, lepton reconstruction and isolation cuts is studied for Higgs boson masses ranging from 120 to 600 GeV. The statistical and systematic uncertainties on the background estimation are evaluated and their impact on the Higgs boson discovery potential and exclusion limits is discussed.

## 1 Introduction

The search for the Standard Model Higgs boson is a major goal of the Large Hadron Collider (LHC). The first proton-proton LHC data at 14 TeV center of mass energy are expected in 2009. The Higgs boson mass is a free parameter in the Standard Model, however there is strong expectation motivated by precision electroweak data [1] and direct searches [2] that a low mass Higgs boson (114.4 – 199 GeV, 95% confidence level) should be discovered at the LHC. The experimentally cleanest signature for the discovery of the Higgs boson is its “golden” decay to four leptons (electrons and muons):  $H \rightarrow ZZ \rightarrow 4\ell$ . The excellent energy resolution and linearity of the reconstructed electrons and muons leads to a narrow 4-lepton invariant mass peak on top of a smooth background. The expected signal to background ratio after all experimental cuts depends on the Higgs boson mass itself. The major component of the background consists of irreducible  $ZZ \rightarrow 4\ell$  decays. The most challenging mass region is between 120-150 GeV where one of the  $Z$  bosons is off-shell giving low transverse momentum leptons. In this region backgrounds from  $Zb\bar{b} \rightarrow 4\ell$  and  $t\bar{t} \rightarrow 4\ell$  are important and require tight lepton isolation cuts to keep their contribution well below the  $ZZ$  continuum.

## 2 Detector simulation, Monte-Carlo samples, trigger and event reconstruction

In this section a brief summary of the detector simulation is presented and the Monte-Carlo (MC) samples used in the analysis are described. This includes an outline of the various cross-sections and the corresponding theoretical uncertainties. Finally a brief description of the electron and muon trigger and offline reconstruction is presented.

### 2.1 Detector simulation and Monte-Carlo samples

The ATLAS detector is simulated by the GEANT4 [3] software. Simulation, digitization and reconstruction are all performed within the ATLAS software framework ATHENA. The set of  $H \rightarrow 4\ell$  samples used in this analysis covers the mass range from 120 to 600 GeV. Simulation of pileup, cavern background and minimum bias events is performed by mixing them with the Higgs boson signal at digitization level [4], [5]. An instantaneous constant luminosity of  $10^{33} \text{ cm}^{-2} \text{ s}^{-1}$  is assumed. The cavern background consists of thermalized slow neutrons and low energy photons escaping the calorimeters [6]. The expected level of cavern background is increased by an overall “safety factor”: in this analysis a

safety factor of 5 is used.

The  $H \rightarrow 4l$  analysis is sensitive to uncertainties in the knowledge of the material distribution in ATLAS, to distortions of the magnetic fields, and to the accuracy of the Inner Detector (ID) and of the Muon Spectrometer (MS) alignment. Some of these uncertainties have been taken into account by using geometrical layouts including extra material. The layout used in this analysis includes additional material in the ID, and between the barrel presampler and strips and barrel cryostat upstream and downstream the calorimeter. The calibration of the LAr Electromagnetic Calorimeter (LAr EMC) is based on the nominal geometry without this extra material and its inclusion in our study provides a realistic systematic effect in the analysis. A detailed description of the layout used in simulation and reconstruction can be found in [7]. In the analysis presented in this note, uncertainties due to misalignment corrections are not included: the same misaligned layout is used both in simulation and reconstruction.

The Higgs boson signal samples were generated exclusively by PYTHIA [8] (version 6.3 for  $m_H = 130$  GeV and version 6.4 for the rest of the masses), while for the background samples various event generators were used. For the signal, PYTHIA calculates the cross-sections in leading order (LO) taking into account both gluon and vector boson fusion (VBF) diagrams. Next-to-leading order (NLO) effects are considered by scaling the total PYTHIA cross-sections [9]. During generation, a 4-lepton filter was applied to the samples, requiring 4 true leptons with  $p_T > 5$  GeV/c within  $|\eta| < 2.7$ . The filter acceptance and the cross-section as a function of the Higgs boson mass is given in Table 1. The number of available MC events are shown in the last column.

Process	$\sigma_{LO} \cdot BR [fb]$	$\sigma_{NLO} \cdot BR [fb]$	Filter acc.	Events
$H[120] \rightarrow 4l$	1.68	2.81	0.584	40K
$H[130] \rightarrow 4l$	3.76	6.25	0.633	40K
$H[140] \rightarrow 4l$	5.81	9.72	0.662	40K
$H[150] \rightarrow 4l$	6.37	10.56	0.685	10K
$H[160] \rightarrow 4l$	2.99	4.94	0.704	40K
$H[165] \rightarrow 4l$	1.38	2.29	0.712	40K
$H[180] \rightarrow 4l$	3.25	5.38	0.733	40K
$H[200] \rightarrow 4l$	12.39	20.53	0.753	50K
$H[300] \rightarrow 4l$	7.65	13.32	0.782	10K
$H[400] \rightarrow 4l$	6.07	10.78	0.814	40K
$H[500] \rightarrow 4l$	2.98	5.12	0.842	40K
$H[600] \rightarrow 4l$	1.53	2.53	0.853	40K

Table 1: Monte Carlo signal data samples, 4-lepton ( $e, \mu$ ) filter acceptance, LO and NLO cross-sections, and number of events used in the analysis as a function of the Higgs boson mass in GeV (reported in square brackets). The cross-sections in the table include the branching ratio of the Higgs boson to  $ZZ^*$  and  $Z \rightarrow ll$ ,  $l=e, \mu$ .

### 2.1.1 Corrections to leading order cross-sections for background processes

The backgrounds considered in this analysis, together with their cross-sections and K-factors, defined as the ratio between the NLO and the LO cross-sections, are listed in Table 2. For the generation of these samples several MC generators are employed. The  $t\bar{t}$  background was generated using MC@NLO [10]. The QCD  $ZZ$  was generated with PYTHIA6.3, the  $Zb\bar{b}$  background with AcerMC3.1 [11], and the  $WZ$  background with HERWIG 6.5 [12] interfaced to Jimmy [13] for simulation of the underlying event. The cross-sections listed in Table 2 are all at LO (except for the  $t\bar{t}$  which is at NLO), and they do not include

the lepton filter efficiency. The following corrections are applied to the cross-section of each process to correct for effects of subprocesses not originally included in the generators:

- an additional 30% is applied to the QCD ZZ background cross-section to account for the missing quark box diagram in PYTHIA;
- 8.5 pb are added to the  $Zb\bar{b}$  cross-section to account for the  $q\bar{q} \rightarrow Zb\bar{b}$  diagrams that are not included in the generation.

The last column in Table 2 shows the events available for each sample. Each Z boson in the QCD  $q\bar{q} \rightarrow ZZ$  irreducible background is forced to decay into lepton pairs (including all three flavours).

The  $Zb\bar{b}$  reducible background was generated using ACERMC3.1 [11] with Parton Density Function (PDF) set CTEQ6L, QCD scales  $\mu_R = \mu_F = m_Z$ , massive  $b$ -quark, interfaced to PYTHIA 6.3 for showering and hadronization. The  $Z \rightarrow ll$  ( $l = e, \mu$ ) decay is forced at generator level. The full  $Z/\gamma^*$  interference is taken into account, with a cut on the resonance mass at 30 GeV. The ACERMC dataset includes only the  $g\bar{g} \rightarrow Zb\bar{b}$  process. The  $q\bar{q} \rightarrow (Z/\gamma^*)b\bar{b}$  contribution, where  $q$  is a light quark, is not included; its contribution to the total LO  $Zb\bar{b}$  cross-section is less than 15%. The AcerMC LO cross-section, including the  $Z \rightarrow ll$  branching ratio (BR), evaluated with the above parameter choice, amounts to  $52.03 \pm 0.03$  pb for the  $g\bar{g} \rightarrow (Z/\gamma^*)b\bar{b}$  and  $8.64 \pm 0.01$  pb for the  $q\bar{q} \rightarrow (Z/\gamma^*)b\bar{b}$ .

Process	Generator	$\sigma \cdot \text{BR}$ [fb]	Corrections	FA	Evts [k]
$q\bar{q} \rightarrow ZZ \rightarrow 4\ell$	PYTHIA6.3	158.8	+47.64	[4 $\ell$ ] 0.219	100
$g\bar{g} \rightarrow Zb\bar{b} \rightarrow 2\ell b\bar{b}$	AcerMC/PYTHIA6.3	52030	+8640 ( $q\bar{q} \rightarrow Zb\bar{b}$ )	[4 $\ell$ ] 0.00942	430
$g\bar{g} \rightarrow Zb\bar{b} \rightarrow 2\ell b\bar{b}$	AcerMC/PYTHIA6.3	52030	+8640 ( $q\bar{q} \rightarrow Zb\bar{b}$ )	[3 $\ell$ ] 0.147	200
$g\bar{g}, q\bar{q} \rightarrow t\bar{t}$	MC@NLO/Jimmy	833000		[4 $\ell$ ] 0.00728	400
$q\bar{q} \rightarrow WZ$	Jimmy	26500		[3 $\ell$ ] 0.0143	70
$q\bar{q} \rightarrow Z$ inclusive	PYTHIA6.3	$1.5 \cdot 10^6$		[1 $\ell$ ] 0.89	500

Table 2: Background samples, generators used, acceptance of the multi-lepton filter (FA), LO cross-section (except for  $t\bar{t}$ , which is NLO) and corrections applied. The number of events is given in the last column. For ZZ,  $l = e, \mu, \tau$  while for the rest  $l = e, \mu$ . The relative errors on the filter acceptances (FA) are smaller than 0.4%.

### 2.1.2 Next-to-Leading-Order cross-sections for the background

The  $t\bar{t}$  sample, generated by MC@NLO, is the only sample in Table 2 that already includes NLO processes. To evaluate the NLO cross-sections for the other background processes, the program MCFM [14] is used. The overall conditions for all MCFM NLO calculations are the following: CTEQ6M,  $\mu_R = \mu_F = m_Z$ ,  $m_b = 0$  full  $(Z/\gamma^*)$  interference. Any two final state partons are merged in a single jet if their separation  $\Delta R(jj)$  is smaller than 0.7.

In the case of the  $Zb\bar{b}$  sample, the following additional selections are applied:  $m_Z > 30$  GeV;  $p_T(b) > 10$  GeV,  $|\eta(b)| < 2.5$ . The NLO cross-section obtained from MCFM is:

$$270.4^{+40.6}_{-35.7}(\mu_R)^{+5.4}_{-8.0}(\mu_F) \pm 12.5(\text{PDF}) \pm 1.0(\text{stat}) \text{ pb}$$

where the first two uncertainties come from the QCD renormalization and factorization scales, varying independently the energy scale of the process from  $0.5m_Z$  to  $2m_Z$ , while the last one quotes the PDF uncertainty, calculated by making use of 40 sets of PDFs for CTEQ6M (20 plus and 20 minus). This

$q\bar{q} \rightarrow Z/\gamma^* Z/\gamma^*$	
$m_{Z/Z^*} > 12 \text{ GeV}$	
$m_{ZZ} \text{ (GeV)}$	K-factor
[115,125]	1.15
[125,135]	1.21
[145,155]	1.25
[155,165]	1.34
[175,185]	1.31
[195,205]	1.32
[295,305]	1.40
[395,405]	1.52
[495,505]	1.84
[595,605]	1.81

Table 3: K-factors for the ZZ background. The error on the K-factors is dominated by the systematics (from PDF and renormalization and factorization scales) and amounts to 3.3%.

result has proved to be quite stable with respect to the variation of the cuts both on the minimum jet  $p_T$  and the minimum jet separation  $\Delta R(jj)$ . The LO cross-section evaluated with MCFM on the same phase space is  $189.9 \pm 0.2 \text{ pb}$ , resulting in a K-factor of 1.42. The effective cross-section can be evaluated as follows

$$\sigma_{eff} = \sigma_{LO} \cdot BR(Z \rightarrow ee, \mu\mu) \cdot FA \cdot K = 812.1 \text{ fb},$$

where  $\sigma \cdot BR(Z \rightarrow ee, \mu\mu)$  is the AcerMC cross-section listed in Table 2 rescaled to include the  $q\bar{q}$  contribution, and FA is the acceptance of the generator filter, as reported in Table 2. The statistical error on the filter efficiency is 0.2% for this dataset.

The NLO cross-section for the  $q\bar{q} \rightarrow ZZ^*$  process is calculated with MCFM, applying the same kinematic selection on the Z boson masses as in PYTHIA ( $m_{Z^{(*)}} > 12 \text{ GeV}$ ):

$$\sigma_{NLO} = 22.1^{+0.1}_{-0.2}(\mu_R = \mu_F) \pm 0.7(PDF) \text{ pb}$$

where the statistical error is much smaller than the systematic ones. The effective cross-section used in the analysis can be evaluated according to

$$\sigma_{eff} = \sigma_{LO} \cdot [BR(Z \rightarrow ll)]^2 \cdot FA \cdot (K + 0.3) = 34.82 \cdot (K(m_{ZZ}) + 0.3) \text{ fb},$$

where  $\sigma_{LO} \cdot [BR(Z \rightarrow ll)]^2$  is the LO cross-section, that includes the Z branching ratio to leptons from PYTHIA and amounts to  $159 \pm 0.05 \text{ (stat) fb}$ . The additional 30% accounts for the correction coming from the  $gg \rightarrow ZZ^*$  due to the quark box, as listed in Table 2. The relative statistical error on the filter acceptance FA is 0.3% for this process. The mass-dependent K-factors used in this analysis are shown in table 3.

The NLO cross-section for the WZ background is evaluated by applying the same cut on the boson masses ( $m_{Z^*/W^*} > 20 \text{ GeV}$ ) as in the HERWIG-Jimmy generator used for the LO process:

$$W^- : \sigma_{NLO} = 21.7^{+0.5}_{-0.9}(\mu_R = \mu_F) \pm 0.9(PDF) \text{ pb}$$

$$W^+ : \sigma_{NLO} = 34.8^{+1.2}_{-0.9}(\mu_R = \mu_F) \pm 1.0(PDF) \text{ pb}$$

where the QCD scale uncertainties are included. The statistical error is negligible. The effective cross-section can then be evaluated as follows:

$$\sigma_{eff} = \sigma_{NLO}(W^+Z + W^-Z) \cdot FA = 807 \text{ fb}$$

where  $\sigma_{NLO}(W^+Z + W^-Z)$  refers to the sum of the two contributions. The relative statistical error on the filter efficiency for this process is 0.4%.

## 2.2 Trigger

The simulation of the full ATLAS trigger chain allows to evaluate the impact of the on-line selection on the Higgs boson search. Level-one (LVL1) trigger objects (Region-of-interest, ROI), available in the simulation, correspond to small  $\Delta\eta \times \Delta\phi$  regions where a lepton that satisfies the online selection criteria is found. LVL1 muon thresholds are programmable in the  $p_T$  range from 4 GeV/c to about 40 GeV/c. Similarly to the LVL1 muon Trigger, electron/photon ROIs can be of eight types, depending on the highest  $E_T$  threshold satisfied. The settings in this case are also programmable. In this analysis, two types of electron/photon  $E_T$  thresholds are considered,  $E_T^{thres}=15$  and 22 GeV. For both thresholds, cuts on isolation and on leakage in the hadronic calorimeter are also applied at LVL1. The LVL1 electrons/photons and muons are subsequently confirmed by the High Level Trigger (HLT). The first step is the Level-2 trigger (LVL2) where fast algorithms are used to validate the selected lepton. Events with leptons of a given quality and with energy above certain fixed thresholds are retained for a more accurate reconstruction and selection by the Event Filter (EF), where algorithms based on the offline reconstruction software are used for the final selection. The choice of HLT selection thresholds is optimized for physics performance, assuring that trigger rates satisfy the system latency. The main aspects of the electron and muon trigger systems are described in [15] and [16].

The acceptance of the muon trigger as a function of the generated  $p_T$  for the threshold  $p_T^{thres}=20$  GeV/c, is shown in Fig. 1. The efficiency above threshold is explained by the geometrical coverage of the muon LVL1 trigger detectors; in the barrel, the space occupied by detector feet, supports, services, etc., limits the geometrical acceptance to about 80%, while the efficiency of the trigger algorithm itself is very close to 100%. The trigger efficiencies of electrons for a selection threshold of  $E_T^{thres}=22$  GeV, including electron identification and isolation cuts, is shown in Fig. 2.

Figure 1: Muon trigger: selection efficiencies of the three trigger levels as a function of the true muon transverse momentum. The selection threshold is  $p_T^{thres}=20$  GeV/c.

Figure 2: Electron trigger: selection efficiencies of the three trigger levels as a function of the true electron transverse energy. The selection threshold is  $E_T^{thres}=22$  GeV.

In this paper, several trigger menus foreseen for the LHC running at luminosity  $L=10^{33} \text{ cm}^{-2}\text{s}^{-1}$ , are considered. The trigger efficiency for single and double lepton triggers, for a signal sample with a Higgs

Trigger Menu	Unbiased sample			After event selection		
	4e	4 $\mu$	2e2 $\mu$	4e	4 $\mu$	2e2 $\mu$
1 $\mu$ 20	0.1	95.3	71.3	0.4	98.2	72.7
1e22i	94.7	0.4	68.6	99.8	0.1	78.1
2e15i	76.3	<0.2	33.2	98.9	<0.2	60.2
1 $\mu$ 20 or 1e22i	94.7	95.3	95.7	99.8	98.2	98.9
2 $\mu$ 10 or 2e15i or 1 $\mu$ 10 and 1e15i	76.4	93.3	87.8	98.9	97.6	96.9

Table 4: Trigger selection efficiencies (in %) for various trigger menus, computed for  $H \rightarrow ZZ^* \rightarrow 4l$  ( $m_H=130$  GeV), for the full trigger chain LVL1+HLT. The first three columns show the efficiencies computed on the full event sample. The last three columns show the efficiencies for events selected by the  $H \rightarrow ZZ^* \rightarrow 4l$  analysis. The absolute errors on the efficiencies are 0.4% for the unbiased samples, and 0.2% for events passing the offline selection.

boson mass of 130 GeV, is shown in Table 4. The results are shown for two classes of events: those filtered at generator level, requiring 4 leptons within  $p_T > 5$  GeV and  $|\eta| < 2.7$  (unbiased sample), and those passing the signal selection of reconstructed events, described later in this note. A double-lepton trigger with 10 GeV threshold for the muons and 15 GeV threshold for the electrons (isolation required), selects Higgs boson to four lepton decays with an efficiency higher than 97 %. In the following, the single-lepton menu requiring 1 $\mu$ 20 or 1e22i will be applied as trigger selection.

## 2.3 Electron and muon reconstruction

The leptons used for the efficiency studies are required to satisfy the generator level kinematic cuts  $|\eta| < 2.5$ , and  $p_T > 5$  GeV. The lepton efficiency is defined as the ratio of reconstructed to generated leptons originating from Z decays. The reconstructed leptons include leptons not originating from Z decays (non-prompt leptons) and fakes, so it is important to study these candidates and to estimate the fraction of leptons coming from non-Z decays and fakes. The non-Z lepton fraction is defined as the number of reconstructed leptons matched to true leptons not originating from Z decays, divided by the total number of reconstructed leptons. The fraction of fakes is defined as the number of reconstructed leptons not matched to a true lepton, divided by the total number of reconstructed leptons.

### 2.3.1 Electron reconstruction

The details of electron reconstruction are described in [17] and [18]. Here the electron definitions used in this analysis are briefly summarized. An electron is selected using the offline algorithm requiring:

1. a cluster in the barrel and endcap LAr EMC, reconstructed by the ATLAS offline software;
2. an inner detector track associated with the cluster;
3. cluster containment in the LAr EMC;
4. consistency of the lateral shower shape of the cluster with an electron isolated from hadronic activity;
5. the lateral shower shape to be inconsistent with a  $\pi^0 \rightarrow \gamma\gamma$  decay, using the strip section of the LAr EMC;

6. track quality requirements: a certain number of hits on the Pixel and SCT detector is required, and a transverse impact parameter smaller than 0.1 cm.

The containment and isolation requirements (2,3,4) are satisfied using the so-called *LooseElectron* definition. This definition uses shower shape variables calculated with the middle sampling of the LAr EMC. The addition of requirements 5 and 6 corresponds to the *MediumElectron* definition. In this analysis the *MediumElectron* definition with the addition of calorimetric isolation using all cells (EM and hadronic) inside a  $\Delta R = \sqrt{\Delta\eta^2 + \Delta\phi^2} = 0.2$  cone (*MediumElectron+CaloIso*) has been used. The isolation cuts are  $\eta$ -dependent, as described in detail in [17].

True electrons not originating from a  $Z$  boson decay represent a background to the  $H \rightarrow ZZ^* \rightarrow 4l$  search. Typically they are not isolated and in most cases these electrons originate from heavy quark decays. It should be stressed that leptons from B-mesons are more isolated than those coming from  $D$ -meson decays, and therefore are more difficult to reject. The isolation also depends on the event topology. The non- $Z$  electrons are a small fraction (less than 1%) of the total number of electrons in the  $H \rightarrow ZZ^* \rightarrow 4l$  events. The electron efficiency as a function of the pseudorapidity  $\eta$  and the transverse momentum  $p_T$  for the *Loose*, *MediumElectron* and *MediumElectron+CaloIso* definitions is shown in Fig. 4. A significant drop in efficiency is observed at low  $p_T$ . This is due to the loss of discrimination power of the shower shape cuts. A summary of electron efficiencies and fraction of fakes and non- $Z$

Figure 3: Electron reconstruction efficiency as a function of  $\eta$ . The electron-id criteria are described in the text.

Figure 4: Electron reconstruction efficiency as a function of  $p_T$ . The electron-id criteria are described in the text.

electrons is presented in [17]. The total fraction of fakes depends on the isolation cut and is particularly high for lower  $p_T$ . For low momenta,  $p_T < 15\text{GeV}$ , the fraction of these electrons is about 8% of the total reconstructed electrons in this  $p_T$  range. The contribution from electrons which do not come from  $Z$  decays is a fraction of the fake electrons dominated by heavy flavour (c,b) decays. The b-originated electrons are a factor of 1.5-2 more than the c-originated electrons.

### 2.3.2 Muon reconstruction

The muon identification in ATLAS relies on the Muon Spectrometer (MS) for standalone reconstruction as well as on the ID and Calorimeters for combined muon reconstruction. In order to combine the muon tracks reconstructed in the ID and the MS, the ATLAS offline muon identification packages have been developed. The purpose of these packages is to associate segments and tracks found in the MS with the corresponding ID track in order to identify muons at their production vertex with optimum parameter resolution. Details on the muon system design and performance can be found in [19]. Details on the algorithms of the muon identification described here can be found in [20].

The standalone muon reconstruction algorithm measures the five parameters of the reconstructed tracks with their associated 5x5 covariance matrix at the entrance of the Muon Spectrometer. The muon momentum is corrected using an energy loss parameterization. Overall, the reconstructed track parameters with their full covariance matrices are provided at three locations: 1) at the entrance to the muon spectrometer, 2) at the entrance to the calorimeters, 3) at the perigee of the track. Standalone tracks reconstructed in the MS are combined with tracks reconstructed in the ID in the region of  $\eta < 2.5$ . This combination improves the momentum resolution for tracks with momenta up to 100 GeV and suppresses the rate of fake muons. A statistical combination of the two sets of track parameters is made, weighted by their corresponding covariance matrices. Given a certain  $\Delta R = \sqrt{\Delta\eta^2 + \Delta\phi^2}$  cone, all tracks from the ID are combined with the ones from the MS and the pair giving the best  $\chi^2$  is kept. The same procedure is repeated until no more combinations are possible.

An algorithm has been developed in order to recover muons which fail to be reconstructed in the MS (either because they are low  $p_T$  muons or because the number of stations is insufficient). The principle of the algorithm is based on the extrapolation of ID tracks to the inner stations of the MS and their matching to a segment reconstructed in these stations that was not yet associated to a combined track. The extrapolation is also performed to medium stations, in the regions of  $\eta$  between  $1 < \eta < 1.4$ , where there is a type of inner stations missing, resulting in a drop of the reconstruction efficiency.

The reconstruction efficiency of muons from a 130 GeV Higgs boson sample as a function of their transverse momentum and  $\eta$ , is shown in Figs. 5 and 6 respectively.

Figure 5: Muon reconstruction efficiency as a function of  $p_T$ . Empty (filled) markers show the efficiency of the combined (combined+extrapolated from the ID) algorithm. Reconstructed muons of a Higgs boson sample of 130 GeV mass decaying into four muons are used.

Figure 6: Muon reconstruction efficiency as a function of  $\eta$ . Empty (filled) markers show the efficiency of the combined (combined+extrapolated from the ID) package. Reconstructed muons of a Higgs boson sample of 130 GeV mass decaying into four muons are used.

### 3 Background Rejection

The large  $Zb\bar{b}$  and  $t\bar{t}$  background cross-sections compared to the Standard Model Higgs boson cross-section, require further reduction of these processes by applying additional lepton identification criteria. A reduction well below the irreducible  $ZZ^*$  background yield is a safeguard against large uncertainties on the production cross-sections of these final states. One can exploit the fact that leptons originating from the  $Z$  boson decays are expected to be significantly more isolated than the ones originating from heavy quark leptonic decays. These leptons are also expected to originate from the main interaction point, while  $b, c$ -originating leptons should come from secondary displaced vertices.

In this section, a set of isolation and impact parameter cuts for background rejection is described. In this analysis the cuts have been chosen so that the expected rate for  $Zb\bar{b}$  to 4-leptons ( $4e$ ,  $4\mu$  and  $2e2\mu$ ) is no more than one third of the  $ZZ$  rate. For Higgs boson masses above 160GeV, the reducible background contribution is expected to be less than 10% of the irreducible  $ZZ$ .

### 3.1 Muon Isolation

For the muon final state both calorimetric and track isolation criteria have been considered.

- The calorimetric isolation discriminant is defined as the sum of the transverse energy deposited in the calorimeter inside a cone of a given radius  $\Delta R = \sqrt{\Delta\eta^2 + \Delta\phi^2}$ , around the muon. The energy deposition of the muon itself is subtracted from the isolation energy. The cone energy of the least isolated muon is used as a discriminant.
- The track isolation discriminant is defined as the sum of the transverse momenta of the inner detector tracks in a cone of radius  $\Delta R$  around the muon. The inner detector muon track is excluded from the sum. The least isolated track of all muons in the event, is used as discriminant.

In Figs. 7 and 8 the rejection of the  $Zb\bar{b}$  background as a function of the  $4\mu$  signal efficiency ( $m_H=130$  GeV) is presented, for different calorimetric and track isolation cones, respectively. A cone size of 0.2 is adopted for both calorimetric and track isolation as a conservative choice. Moreover, as shown in Figs. 9 and 10, the background rejection improves when the isolation quantities are normalized to the transverse momentum of the muon, thus the normalized isolation discriminants are used in the analysis.

Figure 7:  $Zb\bar{b}$  rejection versus  $H \rightarrow 4\mu$  efficiency, for  $m_H = 130\text{GeV}$ , for various calorimetric isolation cone sizes. Figure 8:  $Zb\bar{b}$  rejection versus  $H \rightarrow 4\mu$  efficiency, for  $m_H = 130\text{GeV}$ , for various track isolation cone sizes.

The distributions of the normalized calorimetric and track isolation variables calculated using the cones chosen in this analysis for the signal and the main backgrounds are presented in Figs. 11 and 12, respectively. The cuts on the calorimetric and tracker isolation are chosen so that the efficiency for the signal, after application of the two cuts, is close to 90%. The selection cuts are placed at 0.23 and 0.15 for the calorimetric and the tracker isolation, respectively.

### 3.2 Electron Isolation

For the electron final state both calorimetric and track isolation in the inner detector are considered. Although partial calorimetric isolation along the  $\eta$  direction is already part of the electron-id requirements, an extra calorimetric isolation in a cone of  $\Delta R = 0.2$  is applied. The definition of the electron

Figure 9:  $Zb\bar{b}$  rejection versus  $H \rightarrow 4\mu$  efficiency, for  $m_H = 130\text{GeV}$ , for standard and normalized calorimetric isolation calculated in a  $\Delta R=0.2$  cone around the muon track.

Figure 10:  $Zb\bar{b}$  rejection versus  $H \rightarrow 4\mu$  efficiency, for  $m_H = 130\text{GeV}$ , for standard and normalized track isolation calculated in a  $\Delta R=0.2$  cone around the muon track.

Figure 11: Normalized calorimetric isolation ( $\Delta R=0.2$ ) for the signal ( $m_H = 130$ ), the  $Zb\bar{b}$  and  $t\bar{t}$  backgrounds for the  $4\mu$  channel.

Figure 12: Normalized track isolation ( $\Delta R=0.2$ ) for the signal, the  $Zb\bar{b}$  and  $t\bar{t}$  backgrounds for the  $4\mu$  channel.

track isolation is the same as for the muons: it is the sum of the transverse momenta of inner detector tracks in a cone with radius  $\Delta R$  around the direction of the electron track. The  $p_T$  of the electron track is excluded from the sum. In an attempt to remove from the sum tracks originating from conversions of bremsstrahlung photons, only tracks which have at least one hit in the B-layer (the innermost layer of the Pixel detector) are considered in the sum. The track isolation is normalized to the electron  $p_T$ . The distribution of the electron track isolation is shown in Fig. 13, for a cone size  $\Delta R=0.2$ . For the analysis all leptons must satisfy a  $\Sigma p_T/p_T < 0.15$  tracking isolation cut.

### 3.3 Impact parameter analysis

Leptons from  $t\bar{t}$  and  $Zb\bar{b}$  backgrounds are most likely to originate from displaced vertices. Further rejection of these backgrounds can be achieved by placing a cut on the transverse impact parameter significance (defined as  $d0/\sigma_{d0}$ , where  $d0$  is the distance of closest approach in the transverse plane) of the tracks associated to the leptons. For electrons, bremsstrahlung smears the impact parameter distribution, hence reducing the discriminating power of this cut with respect to muons. The impact parameter is calculated with respect to the event vertex fitted using a set of tracks reconstructed in the ID. This allows to remove the effect of the spread of the vertex position, which at LHC is  $15\text{ }\mu\text{m}$  along each of

Figure 13: Signal and background distributions for electron track isolation, normalized to the electron track  $p_T$ , in a cone  $\Delta R < 0.2$ .

the transverse  $x$  and  $y$  axes. In Figs. 14 and 15, the transverse impact parameter significance for muons and electrons is shown. Tracks with  $d0$  significance greater than 3 are not included in the primary vertex fit, and this causes the shoulder visible in the distributions. The discriminating variable used in the event selection for  $Zb\bar{b}$  and  $t\bar{t}$  background rejection, is the maximum lepton impact parameter in the event. This is shown in Figs. 16 and 17 for  $4\mu$  and  $4e$  events, respectively. For electron tracks, the maximum impact parameter normalized to its error is required to be less than 6, while for muons less than 3.5.

Figure 14: Transverse impact parameter significance for muons from signal and reducible background events.

Figure 15: Transverse impact parameter significance for electrons from signal and reducible background events.

## 4 Event selection

In this section the full set of cuts performed in this analysis are summarized and the event kinematic reconstruction is described. These cuts including the isolation and vertexing cuts covered in the previous section are summarized in Table 5.

### 4.1 Event preselection

Events that pass the trigger selection are required to further satisfy certain lepton preselection criteria. An electron must satisfy the *LooseElectron* requirement described in Section 2.3.1, and have an  $E_T > 5$

Figure 16: Maximum impact parameter significance in 4-muon events, for signal and reducible back-

Event Preselection	Four leptons: <i>LooseElectrons</i> or muons. $p_T > 7$ GeV and $ \eta  < 2.5$ , at least two with $p_T > 20$ GeV
<b>Event Selection</b>	
Kinematic Cuts	Lepton quality: 2 pairs of same flavour opposite charge leptons. Electrons must be <i>MediumElectrons</i> satisfying the <i>CaloIso</i> criterion. For $H$ masses of 200 GeV and higher, four <i>LooseElectrons</i> are required instead.  Z, $Z^*$ and Higgs boson reconstruction: single quadruplet with $ m_{ll1} - m_Z  < \Delta m_{12}$ GeV, $m_{ll2} > m_{34}$ .
Isolation and vertexing cuts	Muon Calorimetric isolation ( $\Sigma E_T / p_T < 0.23$ ). Lepton Inner detector track isolation ( $\Sigma p_T / p_T < 0.15$ ). Cut on maximum lepton impact parameter ( $d_0 / \sigma_{d_0} < 3.5$ for muons, $d_0 / \sigma_{d_0} < 6.0$ for electrons).

Table 5: Summary of the analysis cuts for the  $H \rightarrow 4\ell$  analysis. The two lepton pairs are denoted as  $m_{ll1}$  and  $m_{ll2}$ . The values of the mass window  $\Delta m_{12}$  and of the cut  $m_{34}$  are defined in Table 6.

GeV and  $|\eta| < 2.5$ . Muons are selected by requiring  $p_T > 5$  GeV and  $|\eta| < 2.5$  (see section 2.3.2). The final stage of event preselection requires at least four leptons with  $p_T > 7$  GeV and  $|\eta| < 2.5$ , with at least of two these leptons having  $p_T > 20$  GeV.

## 4.2 Event selection and kinematic reconstruction

Following Table 5, in this section we review the kinematic cut part of the event selection. These cuts have been optimized separately for each Higgs boson mass considered in this note.

### Lepton quality requirements:

Events used in this analysis are required to have at least four leptons (e,  $\mu$ ) which can be coupled in pairs of opposite charge and same flavour. These leptons are required to satisfy the requirements:

- Electrons: for Higgs boson masses below 200 GeV, electrons are required to satisfy the *Medium-Electron* quality requirement, and the calorimetric isolation in a  $\Delta R = 0.2$  cone (*CaloIsolation*). For masses above or equal to 200 GeV, due to the higher momentum of the decay electrons, the

*MediumElectron* requirement is relaxed and these electrons are required to satisfy the *LooseElectrons* quality (see Section 2.3.1). This is a conservative choice, due to the fact that complete studies on Z+jets background rejection were limited by the number of simulated events available.

- Muons are required to be either reconstructed by the combined reconstruction algorithm, or by the tagging algorithm which is matching tracks in the inner detector to hit patterns in the muon spectrometer (see Section 2.3.2).

### $Z, Z^{(*)}$ and Higgs boson mass reconstruction

The 4-lepton Higgs boson candidate mass reconstruction proceeds after selecting one single lepton quadruplet in an event. When more than one quadruplet is found, the one with a dilepton mass closest to the nominal Z mass, and with the highest  $p_T$  leptons associated to the second Z, is chosen. The resolution of the dilepton mass can be improved by applying a Z-mass constraint to the pair with a mass closest to the Z invariant mass. When both Z's are on-shell (for Higgs boson masses of 200 GeV and above), the Z-mass constraint can be applied to both lepton pairs. The constraint itself is a convolution between the nominal Z Breit-Wigner distribution, and a gaussian distribution centered at the measured Z value with  $\sigma$  equal to the experimental resolution. The distribution of the Higgs boson mass reconstructed in the case of a 130 GeV Higgs boson is shown in Figs. 18, 19 and 20 for the  $4e$ ,  $4\mu$  and  $2e2\mu$  channels respectively. Only the gaussian region of the distribution is considered in the fit in the case of the  $4e$  channel: the fraction of events falling within  $\pm 2\sigma$  from the mean value is 81.7% in this case. The tail of the distribution is due to electron bremsstrahlung losses upstream the calorimeters.

Figure 18: Reconstructed  $H(130 \text{ GeV}) \rightarrow 4e$  mass after application of the Z-mass constraint fit.

Figure 19: Reconstructed  $H(130 \text{ GeV}) \rightarrow 4\mu$  mass after application of the Z-mass constraint fit.

The Higgs boson mass resolution for masses for which the Higgs boson has a negligible intrinsic width, is shown in Figs. 21 and 22. In these figures it is shown that the Z-mass constraint improves the mass resolution by 10% to 17%. The 4-lepton mass shifts after the Z-mass constraint are shown in Fig. 23 for each of the three decay channels. Independently of the fit, the  $4e$  mass is biased to lower values due to material effects (see Section 2.3.1). For this reason the electron energy has already been corrected by +1% based on the difference of the reconstructed Z mass and the PDG Z mass. The Z-mass constraint is only slightly correcting for these effects. In the  $4\mu$  channel, the bias introduced by the Z-mass constraint is negligible.

Finally, the set of kinematic cuts applied to the reconstructed Z invariant masses is shown in Table 6. The cuts have been optimized using the expected distributions for signal and backgrounds, and the expected dilepton resolution. In this table  $Z_1$  is the dilepton with a mass closest to the nominal Z mass, while  $Z_2$  is the lower mass dilepton pair. To estimate the significance, the events in a  $\pm 2\sigma$  mass window are selected.

Figure 20: Reconstructed  $H(130 \text{ GeV}) \rightarrow 2e2\mu$  mass after application of the Z-mass constraint fit.

Figure 22: Higgs  $\rightarrow 4\mu$  mass resolution as a function of the Higgs boson mass. Open circles denote the resolution obtained when no Z-mass constraint is applied, while full circles show the resolution in the case of the Z-mass constraint.

### 4.3 Event selection results

The cut flow for the selection of a 130 GeV Higgs boson is shown in Tables 7 and 8, for signal and backgrounds respectively. The same is shown for the  $t\bar{t}$  background in Table 9. In this case, the available MC statistics is not sufficient to determine the number of expected events, and only upper limits at 90% CL are set. The final selection efficiencies are shown in Figs. 24 and 25. The distributions of the reconstructed 4-lepton mass, obtained after all cuts, are shown in Figs. 26, 27, 28 for three of the low-mass values (130, 150, and 180 GeV), and in Figs. 29, 30, and 31 for three of the high-mass ones (300, 400, and 600 GeV).

The number of expected events shown for the three decay channels combined is computed using NLO cross-sections (Section 2.1), for a luminosity of  $30 \text{ fb}^{-1}$ . The NLO cross-sections after the full event selection, are shown in Table 10 for the three decay channels separately and combined. In this table, signal events are selected within a  $m_H \pm 2\sigma_{m_H}$  mass window, and systematic errors are not yet taken into account in the significance calculation. Here  $\sigma_{m_H}$  is the experimental 4-lepton mass resolution, shown in Table 6. The significances for the each of the three channels, and their combination, are summarized in Fig. 32.

Figure 23: Shift of the mean 4-lepton mass for each of the three decay channels, with and without the Z-mass constraint on the dilepton mass.

H Mass (GeV)	Z <sub>1</sub> mass window (GeV)	Z <sub>2</sub> mass cut (GeV)	H mass resolution (GeV)		
			4e	4μ	2e2μ
120	±15	>15	2.0	1.8	1.9
130	±15	>20	2.2	1.8	1.9
140	±15	>30	2.2	2.0	2.1

Table 6: Cuts applied to the reconstructed leading and sub-leading Z masses, and the Higgs boson mass resolution values used to define the signal region.

#### 4.4 Estimates of WZ and Z+Jets backgrounds

The contribution of other potentially dangerous backgrounds have also been estimated. Examples are the  $WZ \rightarrow 3\ell$  and the inclusive  $Z + X$  where the Z decays leptonically. In the  $WZ \rightarrow 3\ell$  background pileup and cavern background are included. WZ is found to give a negligible contribution to the total background: the upper limit on the expected number of events is lower than the limit on  $t\bar{t}$  events. The Z+jets process provides one of the most serious backgrounds to the 4e-channel at low masses. With the available MC statistics (500K events, see Table 2), no event survives the lepton quality and  $p_T$  selection cuts. An estimate based on cut factorization leads to an evaluation of the expected number of events after the full event selection, that would correspond to one event after the initial lepton quality and  $p_T$  cuts. This is at the level of about twice the Zbb background, i.e. below the  $ZZ^*$  continuum. The available MC statistics is therefore not sufficient to set stringent limits on the Z+jets background. However, the rejection based on the lepton quality and  $p_T$  cuts should guarantee the complete removal of this background.

Selection cut	Selection step	Signal		
		4e	4 $\mu$	2e2 $\mu$
Trigger selection	1	94.7	95.3	95.7
Lepton preselection	2	57.0	73.8	66.8

Table 8: Fraction of events (in %) selected after each event selection cut for the background processes. The 130 GeV Higgs boson mass selection cuts are applied.

#### 4.5 Effects of pile-up and cavern background

The effects of pile-up and cavern background in the analysis are studied for the analysis for the Higgs boson mass of 130 GeV. The signal selection efficiencies are shown in Fig. 33, for the 4 $\mu$  and 4e channel, as a function of the selection cuts listed in Table 7. Table 12 summarizes the results for the three decay channels. The effect of pileup is to decrease the signal selection efficiency by about 10%, for all three decay channels. This decrease is due to a slight decrease in the trigger efficiency, and of the calorimetric and tracker isolation cut efficiencies. Part of the loss can be recovered by reoptimizing these cuts.

### 5 Systematic uncertainties

Central to the  $H \rightarrow 4l$  analysis is the estimate of the background in a candidate signal region. In this section the systematic uncertainties on quantities associated with the background estimation and the signal efficiency are discussed. First the theoretical uncertainties are presented. Subsequently, the impact of experimental systematic uncertainties on the event selection is discussed. Some of the systematics, like the theoretical uncertainties and systematics on the signal efficiency, affect the estimate of the expected sensitivity. Signal significance extraction from real data is affected by systematics on the knowledge of

Selection cut		$t\bar{t}$		
		4e	4 $\mu$	2e2 $\mu$
Trigger	1	75.1	75.1	75.1
Preselection	2	1.0	4.7	10.1
Lepton quality and $p_T$	3	$6.8 \cdot 10^{-3}$	$7.3 \cdot 10^{-1}$	$5.8 \cdot 10^{-1}$
Z mass cuts	4	$1.6 \cdot 10^{-3}$	$2.0 \cdot 10^{-1}$	$1.0 \cdot 10^{-1}$
Calo Isolation	5	$1.6 \cdot 10^{-3}$	$1.6 \cdot 10^{-3}$	$5.4 \cdot 10^{-3}$
Track Isolation	6	$2.6 \cdot 10^{-4}$	$2.5 \cdot 10^{-4}$	$1.0 \cdot 10^{-3}$
IP cut	7	$2.6 \cdot 10^{-4}$	$< 6 \cdot 10^{-4}$	$2.6 \cdot 10^{-4}$
H Mass window	8	$< 6 \cdot 10^{-4}$	$< 6 \cdot 10^{-4}$	$< 6 \cdot 10^{-4}$

Table 9: Fraction of events (in %) selected after each event selection cut for the  $t\bar{t}$  background. For small available statistics 90% CL limits are considered.

Figure 24: Selection efficiency as a function of the Higgs boson mass, for each of the three decay channels, for the case of only one on-shell Z.

Figure 25: Selection efficiency for as a function of the Higgs boson mass, for each of the three decay channels, for the case of two on-shell Z's.

lepton energy scale and resolution, as determined for example from inclusive Z studies, lepton reconstruction efficiency, and reducible background knowledge from control samples.

## 5.1 Theoretical uncertainties

The major theoretical uncertainties in the prediction of the inclusive background cross-sections are the PDF uncertainties and uncertainties related to the QCD renormalization and factorization scales. Scale uncertainties reflect theoretical uncertainties due to the omission of higher order diagrams. PDF and scale uncertainties have already been discussed and evaluated for the main backgrounds and are only recalled here (see Section 2.1). In summary, for the calculation of the NLO inclusive cross-sections, the QCD scales have been independently varied in the range  $(0.5-2) \times$  the energy scale of the process. The PDF uncertainty has been evaluated by making use of 40 sets of PDF's for CTEQ6M (20 plus and 20 minus).

## 5.2 Experimental uncertainties

Systematic effects on the  $H \rightarrow 4\ell$  analysis arise from experimental uncertainties related to the lepton reconstruction. The major contributions in the total systematic uncertainty in the  $H \rightarrow 4\ell$  yield come from

Figure 26: Reconstructed 4-lepton mass for signal and background processes, in the case of a 130 GeV Higgs boson, normalized to a luminosity of  $30 \text{ fb}^{-1}$ .

Figure 27: Reconstructed 4-lepton mass for signal and background processes, in the case of a 150 GeV Higgs boson, normalized to a luminosity of  $30 \text{ fb}^{-1}$ .

Figure 28: Reconstructed 4-lepton mass for signal and background processes, in the case of a 180 GeV Higgs boson, normalized to a luminosity of  $30 \text{ fb}^{-1}$ .

Figure 29: Reconstructed 4-lepton mass for signal and background processes, in the case of a 300 GeV Higgs boson, normalized to a luminosity of  $30 \text{ fb}^{-1}$ .

uncertainties in lepton energy scale, reconstruction and identification efficiency. The impact of these uncertainties on the analysis is studied by applying variations to offline reconstructed variables. The level of these variations has been provided by the performance groups.

#### Uncertainties in lepton energy scale

Uncertainties on the energy scale of electrons arise from the EM calibration. These are considered by varying by  $\pm 0.5\%$  the  $E_T$  of the reconstructed electrons. Energy scale uncertainties for muons arise due to the imperfect knowledge of the magnetic field. Here the reconstructed muon  $p_T$  is varied by  $\pm 1\%$ . These values are assumed on the basis of the foreseen in-situ determination of the detector performance.

#### Uncertainties in lepton energy resolution

The level of knowledge of the material distributions in ATLAS affects the lepton energy reconstruction. To properly evaluate the impact of this contribution on the analysis, the reconstructed electron energies are smeared with a Gauss function using a  $\sigma_{E_T} = 0.0073 \cdot E_T$ . This extra smearing deteriorates the transverse energy resolution of 50 GeV electrons by a relative 10%. In the muon system, an additional term can be added to this smearing, to take into account misalignment uncertainties. The total muon smearing is  $\sigma_{1/p_T} = 0.011/p_T \oplus 0.00017$  (with  $p_T$  in GeV). In the  $p_T$  range of interest for Higgs boson searches, the second term is negligible. The values of the corrections described above have been chosen so that the

nominal resolution on muon  $p_T$  of 3% is increased to 3.3% after applying the extra smearing.

### Uncertainties in lepton reconstruction efficiency

The impact of uncertainties in the lepton reconstruction efficiency can be estimated by discarding a fixed fraction of leptons before the analysis. The level of uncertainties considered here is 0.2% for electrons and 1% for muons, motivated by performance group studies.

### Material effects in electron efficiency

Uncertainties in electron efficiency receive a large contribution from uncertainties in the knowledge of material upstream the LAr EMC. Systematic effects influence shower shape discriminants included in the electron identification criteria. Examples of such discriminants are the mean energy fraction in a core of  $3 \times 7$  middle sampling cells normalized to a window of  $7 \times 7$  cells, and the mean energy fraction outside a 3-strip core and inside a 7-strip window. As discussed in [17], the presence of extra material shifts and changes the shapes of these distributions, hence reducing the discrimination power of these cuts. The integrated effect in electron efficiency is rather small (less than 2%). However the true systematic uncertainty in the efficiency due to the knowledge of the material depends on how well the material and

Table 10: Cross-sections (in fb) after the full event selection for the signal and irreducible and reducible backgrounds. The cross-sections are given for each of three channels  $4e$ ,  $4\mu$  and  $2e2\mu$ , and for their combination. When no event is passing the event selection, 90% C.L. limits on the cross-section are set. For each channel and for their combination, the expected significance is given for 30 fb<sup>-1</sup>. It is assumed that the background in the signal region is known with negligible uncertainty. The  $t\bar{t}$  background is assumed not to contribute to the significance,

the shower shapes can be measured using data.

### 5.3 Summary of the systematic uncertainties

The impact of the various lepton systematic uncertainties on the Higgs boson signal yield and background rejection is summarized in Table 13 for the various  $4\ell$  final states. Variations have been applied to both signal and background samples, and the analysis algorithm ran with the hypothesis of  $m_H = 130$  GeV. A 3% uncertainty on the luminosity has been taken into account in the total systematic error calculation. The total systematic error on the signal efficiency has been included in the calculation of the exclusion limits described in the following.

## 6 Background extraction from data and significance estimation

In Section 4 the significance has been obtained assuming that the background is known with a negligible uncertainty. In this section various methods to extract the background from data, evaluate the background uncertainties, and include them in the significance calculation, are presented.

Mass (GeV)		200	300	400	500	600

	Significance (30 fb <sup>-1</sup> )	16.5	13.8	12.7	7.1	3.8

Table 11: Cross-sections (in fb) after the full event selection for signal and irreducible background. For Higgs boson masses above 180 GeV the contribution of the reducible backgrounds to the total background cross-section is negligible. The cross-sections are given for each of three channels  $4e$ ,  $4\mu$  and  $2e2\mu$ , and for their combination. When no event is passing the event selection, 90% C.L. limits on the cross-section are set. For each channel and for their combination, the expected significance is given for 30 fb<sup>-1</sup>. It is assumed that the background in the signal region is known with negligible uncertainty.

	$4e$	$4\mu$	$2e2\mu$
No Pileup and CB	12.5±0.3	31.4±0.5	19.2±0.4
With Pileup and CB	12.1±0.3	28.4±0.5	17.0±0.4

Table 12: Selection efficiencies in %, after all cuts, for the signal at 130 GeV, and for each of the three decay channels. The efficiencies are shown for the two cases: with and without the addition of minimum bias low-luminosity pileup and cavern background with safety factor 5.

The main challenge in measuring the background for the  $4\ell$  channel over a very wide mass range (from  $m_{4\ell}$  120 GeV to  $m_{4\ell}$  600 GeV), comes from the fact that signal and background shapes and cross-sections vary considerably. The dominant background comes from the  $ZZ^{(*)}$  continuum. While we expect to measure the  $ZZ$  in the high mass region ( $M_{4\ell} > 180$  GeV) where the reducible backgrounds become negligible, in the low mass region the significant presence of  $Zb\bar{b}$  and  $t\bar{t}$  requires their knowledge. Measurements of these backgrounds with early data will provide upper bounds in their expectation after all Higgs boson analysis cuts.

## 6.1 Significance determination

Most of the systematic uncertainties discussed in the previous section do not contribute to the significance determination if the data distributions are fitted, and signal and background are extracted from the fit. The resulting uncertainty in the knowledge of the background reduces the confidence level for claiming a discovery. In this section a fit-based approach for background and significance extraction is presented. A fit of the selected 4-lepton invariant mass, using the signal hypothesis at a fixed mass and applying the profile likelihood ratio method to extract the significance is considered. The fit method, and

the results obtained after varying the background shape, the fit range and even including background-only fits without the signal hypothesis, are the main subject of this section. An alternative approach with a global two-dimensional (2D) fit on the  $(m_{Z^*}, m_{4\ell})$  plane is also briefly discussed.

The baseline method used as input to the combination of all ATLAS Standard Model Higgs boson searches, is based on a fit of the 4-lepton invariant mass distribution over the full range from 110 to 700 GeV. The method, whose details are described in [21], is summarized below.

The 4-lepton reconstructed invariant mass after the full event selection (except the final cut on the 4-lepton reconstructed mass) is used as a discriminating variable to construct a likelihood function. The likelihood is calculated on the basis of parametric forms of signal and background probability density functions (pdf) determined from the MC. For a given set of data, the likelihood is a function of the pdf parameters  $\vec{p}$  and of an additional parameter  $\mu$  defined as the ratio of the signal cross-section to the Standard Model expectation (i.e.  $\mu = 0$  means no signal, and  $\mu = 1$  corresponds to the signal rate expected for the Standard Model). To test a hypothesized value of  $\mu$  the following likelihood ratio is constructed:

$$\lambda(\mu) = \frac{L(\mu, \hat{\vec{p}})}{L(\hat{\mu}, \hat{\vec{p}})} \quad (1)$$

where  $\hat{\vec{p}}$  is the set of pdf parameters that maximize the likelihood  $L$  for the analysed dataset and for a fixed value of  $\mu$  (conditional Maximum Likelihood Estimators), and  $(\hat{\mu}, \hat{\vec{p}})$  are the values of  $\mu$  and  $\vec{p}$  that maximise the likelihood function for the same dataset (Maximum Likelihood Estimators). The profile likelihood ratio is used to reject the background only hypothesis ( $\mu = 0$ ) in the case of discovery, and the signal+background hypothesis in the case of exclusion. The test statistic used is  $q_\mu = -2\ln\lambda(\mu)$ , and the median discovery significance and limits are approximated using expected signal and background distributions, for different  $m_H$ , luminosities and signal strength  $\mu$ . The MC distributions, with the content and error of each bin reweighted to a given luminosity (in the following referred to as “Asimov data”, see [21]), are fitted to derive the pdf parameters: in the fit,  $m_H$  is fixed to its true value, while  $\sigma_H$  is allowed to float in a  $\pm 20\%$  range around the value obtained from the signal MC distributions. All parameters describing the background shape are floating within sensible ranges. The irreducible background has been modelled using a combination of Fermi functions which are suitable to describe both the plateau in the low mass region and the broad peak corresponding to the second  $Z$  coming *on shell*. The chosen model is described by the following function:

$$f(m_{ZZ}) = \frac{p0}{(1 + e^{\frac{p6 - m_{ZZ}}{p7}})(1 + e^{\frac{m_{ZZ} - p8}{p9}})} + \frac{p1}{(1 + e^{\frac{p2 - m_{ZZ}}{p3}})(1 + e^{\frac{p4 - m_{ZZ}}{p5}})} \quad (2)$$

The first plateau, in the region where only one of the two  $Z$  bosons is *on shell*, is modelled by the first term, and its suppression, needed for a correct description at higher masses, is controlled by the  $p8$  and  $p9$  parameters. The second term in the above formula accounts for the shape of the broad peak and the tail at high masses. This function can describe with a negligible bias the  $ZZ$  background shape with good accuracy over the full mass range. The  $Zb\bar{b}$  contribution is relevant to the background shape only when searching for very light Higgs boson (in this study, only at  $m_H = 120$  GeV). In this case, an additional term is added to the  $ZZ$  continuum, with a functional form similar to the second part of equation 2. For the signal modelling a simple gaussian shape has been used for  $m_H \leq 300$  GeV, while a relativistic Breit-Wigner formula is needed at higher values of the Higgs boson mass. In Figs. 34 and 35 two examples of pseudo-experiments with the resulting fit functions for signal and background are shown.

Figure 34: A pseudo-experiment corresponding to  $30 \text{ fb}^{-1}$  of data for a Higgs boson mass of 130 GeV. The functions fitting the signal and the background are shown.

Figure 35: A pseudo-experiment corresponding to  $30 \text{ fb}^{-1}$  of data for a Higgs boson mass of 180 GeV. The functions fitting the signal and the background are shown.

The results presented in the following approximate the significance from the test statistics as  $\sqrt{-2\ln\lambda(\mu)}$ . In order for the results of the method to be valid, the test statistic  $q_\mu = -2\ln\lambda(\mu)$  should be distributed as a  $\chi^2$  with one degree of freedom. The results obtained with the strategy described above must thus be validated using toy MC. Such validation tests show a good agreement of the test statistic with the expected  $\chi^2$  distribution, as discussed in detail in [21]. This allows to approximate the significance from the test statistic as  $\sqrt{-2\ln\lambda(\mu)}$ . The significances obtained as the square root of the median profile likelihood ratios for discovery,  $-2\ln\lambda(\mu = 0)$  are shown in Table 14 for all  $m_H$  values considered in this paper, and for various luminosities. In Fig. 36, the significance obtained from the profile likelihood ratio, after the fit of signal+background is shown. The significance is compared to the Poisson significance shown in Section 4. The slightly reduced discovery potential is due to the fact that several background shape and normalization parameters are derived from the data-like sample.

Concerning exclusion, the median profile likelihood ratios are calculated under the background only hypothesis, and the integrated luminosity needed to exclude the signal at 95% C.L. is the one corresponding to  $\sqrt{-2\ln\lambda}=1.64$ . The integrated luminosity needed for exclusion is shown in Fig. 37.

The median significance estimation with Asimov data can be validated using toy MC pseudo-experiments. For each mass point, 3000 background-only pseudo-experiments are generated. For each experiment, the profile likelihood ratio method is used to find which  $\mu$  value can be excluded at 95% CL. The resulting distributions are then analysed to find the median and  $\pm 1\sigma$  and  $\pm 2\sigma$  intervals. The outcome of this test is summarized in Fig. 38, where the 95% CL exclusion  $\mu$  obtained from single fits on the full MC datasets is plotted as well. As shown, the agreement is good over the full mass range. Fitting the 4-lepton mass distribution with all parameters left free in function 2 allows the fit to absorb

The result is compared with the one shown in Section 4 where systematic errors on signal and background have not been included, and the significance has been calculated using Poisson statistics.

possible systematics. Inclusion of systematic effects on mass scale and resolution (see Section 5), and on the knowledge of the reducible background, have a total effect smaller than 4% on the significance from the fit.

In addition to the baseline method described above, different fit assumptions have been studied and are discussed below for completeness.

A background-only fit can be performed using pseudo-experiments corresponding to 30 fb<sup>-1</sup> of data, including both signal and backgrounds; the function described in formula 2 is used to describe the background, and the fit is performed over the full range 110-700 GeV, but in this case all the parameters apart from the overall normalization are fixed to the values obtained from a fit of the full MC statistics available. The signal mass window, defined for each value of the Higgs boson mass as described in Section 4, is excluded from the fit (sideband-fit), and the expected background in the signal region is obtained as the integral of the background function in the signal window. The pseudo-experiments fits provide an estimate of background statistical fluctuations and of possible biases introduced by the fit, that must be taken into account in the significance determination. The statistical uncertainty on the background resulting from the fit is no more than 6% over the full mass range.

Another method based on the sidebands consists of calculating, using the full MC statistics, the ratio  $\tau = \frac{B_{MW}}{B_{SB}}$  between the background events in the signal mass window ( $B_{MW}$ ) and those in the sidebands ( $B_{SB}$ ). In the pseudo-experiments, the background level in the signal mass window is estimated as:  $B_{MW}(i) = \tau \times N_{SB}^{obs}(i)$  and the signal as:  $S_{MW}(i) = N_{MW}^{obs}(i) - B_{MW}(i)$ . The resulting uncertainty on the

Figure 38: Validation of the median significance estimation with toy Monte-Carlo experiments. The  $\mu$  value corresponding to 95% CL exclusion obtained from Asimov data is compared to the one obtained using the median profile likelihood ratio from the toy MC pseudo-experiments.

background is no more than 5% over the full mass range. The significance is then obtained, in both cases, using the profile likelihood ratio method applied to the case of a counting experiment, assuming the background mean, and statistical error on the background as from the fit. The results for 130, 150 and 180 GeV Higgs boson mass are summarized in Table 15. The sideband fit and the  $\tau$ -ratio method

Method	Background error	130 GeV	150	180
Sideband	from fit	6.6	14.0	5.9
$\tau$ -ratio	from $\tau$ -ratio	6.7	14.0	5.8

Table 15: The signal significance for various Higgs boson masses, obtained including the background uncertainties from the sideband fit and the  $\tau$ -ratio methods.

can be used to test the impact of some systematic effects, like the mass scale and resolution in the  $ZZ$  threshold region at 180 GeV, and the uncertainties on the reducible  $Zb\bar{b}$  background. The impact of a  $\pm 1\%$  variation of the energy scale on the significance from the fit with all parameters fixed apart from the normalization is of 21% for a Higgs boson mass of 180 GeV, the most critical region. A  $\pm 20\%$  variation of the mass resolution has a 7% effect on the significance. Systematics connected to the knowledge of the reducible  $Zb\bar{b}$  background have been tested removing this background from the samples used to calculate the fit parameters or the  $\tau$ -ratio, and have been found to be at the level of 8%.

The presence of uncertainties in the shape of the  $m_{4\ell}$  distribution at low masses ( $m_{4\ell} < 180$  GeV) and the potential difficulty of predicting the shape in this region using the distribution at higher masses  $m_{4\ell} > 180$  GeV, motivate studies where shape information is extracted from restricted fits in this low mass region. Examples are fits in the region from 110 to 170 GeV, where the background is expected to have a simple shape. In this range we perform both background-only fits excluding the signal region, and fits including the signal hypothesis, using the profile likelihood method but a simpler background parametrization (1st order polynomial). For the background-only fits we extract the significance calculating the p-value as defined in [21], using the method described in [22]. The extracted significance has also been calculated throwing large numbers of toy-MC experiments that were used to calculate the p-value, in order to validate the method of [22]. The background-only fits in the 110 to 170 GeV region

give a significance of  $5.6\sigma$  for a 130 GeV Higgs boson. When the signal hypothesis is included using the profile likelihood method, a significance of  $5.8\sigma$  is found. The small increase in the significance is due to the inclusion of the signal hypothesis which renders the statistical test more powerful. These results for the 130 GeV Higgs boson are close to those obtained from the full mass range fit baseline method (Table 14). Independent measurements (e.g.  $Zb\bar{b}$  background) are expected to provide constraints in the knowledge of the background thus improving the discovery potential.

The fitting approach discussed so far involves one-dimensional fits of the  $m_{4\ell}$  distribution. This approach can be generalized to a global 2D fit on the  $(m_{Z^*}, m_{4\ell})$  plane. Such 2D fits, in contrast to the baseline approach, exploit correlations between  $m_{Z^*}$  and  $m_{4\ell}$ , after a single set of cuts independent of the Higgs boson mass. Having a single set of cuts allows the extraction of the signal through both fixed and floating Higgs boson mass fits. The 2D models on the  $(m_{Z^*}, m_{4\ell})$  plane, have been obtained for the  $ZZ$  and  $Zb\bar{b}$  backgrounds. All available signal samples (for masses from 120 to 600 GeV) have been used to develop a one-parameter family of surfaces (the parameter being  $m_H$ ) that adequately models the signal for any intermediate value of the true Higgs boson mass. Table 16 summarizes the expected significance as a function of  $m_H$ , for both fixed and floating Higgs boson mass window fits, and an integrated luminosity of  $30 \text{ fb}^{-1}$ . These results are obtained using toy MC pseudo-experiments using a median likelihood ratio for the fixed mass case, and a p-value for the floating mass case, as described in [21]. The significances shown in the first row of Table 16 are consistent with the corresponding results of the baseline analysis shown in Table 14.

Mass (GeV)	120	130	140	150	160
2D fit Fixed Higgs boson Mass	2.0	6.3	11.6	14.0	8.3
2D fit Floating Higgs boson Mass	1.1	5.6	10.9	13.2	7.5

Table 16: Median significance from a 2D global fit on the  $(m_{Z^*}, m_{4\ell})$  plane for both fixed and floating Higgs boson mass window and an integrated luminosity of  $30 \text{ fb}^{-1}$ .

## 7 Summary and conclusion

The potential of ATLAS in observing the Higgs boson in its  $H \rightarrow ZZ^* \rightarrow 4\ell$  decay mode was presented. For an integrated luminosity of  $30 \text{ fb}^{-1}$ , ATLAS will discover the Higgs boson in the  $4\ell$  channel-alone in the mass range from 130 – 500 GeV, with the exception of the region around 160 GeV of the WW turn on, where significances of about  $4\sigma$  were found. In the very low mass region of 120 GeV, just above the LEP limit, a significance close to  $3\sigma$  is expected: this is a strong contribution to the combined significance of the various Standard Model decay modes [21]. The  $H \rightarrow ZZ \rightarrow 4\ell$  channel is highly sensitive in the high mass region ( $400 \text{ GeV} > m_{4\ell} > 200 \text{ GeV}$ ), and in the 150 GeV region, where the Higgs boson should be discovered with  $5 \text{ fb}^{-1}$ .

The results obtained in this work include studies of the effect of systematic uncertainties on the signal extraction. In parallel to these studies, several attempts to improve the sensitivity of the channel by increasing the signal yield and keeping the same level of background were performed. Examples are the relaxing of the lepton-id criteria for one of the four leptons, the use of calorimeter for muon tagging, and application of multivariate techniques. Although the first results are encouraging, these studies are beyond the scope of this note since they are still in their very early stages.

# Search for the Standard Model Higgs Boson via Vector Boson Fusion Production Process in the Di-Tau Channels

## Abstract

We outline a search for the Standard Model Higgs boson decaying into a  $\tau$ -pair in association with two jets, which is produced dominantly by the Vector Boson Fusion (VBF) process. The results indicate significant potential for a discovery in the low mass range. We consider fully leptonic, semi-leptonic, and, for the first time, fully hadronic tau decays. Mass reconstruction, central-jet veto, and jet tagging are discussed, and we present an approach to estimate the background from the data. Additional emphasis has been given to trigger issues and the impact of pileup. The results are based on an improved detector description, including misalignments, the most recent reconstruction software, and modern Monte Carlo event generators, including a revised prediction of the underlying event activity.

## 1 Introduction

The search for the Higgs boson and the source of electroweak symmetry breaking is a primary task of the Large Hadron Collider (LHC). It has been shown [1] that the ATLAS detector is capable of discovering the Standard Model Higgs boson with masses ranging from the LEP limit of 114 GeV [2] to about 1 TeV. The low-mass region is preferred from electroweak precision measurements and in this region ( $m_H < 130$  GeV) the searches for Higgs bosons decaying to taus and photons are the most promising for discovery [3–5]. Searches for the Higgs boson produced in Vector Boson Fusion (VBF) tend to have reasonably high signal-to-background ratios, making them more robust to systematic uncertainties.

Within the Standard Model, the ability to observe the Higgs boson in multiple production and decay configurations makes it possible to measure the Higgs boson coupling to fermions and vector bosons [6]. Furthermore, the VBF processes provide a tool for measuring the Higgs boson spin and CP properties [7, 8]. In the context of the Minimal Supersymmetric Standard Model, (MSSM), the branching ratio of a Higgs boson decaying to photons is generally suppressed, which makes the search for Higgs boson decaying to taus very important. The complementarity of the coupling of the light and heavy CP-even, neutral Higgs bosons of the MSSM to taus makes it possible to cover most or all of the  $m_A - \tan\beta$  plane by reinterpreting the results for a Standard Model Higgs boson decaying into taus in the context of the MSSM [9, 10].

A previous ATLAS analysis outlined the sensitivity to a low mass Higgs boson including the first estimates for the VBF channels [4]. These results were primarily based on a fast simulation that parameterized the results of key detector performance studies performed with a full GEANT simulation. In this note we have considered three decay modes: the lepton-lepton ( $ll$ -channel), lepton-hadron ( $lh$ -channel) and the hadron-hadron ( $hh$ -channel) from VBF  $H \rightarrow \tau^+ \tau^-$  signature. The analysis has been done using state-of-the-art Monte Carlo generators, full GEANT-based simulation of the ATLAS detector with realistic misalignments and distortions applied to the expected material in the detector, utilization of our current reconstruction algorithms, and, where possible, incorporation of pileup interactions.

This analysis requires excellent performance from every ATLAS detector subsystem; the presence of  $\tau$  decays implies final states with electrons, muons, hadronic tau decays, and missing transverse momentum, while the Vector Boson Fusion production process introduces jets that tend to be quite forward in the detector. Due to the small rate of signal production and large backgrounds, particle identification must be excellent and optimized specifically for this channel. Furthermore, triggering relies

on the lowest energy lepton triggers or exceptionally challenging tau trigger signatures. The detector performance aspects so important to this analysis are described in Refs. [11–19].

### 1.1 Monte Carlo samples

Estimating the sensitivity of ATLAS to this channel requires the state of the art in Monte Carlo tools. The most challenging aspect of the theoretical calculations is the description of jet activity, an area in which the tools have evolved substantially since ATLAS’ first publication on the sensitivity to the VBF processes. Details of the Monte Carlo samples are outlined in Ref. [20]. The signal samples were produced with HERWIG [21] and PYTHIA [22]. The QCD Z+jets and W+jets samples were produced with ALPGEN [23], which employs the MLM matching [24] between the *hard process* (calculated with a leading-order matrix element for up to 5 jets) and the parton shower of HERWIG. The electroweak (ELWK) Z+jets background was simulated with SHERPA [25]. The  $t\bar{t}$ +jets and diboson background samples were generated with MC@NLO [26]. In all processes with taus, the tau decay was simulated using TAUOLA [27]. Additional photon radiation from charged leptons was simulated with PHOTOS [28]. The production cross-section for the signal is based on the next-to-leading order (NLO) computation and the k-factor (the ratio of the cross-section to that predicted by the lowest order calculation) is around 5% in the target mass range of 100–150 GeV. Note that the k-factor only involves the QCD corrections.

Because the GEANT-based detector simulation is computationally intensive, an event filter was applied to each sample after the parton shower and hadronization. Most processes were required to have at least one lepton in the final state. For background processes a VBF filter was used to remove events that would fail jet-related requirements. The filter bias has been studied and well-validated, but it affects our ability to estimate background rates early in the analysis cut flow. Furthermore, a significant Monte Carlo sample was produced with the ATLAS fast simulation, ATLFast [29], without any event filter. These ATLFast samples are used for systematic studies and to aid in the estimation of background rates (see Section 3.4).

The effect of in-time pileup (i.e. other soft  $p$ - $p$  collisions in the same bunch crossing), out-of-time pileup (i.e.  $p$ - $p$  collisions in neighboring bunch crossings), and the underlying event (i.e. multiparton scattering and soft activity in the  $p$ - $p$  collision of interest) are all important to this analysis. The underlying event has substantial theoretical uncertainty, and different models’ predictions for the underlying event activity vary by large factors when extrapolating to the LHC energy range. Fortunately, the underlying event activity will be one of the first measurements at the LHC and will be well measured by the time the analysis described in this Note is performed. The pileup interactions are incorporated early in the simulation chain, at the time when the detector readout is simulated.

## 2 Event selection

### 2.1 Triggering

While the ATLAS trigger system provides several possibilities for triggering that take advantage of the signal’s complex final state, we restrict ourselves here to simple robust trigger signatures that are expected to have a low rate and an acceptable selection efficiency [12, 13]. For the  $lh$  and  $ll$  final states the events are selected by an isolated electron with  $p_T \geq 22$  GeV (e22i) or an isolated muon with  $p_T \geq 20$  GeV (mu20). The entire trigger chain has been simulated with the use of our current trigger algorithms and trigger menus; however, the dilepton triggers composed of isolated muons with  $p_T \geq 10$  GeV and isolated electrons with  $p_T \geq 15$  GeV considered in Ref. [4] were not used in this study. The trigger efficiency for VBF  $H \rightarrow \tau\tau$  (with  $m_H = 120$  GeV) is 9.0% for events selected by the electron trigger and 9.9% in the case of muons. The trigger efficiencies include detector acceptance and are normalized with

Table 1: The product of efficiency and acceptance for the signal from the e22i, mu20, and L1\_TAU30\_xE40\_softHLT triggers.

Trigger menu	Efficiency $\times$ Acceptance(%)
e22i	$9.08 \pm 0.03$
mu20	$9.88 \pm 0.04$
L1_TAU30_xE40_softHLT	$3.67 \pm 0.02$

respect to the production cross-section for VBF  $H \rightarrow \tau\tau$ . Additional triggers for the  $lh$  and  $ll$  final states, for instance the combined  $\tau + e$  or  $\tau + \mu$  triggers and triggers which take advantage of the tagging jets of the VBF process, are under study.

The all hadronic mode, or  $hh$ -channel, utilizes a different triggering strategy. Unlike the clean signature of the electron and muon triggers, the single tau trigger is expected to be exposed the large QCD jets background. Therefore only tau trigger in combination with other signatures, like missing  $E_T$  or another tau in the event, can be considered. We use L1\_TAU30\_xE40\_softHLT as the primary trigger menu for the  $hh$ -channel in this study. It should be noted that unlike the high  $p_T$  single lepton triggers, both the hadronic tau and  $E_T^{\text{miss}}$  triggers are based on requirements from the first level of the trigger system with only a loose selection in the high-level trigger [30]. The expected trigger acceptance of L1\_TAU30\_xE40\_softHLT is listed in Table 1 as well as those from e22i and mu20 menus. The trigger efficiency for the signal events (for  $m_H = 120$  GeV) is 3.7% for L1\_TAU30\_xE40\_softHLT. The disadvantage of the missing  $E_T$  trigger is the relatively low efficiency on signal; therefore, alternative menus like double tau menus are now being developed.

## 2.2 Electron and muon reconstruction and identification

Electron candidates are formed from a cluster of cells in the electromagnetic calorimeter together with a matched track. The electron identification includes information from the shape of the shower, tracking information, and the consistency of the track and cluster. ATLAS provides multiple working points that trade electron efficiency for improved rejection of fakes. In this analysis we use the *Medium* class electron as it provides sufficient fake rejection and provides a higher signal efficiency. In addition to the standard electron identification, we require that the energy in an isolation cone of radius  $\Delta R = 0.2$  around the electron contains less than 10% of the electron's  $E_T$ <sup>1</sup>. The isolation cut is imposed to reject the contamination from hadronic jets.<sup>2</sup> The reconstruction and identification efficiency is fairly flat after  $p_T \geq 15$  GeV, where it achieves  $69.4 \pm 0.2\%$  efficiency while keeping the fake electron contamination at the order of 0.1%. In the VBF  $H \rightarrow \tau\tau \rightarrow \mu\mu + 4\nu$  signal sample, the probability to reconstruct a fake electron was found to be slightly higher,  $0.25 \pm 0.03\%$ , reflecting some level of process-dependence.

In ATLAS, muon candidates can be seeded from either tracks in the inner detector or in the standalone muon spectrometer. In this analysis we required the highest quality muon candidates, which are formed by extrapolating the track in the muon spectrometer to the interaction point, finding a matching inner detector track, and forming a combined track if the two tracks satisfy various quality requirements [15]. The muon identification is composed of requirements on track quality and hit multiplicity in several muon stations. Similarly to the electrons, we require an isolation condition that the summed  $E_T$  within a radius  $\Delta R$  of 0.2 is less than 10% of the muon  $p_T$  to reject the contamination from jets. The reconstruction and identification efficiency is fairly flat after  $p_T \geq 10$  GeV, and it achieves  $91.9 \pm 0.1\%$  while keeps the fake muon rejection under 0.005%.

<sup>1</sup>Due to a problem with the reconstruction, a correction to the isolation energy in the Tile gap scintillator was required.

<sup>2</sup>A track-based isolation requirement was also studied and shown to have similar performance.

The electron and muon identification criteria are summarized in Table 2. The  $p_T$  thresholds for electron and muon identification are chosen to provide stable identification efficiency and sufficient fake rejection. In addition, we require that the  $p_T$  of the offline reconstructed lepton must satisfy the  $p_T$  thresholds of the corresponding trigger, which is not strictly enforced due to subtle differences between the offline reconstruction and the trigger algorithms.

Table 2: Summary of the identification requirements for electrons and muons.

Lepton identification
<b>Electron ID: Medium</b>
Isolation $E_T(\Delta R = 0.2)/p_T \leq 0.1$
$p_T \geq 25$ GeV for trigger electron (e22i)
$p_T \geq 15$ GeV for other electrons
<b>Muon ID: Combined muon</b>
Isolation $E_T(\Delta R = 0.2)/p_T \leq 0.1$
$p_T \geq 20$ GeV for trigger muon (mu20i)
$p_T \geq 10$ GeV for other muons

### 2.3 Hadronic-tau reconstruction and identification

Approximately 65% of tau leptons decays produce hadrons. The majority of hadronic tau decays are composed of *single-prong* candidates with one charged pion, which provides a track and a hadronic shower, and potentially associated neutral pions that provide an additional electromagnetic sub-cluster. In addition, *three-prong* tau decays are also reconstructed, but with a higher rate of fakes from QCD jets. Due to the high momentum of the taus produced in this process, the decay products are collimated into a narrow region. ATLAS currently employs two hadronic tau reconstruction algorithms [31]; both require a calorimeter cluster matching a track; however, one algorithm is seeded by calorimeter clusters and the other is seeded by the track. The two algorithms' efficiencies are complementary in different  $p_T$  regimes, and provide rejection strategies for their energy measurement and rejection against jets. The calorimeter-seeded algorithm was used for this analysis.

The calorimeter-seeded algorithm provides a log-likelihood ratio that distills discriminating power from a variety of track quality and shower shape information to discriminate between taus and jets [14]. The discriminating variable is designed to maintain a high tau efficiency while rejecting fake tau candidates from jets, leaving the precise working point to be optimized in the context of a specific analysis. The cuts on the discriminating variable and  $p_T$  of the tau candidates were optimized with respect to a simple  $s/\sqrt{s+b}$  performance measure. The background sample included  $Z$ +jets,  $W$ +jets, and  $t\bar{t}$ +jets, which comprises a background sample with a representative mixture of real and fake taus. Our modeling of the jet fragmentation indicates that quark-initiated jets are more collimated and have a 6-8 times higher fake rate than gluon-initiated jets. The relative abundance of real and fake tau candidates depends on the kinematic requirements imposed on the sample, thus the optimization should be performed after the final kinematic requirements described in Sections 2.8 and 2.9. However, the limited size of Monte Carlo samples requires that only a subset of the criteria used in the final event selection are applied during the optimization. Several subsets of the final event selection criterion were evaluated, and the final optimization was found to be reasonably stable and nearly independent of  $p_T$ . After the optimization, the calorimeter-seeded algorithm's log-likelihood ratio was required to be greater than 4, corresponding to an identification efficiency of  $50.0 \pm 0.2\%$  and a fake jet selection efficiency of  $\sim 1\%$  for gluon-initiated jets and  $\sim 2.5\%$  for quark-initiated jets.

Figure 1: Reconstruction and identification efficiency of the hadronic tau (a) and the jet-fake rejection efficiency (b) as a function of  $p_T$ , respectively.

In addition to rejection against jets, an electron-veto was used to reject tau candidates which arise from electrons that have failed the electron identification. This electron-veto was performed by requiring that the tau candidate have at least 0.2% of its energy in the first sampling of the hadronic calorimeter and that the ratio of high-threshold (HT) to low-threshold (LT) hits in the transition radiation tracker (TRT) be less than 20% in the range  $|\eta_\tau| < 1.7$ . This electron-veto procedure suppresses the electron fake rate by 82.5% while retaining 90% of the hadronic tau candidates selected without the veto.

Finally, we present the hadronic tau reconstruction and identification performance in Fig. 1 (a) and the fake-jet tagging rate (b) as a function of  $p_T$ , respectively. The selection criteria for the hadronic tau identification is summarized in Table 3.

Table 3: Selection criteria for the hadronic tau identification from the calorimeter-seeded reconstruction algorithm.

Hadronic tau identification
<b>Tau ID:</b> Calorimeter-seeded
$p_T \geq 30$ GeV
Track multiplicity : 1 or 3 tracks
$ charge  = 1$
$Log Likelihood Ratio \geq 4$
<b>Electron Veto:</b>
minimum TRT $HT/LT \leq 0.2$ if $ \eta_\tau  \leq 1.7$ and $LT \geq 10$
$E_T^{HAD}/p_T \geq 0.002$ in matched electron object

## 2.4 Jet reconstruction

### 2.4.1 Forward tagging jets

The jet activity of the vector boson fusion process is unique in several ways, providing many handles to suppress backgrounds and isolate a sample of signal events with high purity. The most important features of the VBF process are the presence of two high- $p_T$  quark-initiated “tagging jets”, which tend to be relatively forward and well separated in rapidity. Furthermore, due to color coherence in this electroweak process, additional QCD radiation between the tagging jets tends to be suppressed and motivates a Central Jet Veto (CJV) [32]. This section outlines the choice of jet algorithms and their performance, the definition of the tag jets, and several issues related to the CJV.

Figure 2 shows the  $\eta$  spectra of the highest and second highest  $p_T$  jets in signal and various background samples. Because the VBF jets can be very forward, the jet finding efficiency in this region is important in the analysis. Furthermore, the forward calorimeters ( $3.1 \leq |\eta| \leq 4.9$ ) do not have a projective geometry, which leads to different challenges for jet reconstruction. ATLAS currently provides collections of jets based on two algorithms (a seeded cone algorithm with split-merge and a  $k_T$  algorithm), each with two sets of parameters (the cone size and the  $k_T$  cutoff scale), applied to two different input representations of the energy deposits in the calorimeter (towers merged to avoid negative energy fluctuations from electronic noise and clusters based on the ATLAS TopoCluster algorithm) [18]. These different jet algorithms and the different calorimeter pre-clustering result in different performances for jets, especially at low  $p_T$  and high  $|\eta|$ .

Jet identification efficiency and purity are defined to give a quantitative measure of the jet identification. The efficiency and purity were calculated with respect to generator-level jets obtained by running the same jet algorithm on the stable interacting particles after hadronization and before GEANT simulation. To ensure that only hadronic jets are considered, we only use dimuon events, where both taus decay into a muon and neutrinos, or  $Z/W$  bosons directly decay into muons. This avoids any bias in the jet reconstruction produced by the presence of electrons. A reconstructed jet is considered to be matched if the corresponding generator-level jet is within  $\Delta R \leq 0.15$  for jets with a cone size of 0.4. The matching cone size was chosen to avoid a single generator-level jet being matched to more than one reconstructed jet; with the given parameters this effect is at the order of  $10^{-3}$ .

The jet reconstruction efficiency in different  $|\eta|$  regions and two different clustering algorithms is shown in Fig. 3 as a function of the generator-level jet  $p_T$  and  $\eta$ . The reconstruction efficiency rises over 95% for jets with  $p_T$  above 50 GeV. On the other hand, the efficiency drops at  $|\eta| \sim 1.5$  and  $|\eta| \sim 3.2$  for jets in the range of 20-30 GeV of  $p_T$ . This drop in efficiency is due to the crack region in the calorimeter or large amounts of dead material in the corresponding  $\eta$  region. The jet collections based on calorimeter towers show a drop in efficiencies in the forward region due to a higher seed threshold, while the jet collections based on TopoClusters do not show this loss of efficiency. For this reason, jets based on TopoClusters have been chosen for this analysis.

Correctly identifying the quark-initiated tagging jets from the VBF process is very important for the measurement of Higgs boson spin and CP properties and for making precise correspondence with theoretical calculations [8]. Typically, the tagging jets are found in opposite hemispheres, but there are two approaches to incorporating this requirement in the analysis. One option is to define the tagging jets as the two highest  $p_T$  jets in the event, and reject the event from the signal candidates if they are in the same hemisphere (e.g. require  $\eta_{j1} \times \eta_{j2} \leq 0$ ). A second option is to define the first tagging jet to be the highest  $p_T$  jet in the event and the second tagging jet to be the highest  $p_T$  jet in the opposite hemisphere. In this second approach it is not required that the second tagging jet is the second highest  $p_T$  jet in the event. These two strategies were compared, and it was found that the first method more reliably matched the quark-initiated tagging jets from the hard process.

The generator-level jets match the hard-scattered quarks nearly 100% of the time above a certain

Figure 2: Pseudorapidity of the highest  $p_T$  (a) and the second highest  $p_T$  (b) jets for the Cone jet algorithm based on TopoClusters with  $R = 0.4$  in VBF  $H \rightarrow \tau\tau \rightarrow \mu\mu$  ( $m_H=120$  GeV) and background events. Only  $p_T$  cuts were applied to jets. Solid (black) histogram is for signal, dashed (red) histogram is for  $t\bar{t} \rightarrow WW \rightarrow (\mu\mu)$ , and dotted (blue) histogram is for  $Z \rightarrow \mu\mu + n$  jets.

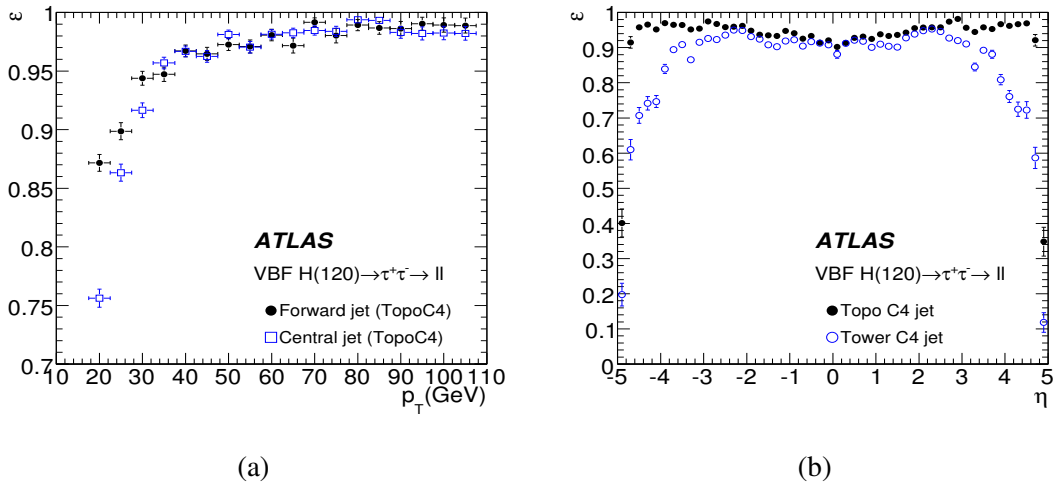

Figure 3: Jet reconstruction efficiency for the Cone jet algorithm with  $R = 0.4$  as a function of the generator-level jet  $p_T$  for the jets based on TopoClusters (a) and  $\eta$  for Tower- and TopoCluster-based jets (b).

$p_T$  threshold. To estimate the purity of the tagging jets, we define the efficiency with respect to the generator-level jets. The reconstructed tag jets have a high purity over the entire  $p_T$  and  $\eta$  range and do not show a strong dependence on the jet algorithms. Integrated efficiencies and purities for jets with  $p_T \geq 20$  GeV indicate that the TopoCluster-based algorithm has better performance for this analysis. Because additional jets often lie in the central detector region, where we wish to employ a central jet veto, jets with smaller cones are favored for the selection. Furthermore, calorimeter noise (including effects from pileup of minimum-bias events) increases with jet cone radius. Thus, we use the cone jet algorithm with  $R = 0.4$  running on TopoClusters as the primary jet algorithm in this analysis.

Having converged on a specific calorimeter pre-clustering and jet algorithm, we now present the kinematic properties of the jets that discriminate between the signal and backgrounds. The  $p_T$  cuts on the tagging jets are effective at reducing several backgrounds and Fig. 2 shows that the pseudorapidity distributions are substantially different. Instead of relying directly on the pseudorapidity of the tagging jets, Fig. 4 shows that the pseudorapidity gap (a) and invariant mass of the two tagging jets (b) provide substantial background rejection.

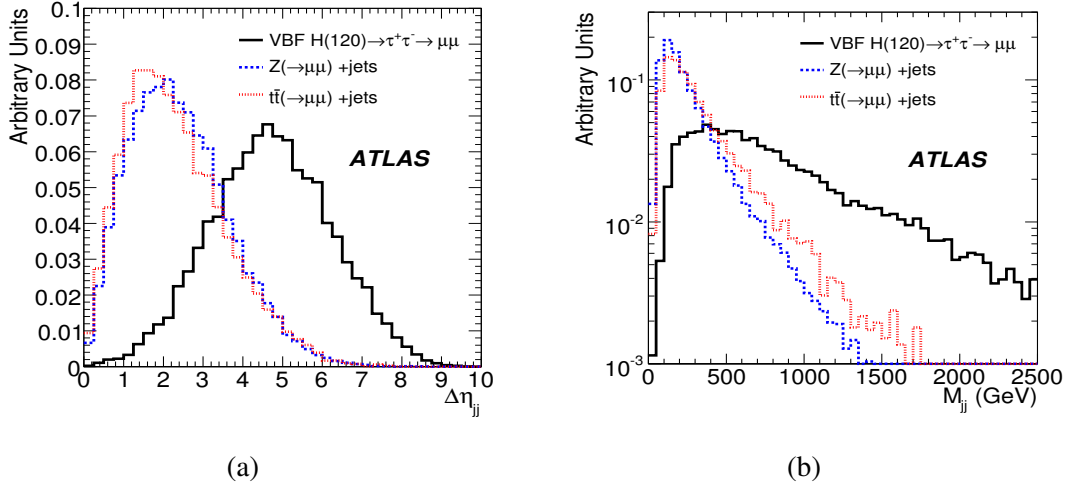

Figure 4: Pseudorapidity gap between tag jets (a) and invariant-mass distributions of tag jets (b) in VBF  $H \rightarrow \tau\tau \rightarrow \mu\mu$  events ( $m_H=120$  GeV). A requirement  $\eta_1 \times \eta_2 \leq 0$  is used in addition to the cuts on jet  $p_T$ . Solid (black) histogram is for signal, dashed (red) histogram is for  $t\bar{t} \rightarrow WW \rightarrow (\mu\mu)$ , and dotted (blue) histogram is for  $Z \rightarrow \mu\mu + n$  jets.

#### 2.4.2 Central jet veto

As mentioned above, the color coherence in the VBF Higgs boson production leads to a suppression of QCD radiation between the tagging jets. This color coherence is also found in the electroweak Z+jets background. In contrast, most of the other backgrounds have a much larger probability for additional QCD radiation in the central region. This is the physical motivation for a central jet veto (CJV). Figure 5 shows the jet multiplicity distribution for the signal and backgrounds after requiring two tagged jets (with  $p_T \geq 20$  GeV) in opposite hemispheres. The fraction of signal events with three or more jets is small.

The experimental challenge for the CJV is to provide a cut that is robust against additional minimum bias events (in-time pileup events). The optimization for the central jet veto has been studied in terms of  $p_T$  and  $\eta$ . The probability to have at least one reconstructed jet with  $p_T \geq 20$  GeV within  $|\eta| \leq 3.2$  is 1.6% from a single minimum-bias event. In Fig. 6, we present the trade-off of background rejection versus signal efficiency from varying the  $p_T$  threshold on the third highest  $p_T$  jet (markers indicate

thresholds of 20 and 30 GeV). A veto based on a fixed  $\eta$ -window was compared to a dynamic  $\eta$ -window defined by the  $\eta$  of the two tagging jets. We maintain the previous central jet veto requirement: no jets in  $|\eta| \leq 3.2$  with  $p_T \geq 20$  GeV. Figure 7 shows the efficiency of the central jet veto for signal, irreducible, and reducible backgrounds at varying levels of pileup.

The CJV poses significant theoretical challenges as well. At the parton-level, the CJV efficiency is expected to be known quite well with little theoretical uncertainty. However, the current tools that allow for the full parton-shower and hadronization (prerequisite for an analysis based on a GEANT-based detector simulation) show significant uncertainties. We have observed significant differences between the central jet activity in signal events generated with PYTHIA and those generated with HERWIG. Knowledge of the uncertainty on the CJV is needed for setting limits on the Higgs boson cross-section and for making coupling measurements; however, it is not needed directly in establishing a deviation from the background-only expectation (see Section 5.3).

In future studies we will also include a veto procedure using track information; in particular using vertexing information to reduce the impact of jets from in-time pileup. Furthermore, a track-based veto and the use of timing information in the calorimeter will also be studied to reduce the impact of out-of-time pileup.

Figure 5: Jet multiplicity distribution for the signal,  $Z$ +jets, and  $t\bar{t}$  background after requiring the cuts up to the  $N$  jets  $\geq 2$  level in the list of cuts for the  $ll$  channel (see Table 5).

Figure 6: Background rejection versus signal sensitivity for the central jet veto with and without pileup. Also shown is the case for  $t\bar{t}$ -only background.

### 2.4.3 $b$ -jet veto

In the  $ll$ -channel, the largest background contribution comes from  $t\bar{t}(+jets) \rightarrow l\nu b l\nu b(+jets)$ . By introducing a veto on  $b$ -tagged forward jets it is possible to reduce this background [19]. Because the tagging jets are fairly forward in the detector, the  $b$ -tagging requirement is rather loose, i.e. efficient, and the  $t\bar{t}$  background can be reduced by a factor  $2\sim 3$ . Figure 8 demonstrates the efficiency of the  $b$ -jet veto as a function of the forward jet  $p_T$  for the signal and  $t\bar{t}$  background. The cut on the  $b$ -tag weight was optimized to achieve 65.1% reconstruction efficiency for  $b$ -quark jets, while 9.4% mis-identification efficiency for the light flavor jets is retained. Note that the  $b$ -jet veto is only used in the  $ll$ -channel.

Figure 7: Central jet veto performance in the presence of varying levels of pileup for signal and background samples.

Figure 8: Efficiency of the  $b$ -jet veto as a function of the forward jet  $p_T$  in for the signal and  $t\bar{t}$  background.

## 2.5 Missing transverse energy

Significant missing transverse energy ( $E_T^{\text{miss}}$ ) is present in  $H \rightarrow \tau^+ \tau^-$  events because neutrinos are always associated with the  $\tau$  decays. The performance of the  $E_T^{\text{miss}}$  algorithm plays a vital role in this analysis because  $E_T^{\text{miss}}$  is used in the mass reconstruction of the tau pair. Ultimately, the  $E_T^{\text{miss}}$  resolution is what limits the  $m_{\tau\tau}$  resolution. Furthermore, the absolute scale of the  $E_T^{\text{miss}}$  must be well calibrated to correctly reconstruct the Higgs boson mass. In addition to the standard  $E_T^{\text{miss}}$  algorithm [17], we have made a dedicated correction in the presence of hadronic tau decays. The correction is based on the calibrated tau energy instead of the default treatment of the object that uses a jet calibration. This removes a  $\sim 1$  GeV bias in the  $E_T^{\text{miss}}$  distribution for the  $lh$ -channel. The sensitivity of the signal efficiency to the absolute energy scale is presented in Section 5.2. By requiring a large  $E_T^{\text{miss}}$ , it is possible to improve the  $m_{\tau\tau}$  resolution and reject many backgrounds that do not contain neutrinos (e.g.  $Z \rightarrow ll$ ). We require  $E_T^{\text{miss}} \geq 30$  GeV for the  $lh$ -channel and  $E_T^{\text{miss}} \geq 40$  GeV for the  $ll$ - and  $hh$ -channels.

## 2.6 Mass reconstruction

Although there are several neutrinos in the event, it is possible to reconstruct the  $\tau^+ \tau^-$  invariant mass by making the approximation that the decay products of the  $\tau$  are collinear with the  $\tau$  in the laboratory frame. This is a good approximation since  $m_H/2 \gg m_\tau$  and hence the taus are highly boosted. This leaves two unknown quantities and two equations: the fraction of each  $\tau$ 's momentum carried away by neutrinos and the constraints from the two components of  $E_T^{\text{miss}}$ . For notational simplicity, consider the  $lh$ -channel and let  $l$  represent the momentum vector for the leptonic visible decay product and  $h$  represent the momentum vector for the hadronic visible decay products. By neglecting the  $\tau$  rest mass and imposing the collinear approximation, we can write

$$m_{\tau\tau} = \sqrt{2(E_h + E_{vh})(E_l + E_{vl})(1 - \cos \theta_{lh})} \quad . \quad (1)$$

By introducing the variables  $x_h$  and  $x_l$ , the fraction of the  $\tau$ 's momentum carried away by the visible decay products, we can re-write the invariant mass as

$$m_{\tau\tau} = \frac{m_{lh}}{\sqrt{x_l x_h}} \quad \text{for } x_{l,h} \geq 0 \quad . \quad (2)$$

One can easily solve for the  $x_\tau$  variables by requiring that the vector sum of the neutrinos coincides with the two measured components of  $E_T^{\text{miss}}$  :

$$x_h = \frac{E_h}{E_h + E_{vh}} = \frac{h_x l_y - h_y l_x}{h_x l_y + E_x^{\text{miss}} l_y - h_y l_x - E_y^{\text{miss}} l_x} = \frac{N}{D_h} \quad (3)$$

and

$$x_l = \frac{E_l}{E_l + E_{vl}} = \frac{h_x l_y - h_y l_x}{h_x l_y - E_x^{\text{miss}} h_y - h_y l_x + E_y^{\text{miss}} h_x} = \frac{N}{D_l}, \quad (4)$$

where we have introduced  $N, D_h$ , and  $D_l$  for convenience. If the two  $\tau$ s are back-to-back, then these equations are linearly-dependent and one cannot solve for the  $x_\tau$ s. For this reason, we require that  $\cos \Delta\phi_{\tau\tau} \geq -0.9$ . Typically the Higgs boson has significant  $p_T$  due to the tagging jets. Events that come from the process  $X \rightarrow \tau\tau$  with no other sources of missing energy should have  $0 \leq x_\tau \leq 1$ , though resolution effects in  $E_T^{\text{miss}}$  may lead to unphysical solutions with either  $x_\tau < 0$  or  $x_\tau \geq 1$ . Equation 2 shows explicitly that cuts on  $x_\tau$  will impose constraints on the reconstructed mass for a given event, viz.  $m_{\tau\tau} \geq m_{lh}$ , which results in an asymmetric distribution for  $m_{\tau\tau}$ .

The sensitivity of  $m_{\tau\tau}$  to a mis-measurement of  $E_T^{\text{miss}}$  depends on the orientation of the  $\tau$ s. This sensitivity can be summarized by a Jacobian factor,  $J$ . Neglecting correlation between the mis-measurement of the  $x$ - and  $y$ -components of  $E_T^{\text{miss}}$ , one can define the Jacobian as follows

$$J = \frac{\Delta m_{\tau\tau}}{\Delta E_{T \ x/y}^{\text{miss}}} = \sqrt{\left(\frac{\partial m_{\tau\tau}}{\partial E_x^{\text{miss}}}\right)^2 + \left(\frac{\partial m_{\tau\tau}}{\partial E_y^{\text{miss}}}\right)^2} \quad . \quad (5)$$

Thus, we arrive at

$$J = \frac{1}{2} \frac{m_{lh} \sqrt{x_l x_h}}{|N|^3} \sqrt{(x_l h_y D_h^2 - x_h l_y D_l^2)^2 + (x_h l_x D_l^2 - x_l h_x D_h^2)^2} \quad . \quad (6)$$

The final mass measurement is a result of a fit to the  $m_{\tau\tau}$  distribution, and it is important to incorporate both the asymmetry and the fact that the width of the  $m_{\tau\tau}$  distribution is not common for all events. The modeling of the asymmetry and Jacobian scaling of the  $m_{\tau\tau}$  distribution is described in Section 4.2.

## 2.7 Summary of the event selection for $ll$ -channel

The event selection for  $ll$ -channel is summarized below, including some kinematic requirements specific to the  $ll$ -channel.

- Trigger: electron trigger e22i or muon trigger mu20.
- Trigger lepton: at least one lepton must have a reconstructed  $p_T$  greater or equal to the corresponding trigger requirement.
- Dilepton: exactly two identified leptons with opposite charge.
- Missing  $E_T$ :  $E_T^{\text{miss}} \geq 40$  GeV.

- Collinear approximation:  $0 \leq x_{l1,l2} \leq 0.75$  and  $\cos \Delta\phi_{ll} \geq -0.9$ .  
The tighter cut on  $x_\tau \leq 0.75$  has been found to provide a better background rejection in the  $ll$ -channel. The shape of the control samples used to estimate the signal sensitivity are obtained after these cuts; additional details of the data-driven background estimation are given in Section 3. In addition to the cuts above, the signal candidates are also required to satisfy the following cuts.
- Jet multiplicity: at least one jet with  $p_T \geq 40$  GeV and at least one additional jet with  $p_T \geq 20$  GeV.
- Forward jets: in opposite hemispheres  $\eta_{j1} \times \eta_{j2} \leq 0$ , with tau centrality  $\min\{\eta_{j1}, \eta_{j2}\} \leq \eta_{lep1,2} \leq \max\{\eta_{j1}, \eta_{j2}\}$  for the two highest  $p_T$  jets.
- $b$ -jet veto: the event is rejected if either tag jet has  $b$ -tag weight greater than 1.
- Jet kinematics:  $\Delta\eta_{jj} \geq 4.4$  and dijet mass  $m_{jj} \geq 700$  GeV for two forward jets.
- Central jet veto: the event is rejected if there are any additional jets with  $p_T \geq 20$  GeV in  $|\eta| \leq 3.2$ .
- Mass window:  $m_H - 15$  GeV  $\leq m_{\tau\tau} \leq m_H + 15$  GeV around the test mass  $m_H$ .

Table 4 summarizes the cross-section for signal events after each of the cuts described above.

Table 4: Signal cross-section (fb) for the  $ll$ -channel for various Higgs boson masses.

## 2.8 Summary of the event selection for $lh$ -channel

The event selection for  $lh$ -channel is summarized below, including some kinematic requirements specific to the  $lh$ -channel.

- Trigger: electron trigger e22i or muon trigger mu20.
- Trigger lepton: at least one lepton must have a reconstructed  $p_T$  greater or equal to the corresponding trigger requirement.
- Dilepton veto: exactly one identified lepton (ensures this sample is disjoint from the  $ll$ -channel).
- Hadronic  $\tau$ : exactly one identified hadronic  $\tau$  with opposite charge of the lepton.
- Missing  $E_T$ :  $E_T^{\text{miss}} \geq 30$  GeV.

- Collinear approximation:  $0 \leq x_l \leq 0.75$ ,  $0 \leq x_h \leq 1$ , and  $\cos \Delta\phi_{lh} \geq -0.9$ .  
The asymmetric treatment of  $x_h$  and  $x_l$  provides background rejection in the  $lh$ -channel.
- Transverse mass: in order to further suppress the  $W$  + jets and  $t\bar{t}$  backgrounds, a cut on the transverse mass of the lepton and  $E_T^{\text{miss}}$

$$m_T = \sqrt{2 p_T^{\text{lep}} E_T^{\text{miss}} \cdot (1 - \cos \Delta\phi)} \leq 30 \text{ GeV} \quad (7)$$

is required, where  $p_T^{\text{lep}}$  is the transverse momentum of the lepton in the  $lh$ -channel and  $\Delta\phi$  is the angle between that lepton and  $\vec{E}_T^{\text{miss}}$  in the transverse plane. The shape of the control samples used to estimate the signal sensitivity are obtained after these cuts; additional details of the data-driven background estimation are given in Section 3. In addition to the cuts above, the signal candidates are also required to satisfy the following cuts.

- Jet multiplicity: At least one jet with  $p_T \geq 40$  GeV and at least one additional jet with  $p_T \geq 20$  GeV.
- Forward jets: in opposite hemispheres  $\eta_{j1} \times \eta_{j2} \leq 0$ , with tau centrality  $\min\{\eta_{j1}, \eta_{j2}\} \leq \eta_{\text{lep}, \tau} \leq \max\{\eta_{j1}, \eta_{j2}\}$  for the two highest  $p_T$  jets.
- Jet kinematics:  $\Delta\eta_{jj} \geq 4.4$  and dijet mass  $m_{jj} \geq 700$  GeV for two forward jets.
- Central jet veto: the event is rejected if there are any additional jets with  $p_T \geq 20$  GeV in  $|\eta| \leq 3.2$ .
- Mass window:  $m_H - 15 \text{ GeV} \leq m_{\tau\tau} \leq m_H + 15 \text{ GeV}$  around the test mass  $m_H$ .

Table 5 summarizes the cross-section for signal events after each of the cuts described above. With  $30 \text{ fb}^{-1}$  integrated luminosity, about 20 signal events are expected in the mass window.

Table 5: Signal cross-sections (fb) for the  $lh$ -channel for various Higgs boson masses.

Mass (GeV)	105	110	115	120	125	130	135	140

## 2.9 Summary of the event selection for $hh$ -channel

The event selection for  $hh$ -channel is summarized below, including some kinematic requirements specific to the  $hh$ -channel.

- Trigger: a combination of the hadronic tau and missing  $E_T$  trigger L1\_TAU30\_xE40\_softHLT.

- Hadronic taus: two identified hadronic taus are required  $p_T$  above 35 GeV and 30 GeV with opposite charge.
- Missing  $E_T$ :  $E_T^{\text{miss}} \geq 40$  GeV.
- Collinear approximation:  $0.2 \leq x_{h1,h2} \leq 1$ , and  $\cos \Delta\phi_{hh} \geq -0.9$ .
- Di-tau transverse mass: in order to further suppress fake- $\tau$  candidates from  $W$  + jets and  $t\bar{t}$  backgrounds, a cut on the di-tau transverse mass

$$m_T^{hh} = \sqrt{2 p_T^{hh} E_T^{\text{miss}} \cdot (1 - \cos \Delta\phi)} \leq 80 \text{ GeV} \quad (8)$$

is required, where  $p_T^{hh}$  is the transverse momentum of the two hadronic tau system and  $\Delta\phi$  represents the azimuthal angle between  $p_T^{hh}$  and  $E_T^{\text{miss}}$ . This variable has been identified as potentially useful for the analysis. The optimal value of this cut depends heavily on the relative amount of the  $W$ +jets,  $t\bar{t}$  and QCD backgrounds, therefore, the requirement is kept fairly loose.

- Jet multiplicity, forward jets, angular cuts, and central jet veto in the case of the  $lh$ -channel.
- Total  $p_T$ : to reject events with many jets like  $t\bar{t}$ , a cut on the total  $p_T$  is applied:

$$||\vec{p}_T^{h1} + \vec{p}_T^{h2} + \vec{p}_T^{j1} + \vec{p}_T^{j2} + E_T^{\text{miss}}|| \leq 60 \text{ GeV} \quad . \quad (9)$$

- Jet kinematics:  $\Delta\eta_{jj} \geq 4$  and dijet mass  $m_{jj} \geq 700$  GeV for two forward jets.
- Central jet veto: the event is rejected if there are any additional jets with  $p_T \geq 20$  GeV in with  $|\eta| \leq 3.2$ .
- Mass window:  $m_H - 15 \text{ GeV} \leq m_{\tau\tau} \leq m_H + 20 \text{ GeV}$  around the test mass  $m_H$ .

Table 6 summarizes the cross-section for signal events after each of the cuts described above. The events used in the analysis have been generated applying a filter that requires two hadronic taus with  $p_T \geq 12$  GeV in the final state, produced in  $|\eta| \leq 2.7$  and with  $\Delta\phi \leq 2.9$ .

Table 6: Signal cross-sections (fb) for the  $hh$ -channel for various Higgs boson masses. The events used in the analysis had a filter applied at generation that required two hadronic taus with  $p_T \geq 12$  GeV in the final state, produced in  $|\eta| \leq 2.7$  and with  $\Delta\phi \leq 2.9$ .

### 3 Background estimation

#### 3.1 Overview

Despite the advances in theoretical tools and extraordinarily detailed simulation of the ATLAS detector, it is preferable to estimate backgrounds from data instead of relying entirely on Monte Carlo estimates. Below we describe data-driven background estimation techniques for each of the major backgrounds and estimate the systematic uncertainty of the estimates. Each technique has been developed to address the aspects of the background estimation which are most relevant for the analysis: the shape of the  $m_{\tau\tau}$  tail from the irreducible  $Z \rightarrow \tau\tau$ , the fake tau contribution in the  $lh$ -channel, and the normalization of the QCD backgrounds. Section 4 describes how these techniques are incorporated into the final signal extraction, significance calculation, and mass measurement.

While it is possible to use Monte Carlo to estimate the systematics associated with the data-driven background estimation techniques, we must wait for data until we can employ these methods to produce reliable *estimates* of the backgrounds. Thus, in a feasibility study such as this one we face the additional challenge of *predicting* the expected backgrounds with Monte Carlo. The challenge of predicting our background and the associated uncertainties are distinct from the ones that we will face once we have collected  $\sim 30 \text{ fb}^{-1}$  of data.

The major challenge in background prediction is related to the limited size of our Monte Carlo samples. Backgrounds from mis-identified leptons are difficult to estimate due to the large rejection factors of the identification algorithms. Even the irreducible  $Z \rightarrow \tau\tau$  backgrounds are suppressed by several orders of magnitude due to the kinematic requirements. The  $t\bar{t}$  background requires particularly large sample sizes because it is suppressed by both identification and kinematic requirements. Table 7 summarizes the size of the Monte Carlo samples used in this study and their corresponding luminosity. Despite the large computing investment and generator-level filters<sup>3</sup>, many background samples were not sufficiently large to estimate rates deep in the analysis where rejection is at the order of  $10^6 - 10^8$ . Thus, the “full” GEANT simulation was augmented with a fast simulation sample  $\sim 100$  times larger and a cut factorization method was used to predict the final background rates. While these procedures have large uncertainties, they are only relevant to our ability to estimate our sensitivity and will not plague the analysis once we have data.

#### 3.2 $Z + \text{jets}$

While there is some theoretical uncertainty in the  $Z \rightarrow \tau\tau + \text{jets}$  background [33], the most serious danger of this background comes from the high-side tail in the  $m_{\tau\tau}$  distribution, where we would expect to see the signal. This tail is dominated by instrumental effects; particularly mis-measurement of  $E_T^{\text{miss}}$ , which is correlated to instrumental effects related to jet energy mis-measurement. Thus, we have developed a data-driven background estimation technique, which begins with a signal-free  $Z \rightarrow \mu\mu + \text{jets}$  sample and transfers the dominant instrumental effects to the  $Z \rightarrow \tau\tau + \text{jets}$  sample. This is achieved by replacing the muons with an equivalent tau, and carefully treating the decay of the tau. This technique is justified because the  $Z \rightarrow \mu\mu + \text{jets}$  events have identical jet activity and kinematics as  $Z \rightarrow \tau\tau + \text{jets}$  (before the tau decays) and because the relevant features of tau decays are well understood. We restrict the technique to the  $Z \rightarrow \mu\mu + \text{jets}$  control sample because muons lose only a small fraction of their energy in the calorimeter, and the effect on  $E_T^{\text{miss}}$  is easier to estimate. After creating the emulated  $Z \rightarrow \tau\tau + \text{jets}$  control sample, the full event selection is applied. The normalization of the  $Z \rightarrow \tau\tau$  background does not

<sup>3</sup>VBFCut :  $N_{e/\mu} \geq 1$  or 2, or  $N_\tau \geq 1$  with  $p_T \geq 10 \text{ GeV}$ ,  $|\eta| \leq 2.7$  for electron, muon and tau from  $W$  and  $Z$ , respectively. For the hadron level jets with cone size 0.4,  $N_{jet} \geq 2$  with  $p_T^1 \geq 20 \text{ GeV}$  for the highest  $p_T$  jet,  $p_T^2 \geq 15 \text{ GeV}$  for the second highest  $p_T$  jet, and  $|\eta| \leq 5$ ,  $m_{jj} \geq 300 \text{ GeV}$ ,  $\Delta\eta_{jj} \geq 2$ .

Table 7: Details of the background samples used in this study. The VBFCut filter is applied for  $Z/W$ +jets events at generator level. The corresponding luminosities for  $Z/W$ +jets and di-boson events are estimated for 2 jets events for  $Z$  and 3 jets events for  $W$ , and  $WW$  events for di-boson process respectively. In  $t\bar{t}$  samples, the actual physics events are approximately 70% to the total number of simulated events according to the treatment of the negative weighted events.

Process	cross-section (pb)	Simulated events	Luminosity ( $\text{fb}^{-1}$ )
$Z \rightarrow ll$ +jets	35.1	714,500	63.1
$W \rightarrow l\nu$ +jets	346.3	765,000	3.43
$t\bar{t}$ +jets (full)	450.0	1,012,941	1.65
$t\bar{t}$ +jets (fast)	833.0	96,250,000	84.3
$t\bar{t}$ (2-muon, full)	32.6	904,000	20.4
$WW/WZ/ZZ$ +jets	174.2	258,094	0.57
QCD di-jets (full)	$\sim 1.4 \times 10^9$	1,503,250	$\sim 10^{-6}$
QCD di-jets (fast)	$\sim 1.4 \times 10^9$	80,000,000	$\sim 5 \times 10^{-5}$

require this emulation because it can be estimated directly from the height of the  $Z$ -peak in  $m_{\tau\tau}$  spectrum obtained with the signal candidates.

The first task is to obtain a signal-free dimuon control sample. Both loose and tight control samples have been used in this data-driven estimation technique. The loose control sample is used to estimate the ditau background not only from  $Z \rightarrow \tau\tau$ +jets events but also from  $t\bar{t}$  or di-boson backgrounds, while the tight control sample can be used for the  $Z \rightarrow \tau\tau$  background estimation by obtaining relatively pure  $Z \rightarrow \mu\mu$ +jets events. The loose control sample requires only a minimum sets of cuts from the  $ll$ -channel, hence  $\sim 10\%$  of this control sample includes other processes such as  $t\bar{t}$ , diboson or even  $Z \rightarrow \tau\tau$ . The tight control sample, in contrast, selects pure  $Z \rightarrow \mu\mu$  events with less than 1% contamination from the other processes. A tighter event selection is used to define this control sample, it is identical to the final event selection in the  $ll$ -channel but excludes of the  $E_T^{\text{miss}}$ , collinear approximation, and mass window cuts. To improve the purity of  $Z$  events, a  $Z$  mass window cut is used:  $m_{\mu\mu} \geq m_Z - 10 \text{ GeV}$ . Due to a strong correlation between the  $m_{\tau\tau}$  and  $m_{\mu\mu}$  distributions before the  $\mu \rightarrow \tau$  conversion, the  $m_{\tau\tau}$  distribution is biased by a cut on  $m_{\mu\mu}$ . The lower bound on  $m_{\mu\mu} \geq m_Z - 10 \text{ GeV}$  has little influence of the shape in the signal region; however, an upper mass cut causes a large bias. Therefore, no upper bound is placed on  $m_{\mu\mu}$ . After obtaining the dimuon events, the reconstructed muons are replaced by the Monte Carlo tau, then decayed and simulated in the ATLAS detector simulation and reconstruction software.

Two different techniques for replacing the muon with the tau decay products were evaluated in this study. One uses the TAUOLA decay package [27] and the other uses a simple re-scaling of the momentum and efficiency of taus, since the technical complexity of re-simulation by TAUOLA are rather difficult in the full detector simulation and reconstruction. A comparison of the two different methods provides a quantitative validation of this procedure. Several comparisons of the  $Z \rightarrow \tau\tau$ +jets control sample emulated from  $Z \rightarrow \mu\mu$  and the true  $Z \rightarrow \tau\tau$  background were performed after imposing the full event selection criteria for the  $ll$ - and  $lh$ -channels. Figure 9 shows the  $p_T$  of the leptons and the  $E_T^{\text{miss}}$  distributions of the emulated sample compared to the true  $Z \rightarrow \tau\tau \rightarrow ll + 4\nu$  process. Figure 10 (a) depicts the reconstructed visible mass for the true and emulated samples in the  $lh$ -channel and (b) shows the bin-by-bin ratio of these distributions. Excellent agreement between the true and emulated distributions are also observed in each of the  $ll$ -,  $lh$ -, and  $hh$ -channels in the region of interest. The gray horizontal band in the figure represents  $\pm 10\%$  around a ratio of 1, which is used to reflect the uncertainty

in the shape from the tau modeling and sensitivity to the analysis cuts. With this method we are able to accurately model both the shape and normalization of the  $Z \rightarrow \tau\tau$  backgrounds for all tau decays.

Figure 9: Transverse momentum of the leptons (a) and missing transverse energy (b) for the two processes rescaled  $Z \rightarrow \mu\mu$  and true  $Z \rightarrow \tau\tau \rightarrow ll + 4\nu$ .

Figure 10: Reconstructed invariant mass distribution (a) and its bin-by-bin ratio (b) generated from the true and emulated  $Z \rightarrow \tau\tau \rightarrow lh + 3\nu$  events. The gray band represents  $\pm 10\%$  around a ratio of 1.

### 3.3 QCD background in $lh$ -channel

The method described above estimates the contribution of taus for all processes, including  $t\bar{t}$ , but does not estimate the contribution of the fake taus. The fake rate of leptons is much smaller as compared to the contribution from real leptons from  $W$  and  $\tau$  decays in the  $ll$ -channel. In contrast, in the  $lh$ -channel roughly half of the  $t\bar{t}$  background come from fake hadronic-taus. In addition, the  $W$ +jets background is comparable to  $t\bar{t}$  in the  $lh$ -channel; therefore, estimating the QCD fake contribution to the  $lh$ -channel requires a dedicated procedure. Estimation of the QCD fake rate is determined from a data-driven method.

The technique used here exploits the track multiplicity in a cone around the tau candidate. Real taus typically have one or three tracks, with some spread due to tracking efficiency or the presence of spurious tracks. Electrons have dominantly a single track, while jets have a broad distribution with a higher average multiplicity. Figure 11 shows the track multiplicity distribution for taus, electrons, and jets in a cone of radius 0.7 after removing outlying tracks. It is clear that the track multiplicity can be used to constrain the relative abundance of the three components to the distribution. While Fig. 11 was created from Monte Carlo, the electron and jet track multiplicity distributions can easily be obtained from data.

Given a sample of tau candidates, the relative abundance of taus, electrons, and jets can be found by fitting the track multiplicity distribution with the extended likelihood function

$$\begin{aligned}
 L_{\text{track}}(r_{QCD}, r_{\text{tau}}) = & \prod_i^N \text{Pois}(n_{\text{exp}}^{\text{tot}} \times (r_{\text{tau}} f_{\text{tau}}^i + r_{QCD} f_{\text{jet}}^i + (1 - r_{\text{tau}} - r_{QCD}) f_{\text{lep}}^i) | N_{\text{obs}}^i) \\
 & \times \text{Gaus}(N_{\text{obs}}^{\text{tot}} | n_{\text{exp}}^{\text{tot}}, \sqrt{n_{\text{exp}}^{\text{tot}}}) \\
 & \times \text{Gaus}(N_{\text{lep}}^{\text{measured}} | n_{\text{exp}}^{\text{tot}} (1 - r_{\text{tau}} - r_{QCD}), \Delta_{\text{lep}} n_{\text{exp}}^{\text{tot}} (1 - r_{\text{tau}} - r_{QCD}))
 \end{aligned} \tag{10}$$

where  $n_{\text{exp}}^{\text{tot}}$  is the total number of events estimated by the fit,  $r_{\text{tau}}$  ( $r_{QCD}$ ) is the fraction of the tau (jet) contribution with respect to the estimated total number of events,  $\Delta_{\text{lep}} = 10\%$  is the relative uncertainty on lepton measurement, and  $f^i$  is the normalized probability for the  $i^{\text{th}}$  bin of the track multiplicity distribution. The second term constrains the normalization, and the third term is an additional constraint term for the lepton contribution estimated by an independent analysis. The fit is performed to find the maximum likelihood estimate with MINUIT [34].

The track multiplicity distribution for the QCD jets is modeled from samples of QCD dijets that produce tau candidates with  $p_T$  in the range of 17- 280 GeV. No event level selections are applied at this stage. Similarly, the multiplicity distribution of the tau signal and lepton background are modeled with Drell-Yan Monte Carlo samples; however, all analysis requirements up to transverse mass cut are applied. Pseudo-datasets were generated for various luminosities based on the corresponding cross-sections and multiplicity distributions. The highly uncertain QCD multi-jet background was scaled to be five times larger than the estimated rates of  $t\bar{t}$  and  $W$ +jets after event selection. A fit was performed for each of the 2000 pseudo-datasets and the results were used to estimate quantify the performance of the method. The expected error on the fraction  $r_{\text{tau}}$  is presented in Fig. 12 as a function of luminosity.

The fraction  $r_{\text{tau}}$  in the signal candidates remaining after the transverse mass cut can be measured to within 5% accuracy with  $1 \text{ fb}^{-1}$  integrated luminosity. The largest uncertainty in this method comes from the dependence of the track multiplicity on the jet  $p_T$ . The systematics were estimated by dividing the jet into two samples; those with  $p_T \leq 70 \text{ GeV}$  and those with  $p_T \geq 70 \text{ GeV}$ . Additionally, the presence of  $E_T^{\text{miss}}$  in the pure QCD processes is strongly correlated to the event kinematics. Thus, we assign an additional systematic associated with the variation observed when repeating the method with modified track multiplicity distributions with and without the requirements on  $E_T^{\text{miss}}$ . The systematics associated with the QCD shape contribute about 2% to  $r_{\text{tau}}$  measurement.

### 3.4 Cut factorization method

The analysis cuts described in Section 2 have rejections against backgrounds of the order of  $10^8$ . Only a few tens of events are expected with  $30 \text{ fb}^{-1}$  of data, and the background Monte Carlo samples generally correspond to  $5 \text{ fb}^{-1}$  or less. The lack of sufficiently large Monte Carlo samples requires an approximate procedure to predict the background rate at the end of the analysis. We utilize a cut factorization method in which the analysis cuts are divided into three categories that are roughly uncorrelated so that the rejection can be factorized. The first category are related to the tau decays from the Higgs boson

Figure 11: Track multiplicity distribution for QCD fake events and electron-fake events as well as the  $\tau$  signal.

Figure 12: Expected errors of the fraction  $r_{\tau\tau}$  as a function of luminosity. The QCD events are scaled to  $\times 2$  and  $\times 5$ .

candidate (trigger, lepton ID, hadronic tau ID,  $E_T^{\text{miss}}$ , the collinear approximation, and the transverse mass) and the rejection is dominated by detector performance issues. The second category of cuts are related to the tagging jets (forward jets, jet separation, and dijet mass) and the rejection is dominated by the kinematic properties of the events. The third category consists of those cuts which are strongly correlated to both the forward tagging jets and the tau decay products (centrality, central jet veto, and mass window cut). The method itself is simple; the background rejection rate is determined for each of the categories individually, and the product of these rejection rates is used to estimate the total rejection rate. Two variations on this cut factorization procedure were considered. In the first approach, the rejection of the jet-related cuts were calculated without any tau-related cuts. The second approach differed in that it included the lepton and tau identification in order to avoid bias effects from the contribution of fake leptons and taus. The residual correlations between the categories of cuts contributes to an uncertainty in this technique. The uncertainties were estimated with the use of larger samples produced with fast simulation and fully simulated samples with generator-level filters, which enrich the backgrounds in the signal-like region. The factorization process was used for all background processes except for the irreducible  $Z \rightarrow \tau\tau$  background.

For the  $W \rightarrow l\nu + \text{jets}$  and  $Z \rightarrow ll + \text{jets}$  backgrounds, ALPGEN samples with up to 5-jets corresponding to  $4 \text{ fb}^{-1}$  integrated luminosity were used. Table 8 shows the average of the jet rejection from the two approaches, which is used as our final prediction. The  $Z$  events in  $ll$ -channel indicate that the jet-related cuts are not strongly correlated with the tau-related cuts, since the rejection rate is the same in the electron and muon modes. The correlation between the categories of cuts was investigated with an ALPGEN  $Z \rightarrow \tau\tau + n \text{ jets}$  sample enriched with the VBFCut filter. The production kinematics are the same, but the enhanced  $E_T^{\text{miss}}$  due to the  $\tau$  decays lets a sufficient number of events survive all the analysis cuts. The background predictions with and without cut factorization are consistent within the 20% statistical error. Thus, we assign a 20% systematic uncertainty for this evaluation method on this process.

The  $t\bar{t}$  background is the most complicated process in that it includes both irreducible and reducible contributions in all channels. We use  $10^6$   $t\bar{t}$  events produced by the MC@NLO generator. The events do not include the process in which both  $W$ s decay hadronically, thus the sample corresponds to  $1.6 \text{ fb}^{-1}$  of integrated luminosity. While the rejection of the tau-related cuts can be reliably estimated, the rejection of the jet-related cuts suffers from the limited sample sizes. The rejection of the jet-related cuts is expected to be very high ( $\times 10^4$  for  $t\bar{t}$ ), resulting in a  $\sim 30\%$  statistical error in the final background predictions.

Table 8 summarizes the rejection of the jet-related cuts subdivided into events with a real or fake hadronic tau for the  $lh$ -channel and by lepton flavor for the  $ll$ -channel. Again, the average of the two approaches is used for the final background prediction. Table 8 shows that there is a considerable contribution of fake-tau events for the  $lh$ -channel. In the  $ll$ -channel, the contribution from semi-leptonic decays of  $B$ -hadrons was found to be very small. An estimate of the uncertainty in the method was found by comparing the prediction from cut-factorization to the direct estimate from an enriched sample filtered to require at least two muons in the event. Furthermore, the cut-factorization results were compared to a sample produced with the fast simulation that was approximately 100 times larger. Based on these comparisons, we assign 50% uncertainty in the  $t\bar{t}$  background prediction.

The diboson background contribution was predicted with the same cut-factorization procedure. Even after using the cut-factorization procedure, the statistical uncertainty in the prediction is very large. Fortunately, the diboson production cross-section is much smaller than the  $t\bar{t}$  processes, so the effect of this background is very small. The results of the cut factorization prediction are presented in Table 8, and we assign a large uncertainty of 50% for diboson background rate. While a number of tests were performed to validate the method, it is clear that this is an approximate procedure and that the limited size of the Monte Carlo samples fundamentally limits our ability to predict this background.

Table 8: Rejection rates of the jet-related cuts for  $Z/W$ +jets,  $t\bar{t}$  and diboson events in  $ll$ - and  $lh$ -channels, respectively.

Acceptance (%)	$ll$ -channel

### 3.5 Background for the $hh$ -channel

In addition to the  $Z$ +jets,  $W$ +jets and  $t\bar{t}$  backgrounds, the  $hh$ -channel also has a background from the pure QCD multi-jet process. The estimation of QCD multi-jets must be made from data. A few handles exist for estimating the pure QCD background. First, one can utilize a sample of same-sign tau candidates to estimate the fake tau contribution since the sign of the tau candidate from QCD is approximately random. Potentially, one can utilize constraints from the track multiplicity distribution as described in Section 3.3. Furthermore, one can loosen the identification requirements on the tau candidates to obtain a sample dominated by QCD fakes, and then extrapolate this background into the signal region using knowledge of the fake tau's likelihood distribution obtained with data. The efficiency of these techniques must also be established with data, but here we assume that the same-sign sample will be able to estimate the QCD background with an uncertainty given by two components. The first component of this uncertainty is the statistical error in the control sample, which scales like  $1/\sqrt{N_{SS}}$ , where  $N_{SS}$  is the size of same sign sample coming from QCD backgrounds. The second component is a systematic uncertainty associated with using the same sign sample to estimate the opposite sign sample. Experience from the Tevatron shows that charge correlations can be of order 13% with an uncertainty of order 3% [35, 36]. Given that the final state requires two additional jets, which can alter the contribution of quark and gluon-initiated

jets, we assume a 10% systematic error associated with the charge correlation. In addition, the same sign sample will also include a contribution from  $W \rightarrow \tau\nu$ +jets, where the Tevatron experiments observed a charge correlation that was much higher with a 40% uncertainty [35]. The experience from the Tevatron provides some insight into this approach, but the results are not directly relevant because the LHC is not a  $\bar{p}$ - $p$  machine.

As in the  $ll$  and  $lh$ -channels we do not have sufficiently large Monte Carlo samples to predict the background for the  $hh$ -channel. We employ the same cut factorization method for the  $Z$ +jets,  $W$ +jets and  $t\bar{t}$  backgrounds as described above. The prediction of the pure QCD multi-jet background from Monte Carlo is hopeless without factorizing the analysis even further. A sample of 80 million QCD dijet events (including  $c\bar{c}$  and  $b\bar{b}$  processes) were simulated with the fast detector simulation. The tau fake rate was parameterized from full simulation as a function of  $\eta$  and  $p_T$  and used to re-weight the dijet sample. In order for a pure QCD process to satisfy the event selection, there must be at least four high- $p_T$  jets. Previous studies have shown that the parton shower underestimates the tagging jet requirement by a factor of 2-3 [4]. Therefore, we multiply the prediction from QCD dijets after the forward jet requirement by a factor of 5 to include the underestimate from the parton shower and an additional safety factor. Table 11 shows that the analysis cuts are extremely effective at rejecting QCD backgrounds, but a realistic estimation of the remaining background requires data.

### 3.6 Summary of the background predictions

Tables 9, 10, and 11 summarize the background predictions for the  $ll$ -,  $lh$ -, and  $hh$ -channels, respectively. The tables also indicate the statistical uncertainty on the estimates from the limited size of the Monte Carlo samples. Note that the mass window cut is set with respect to the test Higgs mass of 120 GeV. The effective cross-sections estimated with the cut-factorization method are marked with an asterisk. Furthermore, the predictions from the  $t\bar{t}$  sample simulated with the fast simulation are shown, where the effective cross-section was normalized to the fully simulated sample after the collinear approximation for the  $ll$ -channel and after the transverse mass cut for the  $lh$ -channel.

Table 9: Summary of the backgrounds for the  $ll$ -channel. An asterisk is used to indicate cross-sections estimated from the cut factorization method. Note that at least one of taus are decayed leptonically in QCD  $Z \rightarrow \tau^+\tau^-$ +jets process.

## 4 Signal sensitivity

### 4.1 Overview

In this section we outline the method for extracting the signal significance from the data and measuring the Higgs boson mass. In addition to a simple method based on counting the number of events in a mass window, we present a method based on fitting the  $m_{\tau\tau}$  spectrum. Particular care has been given to the incorporation of uncertainty in both the rate and shape for the signal and backgrounds. The fitting strategy constrains the shape of the  $Z \rightarrow \tau\tau$  background from the data-driven techniques described in Section 3.2. The data-driven estimates for the  $t\bar{t}$  and  $W$ +jets background are not finalized, thus we rely on Monte Carlo to constrain the shape of those backgrounds and allow for large variation in the shape. In the  $lh$ -channel, the normalization of the fake-tau contribution is constrained from the track multiplicity measurement outlined in Section 3.3. Sections 4.2 and 4.3 describe the parameterization of the signal and backgrounds, while Sections 4.4 and 4.5 describe how the control samples are incorporated to constrain the normalization and shape uncertainties. The expected signal sensitivity is estimated by considering a hypothetical data set given by the median of the signal-plus-background estimate. The normalization of the background predictions are described in Section 3.6. Due to the limited size of the Monte Carlo samples, the shape of the  $m_{\tau\tau}$  spectrum for the  $t\bar{t}$  and  $W$ +jets background was obtained from an earlier point in the event selection, just after the collinear approximation requirement in the  $ll$ -channel and after the transverse mass cut in the  $lh$ -channel (see Sections 2.7 and 2.8). Similarly, the shape of the  $Z \rightarrow \tau\tau$  background in the control sample, which can be estimated by the data-driven techniques described in Section 3.2, was obtained from a  $Z \rightarrow \tau\tau$  Monte Carlo sample just after the same points in the event selection. Depending on how the analysis evolves, the shape of the  $m_{\tau\tau}$  spectrum from an earlier point in the event selection – which is dominated by backgrounds – may also provide a useful control sample to validate the data-driven background estimation techniques since it is fairly stable in the later stages of the event selection.

For the first time ATLAS has investigated the  $hh$ -channel. While the signal efficiency and  $m_{\tau\tau}$  mass resolution are roughly comparable to the  $ll$ - and  $lh$ -channels, a reliable estimate of the QCD background can only be provided with data. Therefore, we do not report on an estimated sensitivity for the  $hh$ -channel below.

### 4.2 Shape parameterization for $H \rightarrow \tau\tau$ and $Z \rightarrow \tau\tau$

The shape of the  $m_{\tau\tau}$  distribution for signal and  $Z \rightarrow \tau\tau$  events is dictated by the resolution of  $E_T^{\text{miss}}$  and the kinematics of the collinear approximation. As discussed in Section 2.6, the width of the  $m_{\tau\tau}$  distributions is given by the  $E_T^{\text{miss}}$  resolution scaled by a Jacobian factor and the cuts on the  $x_\tau$  variables introduce an asymmetry in the  $m_{\tau\tau}$  distribution. A full solution would include an event-by-event Jacobian scaling of the width and truncation at  $m_{\tau\tau} \geq m_{\text{vis}}/\sqrt{x_1^{\text{cut}} x_2^{\text{cut}}}$ . An approximate parameterization can be constructed with these features in mind. First, we consider three sub-samples of events with  $J \leq 2$ ,  $2 < J \leq 5$ , and  $J > 5$ . Let,  $\langle J \rangle_i$  and  $N_i$  denote the mean of the Jacobian and the number of events in the  $i^{\text{th}}$  subsample, respectively. We account for the Jacobian scaling of the width by using a triple Gaussian with identical mean, normalizations according to the ratios of the  $N_i$  and widths according to the ratios of  $\langle J \rangle_i$ . To account for the asymmetry introduced by the  $x_\tau$  cuts, we modulate the triple Gaussian by an efficiency envelope derived from the  $m_{\text{vis}}$  spectrum. The efficiency envelope reflects the probability that  $m_{\tau\tau}$  is greater than  $m_{\text{vis}}$  and is parameterized as:  $1/2 + 1/2 \text{erf}\{[m_{\tau\tau} - \langle m_{\text{vis}} \rangle]/\sqrt{2}\sigma_{\text{vis}}\}$ , where  $\langle m_{\text{vis}} \rangle$  and  $\sigma_{\text{vis}}$  are the mean and standard deviation of the spectrum for those events which fail the  $x_\tau$  cuts. The parameter  $\langle m_{\text{vis}} \rangle$  depends on the Higgs boson mass and was linearly parameterized by

Figure 13: Figures (a) and (b) show the result of a fit to a pure Monte Carlo samples of  $Z \rightarrow \tau\tau$  and signal ( $m_H = 120$  GeV) in the  $lh$ -channel, respectively. The dashed lines represent the three components of the model and the dotted curve represents the erf() efficiency envelope. These samples do not include pileup.

$0.576m_H + 60$  GeV; the width  $\sigma_{vis}$  was fixed at 10 GeV. We parametrize the  $m_{\tau\tau}$  distribution as

$$L_{H/Z}(m_{\tau\tau}|m, \sigma_{H/Z}) = \mathcal{N} \left[ \frac{1}{2} + \frac{1}{2} \operatorname{erf} \left( \frac{m_{\tau\tau} - \langle m_{vis} \rangle}{\sqrt{2}\sigma_{vis}} \right) \right] \times \sum_{i=1}^3 N_i \operatorname{Gaus}(m_{\tau\tau}|m, \sigma_{H/Z} \langle J \rangle_i), \quad (11)$$

where the resulting function's normalization constant  $\mathcal{N}$  was found by numerical integration with the ROOTFIT package [37].

The  $Z \rightarrow \tau\tau$  control sample described in Section 3.2 is used to constrain the mean,  $m_Z$ , and the overall width of the distribution,  $\sigma_Z$ , which are the only free parameters in the  $Z \rightarrow \tau\tau$  background model. The error bars in the control sample were scaled by 10% to account for the 10% shape uncertainty in the  $\mu \rightarrow \tau$  rescaling method and the extrapolation from the control region to the final signal region. Figure 13 shows the result of the fit to the  $Z \rightarrow \tau\tau$  and Higgs boson signal in the  $lh$ -channel.

An alternate parameterization was also considered. This parameterization was also composed of three components, but the asymmetry in the shape was modeled with a “bifurcated” or “dimidated” Gaussian [38], in which the width of the lower half was smaller than the width of the upper half of the distribution. This alternate parameterization did not fix the ratio of the widths and normalizations for the three components based on the distribution of the Jacobian; instead, these parameters were themselves parameterized as a piece-wise linear function of  $m_H$ . Each of the three components required four parameters to model the widths, together with two parameters for normalization constants, and two parameters for the linearity in the Higgs boson mass. In total the signal model was represented by 16 parameters. Results from these two parameterizations were in good agreement.

### 4.3 Shape parameterization for $t\bar{t}$ and $W$ +jets

In contrast to the irreducible  $Z \rightarrow \tau\tau$ +jets background, the  $W$ +jets background is dominated by situations in which one of the tau decay products comes from a  $W$  decay and the second tau decay product is a fake from a jet. The  $t\bar{t}$  background is even more complicated because the decay products from top contain a real tau contribution as well as a fake tau contribution. It is difficult to estimate this background using Monte Carlo because one must understand in detail both the jet kinematics for as well as the lepton or  $\tau$  fake rate as a function of  $p_T$  and  $\eta$ . Instead, it is desirable to estimate this background with data. Since the

data-driven strategy for the  $W$ +jets background is under development, we simply rely on Monte Carlo to provide a control sample for this background. Figure 14(a) shows the shape of the fully simulated  $W$ +jets background and the fast simulation  $t\bar{t}$  background sample after the transverse mass cut. The shapes are consistent within statistical errors. While the shapes from those backgrounds remain stable through the final stages of the event selection, a conservative 50% error is applied to each bin in the combined  $t\bar{t}$  and  $W$ +jets control sample to reflect uncertainty in how this shape changes as the remainder of the analysis cuts are applied.

The shape of the QCD background was parameterized with the following equation

$$L_{QCD}(m_{\tau\tau}|a_1, a_2, a_3) = \mathcal{N}\left(\frac{1}{m_{\tau\tau} + a_1}\right)^{a_2} m_{\tau\tau}^{a_3} . \quad (12)$$

The form is motivated by a competition between the parton distribution functions and the matrix element. In the  $lh$ -channel, the normalization of the backgrounds with fake taus can be constrained by using the track multiplicity constraint described in Section 3.3; however, there is an additional uncertainty associated with how well the fake fraction can be extrapolated from the control sample to the signal like region. We apply a conservative 50% systematic on this fraction associated with the extrapolation. Figure 14(b) and (c) show the result of the simultaneous fit to the fake tau background described in the Section 4.5 with (solid) and without (dashed) the signal contribution for the  $ll$ - and  $lh$ -channel, respectively. The variation reflects the magnitude of the shape uncertainty.

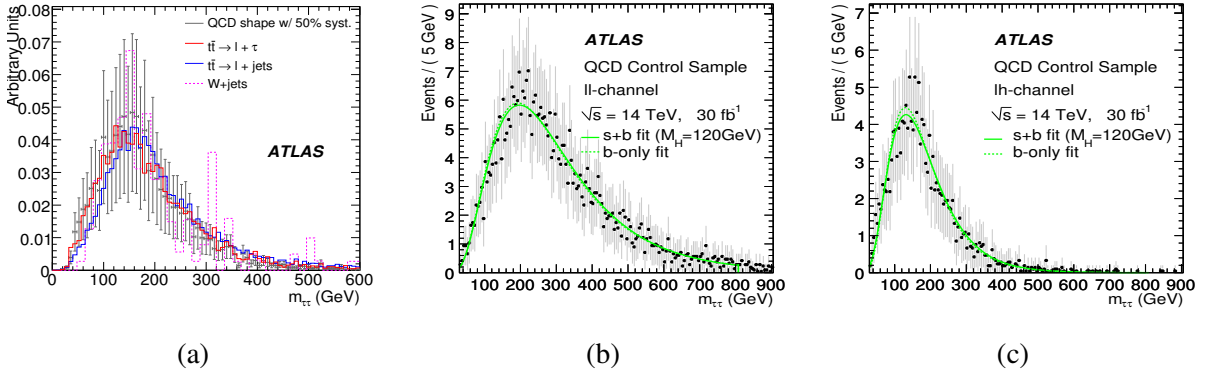

Figure 14: Figure (a) shows that the shapes are similar for these backgrounds and that the shape is stable in the final stages of the cut flow. The  $m_{\tau\tau}$  spectrum for  $t\bar{t}$  and  $W$ +jets backgrounds after all cuts for the  $ll$ -channel (b) and  $lh$ -channel (c) with a fit to the spectrum. The solid and dashed curves show the result of the simultaneous fit to the control sample and signal candidates with and without the signal contribution, respectively.

#### 4.4 Signal significance neglecting shape uncertainty

For a given hypothesized Higgs boson mass,  $m_H$ , the mass window has been defined as  $m_H - 15 \text{ GeV} \leq m_{\tau\tau} \leq m_H + 15 \text{ GeV}$ . A simple approach to estimating the expected significance of the signal is to count events in this range and calculate the probability for at least this many events from the background-only prediction. An alternate approach is to fit the  $m_{\tau\tau}$  spectrum and use the resulting signal yield as a test statistic. Table 12 shows the significance obtained from number counting assuming a 10% background uncertainty as was done in Ref. [4] and the result from the fitted signal yield. The next subsection provides a final result indicating a more realistic treatment of both normalization and shape uncertainties.

Table 12: Expected signal significance for several masses based on number counting in a mass window with  $30 \text{ fb}^{-1}$  of data. Results are shown neglecting uncertainty in the background rate and incorporating it with two methods (see text). These results do not include the impact of pileup, which is discussed in Section 4.7.

$m_H$	$ll$ -channel		$lh$ -channel		combined	
	Counting	Fitted Yield	Counting	Fitted Yield	Counting	Fitted Yield
105	2.20	2.43	2.85	3.46	3.80	4.17

120	2.80	3.17	4.23	4.73	5.36	5.72
125	2.67	2.96	3.97	4.32	5.08	5.28
130	2.42	2.73	3.54	3.88	4.62	4.77
135	2.17	2.37	3.38	3.60	4.35	4.25
140	1.74	2.00	2.66	2.83	3.55	3.35

#### 4.5 Incorporating control samples and shape uncertainty

By fitting the  $m_{\tau\tau}$  spectrum to a model that accurately describes the signal and various backgrounds it is possible to directly incorporate uncertainty in the background shape and take advantage of the shape of the signal within the mass window. In order to constrain the background rate and shape, we simultaneously fit the signal candidates and the background control samples outlined in Section 3. The fit is performed twice, once letting the signal parameters float (the maximum likelihood estimates denoted with a single  $\hat{\phantom{x}}$ ) and once constraining the signal normalization to be zero (the conditional maximum likelihood estimates denoted with a double  $\hat{\phantom{x}}$ ). The ratio of these likelihoods is referred to as the profile likelihood ratio,  $\lambda$ ,

$$\lambda(\mu = 0) = \frac{L(\text{data}|\mu, \hat{b}(\mu), \hat{v}(\mu))}{L(\text{data}|\hat{\mu}, \hat{b}, \hat{v})}, \quad (13)$$

where  $\mu$  represents the signal strength in units of the Standard Model expectation and  $v$  represents the nuisance parameters needed to describe the shape. If the Higgs boson mass is specified, the distribution of  $-2\log\lambda$  ratio asymptotically approaches a  $\chi^2$  distribution with the number of degrees of freedom given by the number of parameters of interest<sup>4</sup>. The motivation for  $\mu$  is that it enforces the relationship of the Standard Model branching ratios when combining the individual channels, maintaining the property that the distribution of  $-2\log\lambda$  is  $\chi^2$  with one degree of freedom. This improves the power compared to a method which lets the signal in each channel vary independently. If the Higgs boson mass is not fixed, then one must take into account the “look-elsewhere” effect, which is discussed in more detail in Section 6. The likelihood function used in the simultaneous fit is simply a product of the likelihoods from the individual measurements:

$$\begin{aligned} L(\text{data}|\mu, m_H, v) &= L_{\text{track}}(\text{track multiplicity}|r_{QCD}) \\ &\times L_Z(Z + \text{jets control}|m_Z, \sigma_Z) \\ &\times L_{QCD}(QCD \text{ control}|a_1, a_2, a_3) \\ &\times L_{s+b}(\text{signal candidates}|\mu, m_H, \sigma_H, m_Z, \sigma_Z, r_{QCD}, a_1, a_2, a_3), \end{aligned} \quad (14)$$

where the  $a_i$  are the parameters used to parameterize the fake-tau background and  $v$  represents all nuisance parameters of the model:  $\sigma_H, m_Z, \sigma_Z, r_{QCD}, a_1, a_2, a_3$ . When using the alternate parameterization

<sup>4</sup>When constraining  $\mu \geq 0$ , the distribution for the background-only hypothesis is modified such that  $-2\log\lambda(\mu = 0) \sim 1/2\delta(0) + 1/2\chi^2$ , and this is taken into account in computing the p-value.

Figure 15: Example fits to a data sample with the signal-plus-background (a,c) and background only (b,d) models for the  $lh$ - and  $ll$ -channels at  $m_H = 120$  GeV with  $30 \text{ fb}^{-1}$  of data. Not shown are the control samples that were fit simultaneously to constrain the background shape. The fits are performed to the signal and background expectation (histograms), while the overlaid data with error bars are only indicative of a possible data set. These samples do not include pileup.

of the signal, the exact form of Equation 14 is modified to coincide with parameters of that model.

Figure 15 shows the fit to the signal candidates for  $m_H = 120$  GeV with (a,c) and without (b,d) the signal contribution. It can be seen that the background shapes and normalizations are trying to accommodate the excess near  $m_{\tau\tau} = 120$  GeV, but the control samples are constraining the variation. Table 13 shows the significance calculated from the profile likelihood ratio for the  $ll$ -channel, the  $lh$ -channel, and the combined fit for various Higgs boson masses with  $30 \text{ fb}^{-1}$  of data. Finally, we present the expected significance as a function of Higgs boson mass in Fig.16.

Table 13: Expected signal significance for several masses based on fitting the  $m_{\tau\tau}$  spectrum with  $30 \text{ fb}^{-1}$  of data. Background uncertainties are incorporated by utilizing the profile likelihood ratio. These results do not include the impact of pileup, which is discussed in Section 4.7.

$m_H$	$ll$ -channel	$lh$ -channel	combined
105	1.95	2.41	3.10
110	2.44	3.35	4.15
115	2.98	4.07	5.04
120	2.92	3.87	4.85
125	2.75	3.75	4.65
130	2.46	3.38	4.18
135	2.21	3.32	3.99
140	1.80	2.70	3.24

Figure 16: Expected signal significance for several masses based on fitting the  $m_{\tau\tau}$  spectrum. Background uncertainties are incorporated by utilizing the profile likelihood ratio. These results do not include the impact of pileup.

#### 4.6 Mass determination

The mass parameter  $m_H$  and its error can be determined from the fits described above; however, the parameter in the model may not be the best estimate of the physical Higgs boson mass. Similarly, the error on the mass parameter from the fit should be validated with a large number of pseudo-experiments. Figure 17 (a) shows the relationship of the input Higgs boson mass and the reconstructed Higgs boson mass (i.e. the parameter  $m_H$  in Equation 11) obtained with 2000 pseudo-experiments per input mass point. Figure 17 (b) shows the  $m_{\tau\tau}$  resolution for the signal as a function of the input Higgs boson mass. When scaling the deviation by the MINOS errors, the pull distribution of  $m_H$  was found to be consistent with the normal distribution  $N(0, 1)$ . The mass resolution is found to be in the range of 8~10 GeV. A similar mass resolution was found in the  $hh$ -channel when analyzing signal Monte Carlo samples.

#### 4.7 Influence of pileup

The presence of pileup has three major effects on the analysis. First, additional  $p$ - $p$  interactions can produce hadronic activity in the central region which causes events to fail the central jet veto. Secondly, the presence of pileup generally degrades the  $E_T^{\text{miss}}$  resolution, which, in turn, reduces the efficiency of the collinear approximation cuts and degrades the  $m_{\tau\tau}$  resolution. Thirdly, pileup degrades the hadronic

Figure 17: The linearity of the fitted mass versus the input mass (a) and the mass resolution versus the input mass (b). These results do not include the impact of pileup, which is discussed in Section 4.7.

tau identification. Fortunately, the electron and muon identification have been shown to be quite robust against pileup [15, 16]. While the jet performance is affected by pileup, the analysis is fairly robust against those effects.

The simulation of pileup is technically very challenging since it is performed at a very low level in the detector simulation. Limited samples with pileup were available at the time of writing, and the  $E_T^{\text{miss}}$  and hadronic tau identification algorithms were not re-tuned in this context. The distribution of the log likelihood ratio discriminant for the calorimeter-based hadronic tau identification algorithm is shifted to lower values for both real taus and jet fakes. By simply adjusting the cut on the log likelihood ratio to 0, the same signal efficiency can be maintained with approximately a 50% drop in jet rejection. By re-tuning the discriminant in the context of pileup, improved jet rejection should be possible. In all three channels, the mass resolution is degraded from  $\sim 9.5$  to  $\sim 11.5$  GeV for  $m_H = 120$  GeV due to the degradation of the  $E_T^{\text{miss}}$  resolution. Figure 8 shows that the central jet veto survival probability drops from  $\sim 88\%$  to  $\sim 75\%$  at  $10^{33} \text{ cm}^{-2} \text{ s}^{-1}$  and  $\sim 65\%$  at  $2 \times 10^{33} \text{ cm}^{-2} \text{ s}^{-1}$ . Studies indicate that the use of tracking and calorimeter timing information can be used to mitigate this loss in signal efficiency.

Given the lack of background samples simulated with pileup and the need to re-optimize the reconstruction and analysis in that context, we do not report signal significance estimates.

## 5 Systematic uncertainties

### 5.1 Overview

The data-driven background estimation methods described above have been developed so that uncertainty in the background shape and normalization are included directly into the significance calculation. Because the discovery criterion is simply testing the presence or absence of the signal, it is not sensitive to some of the sources of systematic uncertainty. In contrast, measurement of the Higgs boson mass is sensitive to the energy scale of electrons, muons, hadronic taus and  $E_T^{\text{miss}}$ . Furthermore, measurement and exclusion of  $\sigma(pp \rightarrow qqH) \times BR(H \rightarrow \tau\tau)$  are sensitive to the uncertainty on the signal selection efficiency. Below we discuss the impact of these systematics on the analysis.

## 5.2 Systematic mis-measurement of the signal

First, we consider the purely experimental sources of systematics. The approach here is to assume that once we have data, the estimates of the energy scales, resolutions, and efficiencies might be systematically biased. Estimates of the systematic uncertainty from various sources are given in Table 14. The uncertainty estimates are common for all this series of notes, except for the uncertainties on the central jet veto and forward jet tagging efficiency. There is not yet a dedicated study of the expected uncertainty on these efficiencies from data, thus we assume uncertainty on the reconstruction efficiency to be half the tau identification efficiency and point out that most effects relevant to the jets have already been included in the jet energy scale uncertainty. We use the nominal detector performance as the central value and then manipulate the Monte Carlo signal to reflect these changes. For instance, in the case of the electron energy scale uncertainty, we coherently change all electrons to have 0.5% higher  $E_T$ , modify the  $E_T^{\text{miss}}$  vector accordingly, and recalculate the signal efficiency. This is done individually for each source of systematic and upward and downward fluctuations are treated separately. In the case of the jet energy scale, only some elements of the uncertainty are relevant for  $E_T^{\text{miss}}$ . A study of  $E_T^{\text{miss}}$  projected onto the direction of the reconstructed  $Z$  in  $Z \rightarrow ll + \text{jets}$  with a subset of the analysis cuts indicated that the  $E_T^{\text{miss}}$  scale can be measured within 5%; thus we only manipulate the  $E_T^{\text{miss}}$  vector according to a 5% jet energy scale shift. In the case of systematic uncertainty on resolution, we only considered a degradation in the resolution by the tabulated amount. Finally, for systematics on reconstruction and identification efficiency we assume a 1-to-1 transfer to the uncertainty on the signal efficiency and include a factor of two when the signal efficiency scales as the square (e.g. the electron efficiency in the  $ll$ -channel). Table 14 summarizes the effect of systematic mis-measurement on the signal efficiency.

Table 14: Estimated scale of systematic mis-measurements and their effect on the signal efficiency.

<sup>†</sup> When varying the jet energy scale, only a 5% mis-measurement of the jet energy was used in manipulating the  $E_T^{\text{miss}}$  vector. See text for details.

Source	Relative uncertainty	Effect on signal efficiency
luminosity	$\pm 3\%$	$\pm 3\%$

forward tagging efficiency	$\pm 2\%$	$\pm 2\%$
central jet reconstruction efficiency	$\pm 2\%$	$\pm 2\%$
total summed in quadrature		$\pm 20\%$

### 5.3 Theoretical uncertainty

In addition to the effect of systematic mis-measurement on the signal efficiency, theoretical uncertainties also limit our ability to estimate the signal efficiency. Next-to-leading order QCD calculations are now available for the vector boson fusion process. A dedicated study [39] investigated the overall renormalization and factorization scale dependence (2%) as well as the parton distribution function (PDF) uncertainties (3.5%). Next-to-leading order electroweak corrections are also quite large for the vector boson fusion process, giving a 3% uncertainty for the full next-to-leading order calculation [40]. Recently, the dominant next-to-leading order QCD corrections to the Higgs boson plus three jets have been calculated for vector boson fusion, providing a scale uncertainty on the parton-level central jet veto survival probability of 1% [41].

While the parton-level theoretical uncertainties are under very good control and below the level of both the statistical error and measurement-related systematics, the same is not true for the theoretical uncertainty related to the parton-shower and underlying-event. We rely on Monte Carlo simulations that model the parton-shower, hadronization, and underlying event to simulate the detector response. The uncertainty in these calculations is not comparable to the accuracy of the parton-level predictions. The central jet veto efficiency was studied with the signal process generated with PYTHIA (with various tunings), HERWIG and SHERPA and the fast detector simulation. After the analysis cuts, the different generators differ by 41%. Studies focusing specifically on the matrix element–parton shower matching indicate a substantially smaller uncertainty [33, 42]. We will measure the underlying event [43, 44] and tune the parton shower and hadronization with data, but it is likely that this contribution of the uncertainty will remain significant. Currently there is no estimate of the expected uncertainty related to the parton-shower, hadronization, and underlying event tuning. Clearly, this is an area that deserves attention as such a large uncertainty will hinder exclusions if a Higgs boson does not exist in this mass range and cross-section and coupling measurements if one does. After discussions with the authors of PYTHIA, HERWIG and SHERPA we feel that the residual uncertainty in the parton shower after tuning to the data will be less than the 18% uncertainty quoted for the jet energy scale. Thus, the uncertainty in the signal efficiency will be dominated by the jet energy /  $E_T^{\text{miss}}$  scale uncertainty and the precise uncertainty in the parton shower is not relevant. Table 15 summarizes the theoretical uncertainties for the signal production.

Table 15: Theoretical uncertainties which affect the estimation of the signal efficiency.

Source	Relative uncertainty	Effect on signal efficiency
PDF uncertainties	$\pm 3.5\%$	$\pm 3.5\%$
scale dependence on cross-section	$\pm 3\%$	$\pm 3\%$
scale dependence CJV efficiency	$\pm 1\%$	$\pm 1\%$
parton-shower and underlying event	$\pm \leq 10\%$	$\pm < 10\%$
total summed in quadrature		$\pm < 10\%$

## 6 Discussion

The expected signal significances in Table 13 are qualitatively consistent with the results found in Ref. [4]; however, the predicted cross-sections in Tables 9 and 10 are significantly different. In particular, the initial cross-section of the Z+jets background is smaller by nearly a factor of four and the  $t\bar{t}$  background in the  $ll$ -channel is larger by nearly a factor of 2. Much of this difference reflects the evolution

Figure 18: The ratio of expected p-values for the floating and fixed mass fits as a function of the Higgs boson mass. This plot summarizes the impact of the “look-elsewhere” effect in this analysis.

Figure 19: Expected 95% exclusion of the signal rate in units of the Standard Model expectation,  $\mu$ , as a function of the Higgs boson mass for the  $ll$  and  $lh$ -channels with  $10 \text{ fb}^{-1}$  of data. The exclusion takes into account the uncertainty on the signal efficiency described in Section 5.

in the Monte Carlo generators for these challenging backgrounds. In the case of the  $Z$ +jets background, differences in the choice of renormalization and factorization scales and parton density functions are the source for part of the discrepancy; however, approximately a factor of two comes from the treatment of soft and collinear divergences. After substantial investigation, we concluded that the  $Z$ +jets background estimate used in Ref. [4] was conservative. In the case of  $t\bar{t}$ +jets, the necessary matching between matrix elements and parton showers had not been developed when Ref. [4] was written. The recipe used to merge the  $t\bar{t}$ +0,1,2 jet samples at that time and the more realistic  $b$ -tagging performance limits our ability to understand in detail the source of the differences. We are confident that MC@NLO and our current detector simulation and offline reconstruction provide a superior prediction of this background.

For the first time, ATLAS has investigated the potential of the  $hh$ -channel. Much of this work has been devoted to the development and study of tau and missing  $E_T$  triggers. It now appears that the trigger is feasible, and the reconstruction of the signal maintains an efficiency and  $m_{\tau\tau}$  mass resolution comparable to the  $ll$ - and  $lh$ -channels. The open question for this channel is the size of the QCD background – a question that can only be answered with data.

The results shown in Section 4 are based on a fixed mass hypothesis. If one leaves the Higgs boson mass a free parameter in the likelihood fits, then one must take into account the “look-elsewhere” effect. Naively, one would expect the magnitude of the effect to be rather small for this channel given the  $\sim 10 \text{ GeV}$  mass resolution and the  $\sim 30 \text{ GeV}$  mass range of interest. Detailed study shows that it is a mixture of two effects. First, the distribution of  $-2\log\lambda(\mu=0)$  is not  $\chi^2$ -distributed under the background-only hypothesis; it has a longer tail which raises the p-value. Secondly, the median of  $-2\log\lambda(\mu=0)$  under the signal-plus-background hypothesis is systematically larger in the floating mass case because the model can adapt to fluctuations in the signal mean. Figure 18 summarizes the impact of these two effects.

Future work for this channel includes an extensive study of performance in the context of pileup, including optimization of the hadronic tau identification and  $E_T^{\text{miss}}$  reconstruction. The data-driven background estimation for the  $t\bar{t}$  and  $W$ +jets backgrounds must be further developed. In order to measure  $\sigma(pp \rightarrow qqH) \times BR(H \rightarrow \tau\tau)$  at the desired level, the systematics associated with the signal efficiency must be reduced. This requires a technique to measure the central jet veto and forward jet tagging efficiency in data. Additionally, the use of the  $E_T^{\text{miss}}$  projection method should be further developed to mitigate the impact of the jet energy scale uncertainty.

While the results shown in Section 4 only include the contribution of Higgs bosons produced via vector boson fusion, an additional 10% contribution from the gluon-fusion production process could be expected at  $m_H = 120$  GeV. Finally, the theoretical uncertainty associated with the parton shower and underlying event, which currently gives the largest uncertainty on the signal efficiency, must be addressed. The tuning of the parton shower, hadronization, and underlying event model will be among the earliest measurements at the LHC. If the residual theoretical uncertainty is not reduced sufficiently, a different strategy may need to be found for the central jet veto. The expected exclusion power based on the uncertainty in the signal efficiency is shown in Fig. 19.

## 7 Summary and conclusion

The sensitivity of the ATLAS detector to a Standard Model Higgs boson produced via vector boson fusion with subsequent decay into taus has been investigated with state-of-the-art Monte Carlo generators, a full GEANT-based simulation of the ATLAS detector and our current trigger and reconstruction algorithms. Particular emphasis has been placed on data-driven background estimation strategies and the estimation of the associated uncertainties in normalization and shape. The impact of pileup has not been fully addressed; however, results without pileup indicate that a  $\sim 5\sigma$  significance can be achieved for a Higgs boson mass in the range 115 – 125 GeV after collecting  $30 \text{ fb}^{-1}$  of data and combining the  $ll$ - and  $lh$ -channels. The Higgs boson mass resolution is approximately 10 GeV, leading to approximately 3.5% mass measurement. The  $hh$ -channel has also been investigated and gives similar results for signal and non-QCD backgrounds as the other channels; however due to the challenge of predicting the QCD background, we do not report on an estimated sensitivity for that channel. Currently, measurement-related systematics and large theoretical uncertainties limit the ability for a measurement of the product of cross-section and branching ratio. Future work is needed to constrain these uncertainties in order to measure the Higgs boson couplings, spin and CP properties.

# Higgs Boson Searches in Gluon Fusion and Vector Boson Fusion using the $H \rightarrow WW$ Decay Mode

## Abstract

The prospects for Higgs searches in the  $H + 0j$  ( $H \rightarrow WW \rightarrow e\nu\mu\nu$ ),  $H + 2j$  ( $H \rightarrow WW \rightarrow e\nu\mu\nu$ ), and  $H + 2j$  ( $H \rightarrow WW \rightarrow \ell\nu qq$ ) channels at ATLAS are presented, including realistic effects such as trigger efficiencies and detector misalignment, with an emphasis on practical methods to estimate the backgrounds using control samples in data. With  $10 \text{ fb}^{-1}$  of integrated luminosity, one would expect to be able to discover a Standard Model Higgs boson in the mass range  $135 < m_H < 190 \text{ GeV}$  and to be able to measure its mass with a precision of about 7 GeV if its true mass is 130 GeV or about 2 GeV if its true mass is 160 GeV.

## 1 Introduction

The nature of the Electroweak symmetry breaking sector is arguably the most important unknown in particle physics today. An introduction to the Higgs mechanism and an overview of the possible search channels for a (standard model) Higgs boson at the LHC can be found in Ref. [1]. This note studies the sensitivity of Higgs boson searches in the decay mode  $H \rightarrow WW$  to a Standard Model Higgs boson. Special emphasis is placed on in-situ control samples that can be used to estimate the background contributions using data and on the systematic uncertainties associated with these background determination methods.

The note is organised as follows: Section 2 discusses the production mechanisms and final states under study, the relevant backgrounds for each process and the Monte Carlo generators used to model them. In Section 3, the performance of the reconstruction for the various final-state particles is described. In Section 4, an overview of statistical issues common to most of the analyses is presented. Section 5 describes the event selection and control samples for a search for  $H \rightarrow WW \rightarrow e\nu\mu\nu$  in events where no hard jets are reconstructed in the detector. In Section 6, the analysis of the  $H + 2j$ ,  $H \rightarrow WW \rightarrow e\nu\mu\nu$  channel is presented, and in Section 7, an analysis of events where one of the  $W$  bosons decays to two jets is discussed. Finally, in Section 8, the combined sensitivity of the ATLAS detector to the presence of neutral scalar resonances in the  $W$  pair final state is presented.

## 2 Physics Processes and Monte Carlo

In the Standard Model, there are two dominant production modes of the Higgs boson in the kinematic region of interest for the  $H \rightarrow WW$  decay mode: gluon fusion and Vector Boson Fusion (VBF). In studies of the former production mode, one must consider background processes that yield two leptons and significant missing transverse energy in the final state; in the latter, the final state also includes two hard jets (from the struck quarks) which tend to be well-separated in pseudorapidity. This note considers the following signal and background processes:

- Higgs boson production via gluon fusion: This is the dominant production mechanism for the signal considered in the analysis of Section 5; it is modeled with 48500 events generated by MC@NLO [2, 3]. A Higgs boson decay matrix element similar to the one used in Ref. [4] was used to reweight this Monte Carlo sample to include the complete spin correlations for the Higgs decay.

- Higgs boson production via Vector Boson Fusion: This is the dominant production mechanism for the Higgs boson searches of Sections 6 and 7. This process is modeled with the generators provided in PYTHIA [5] (14500 events), HERWIG [6] (18050 events), and SHERPA [7] (19950 events).
- $pp \rightarrow WW$  production. This is the dominant background contribution to the analysis studied in Section 5; in that analysis, it is modeled with 178450 events generated by MC@NLO. It is important to note that MC@NLO only calculates the  $O(\alpha_s^0)$  and  $O(\alpha_s^1)$  contributions to this process; it does not compute the  $O(\alpha_s^2)$  contributions. Because of the large gluon luminosity expected at LHC it is important to include at least the gluon-initiated component (where the  $W$  pair production proceeds via a quark box) for the analysis of the fully jet-vetoed final state. This contribution is modeled with 176300 events produced using the generator in Ref. [8].

In the Vector Boson Fusion searches, the contributions from processes like  $qq \rightarrow WWqq$  (mediated by the exchange of a weak boson or a gluon) become important. Therefore, a sample of 171250 events generated with ALPGEN [9, 10] is used instead of MC@NLO to model the  $pp \rightarrow WWjj$  background in the analysis of Section 6.

- $t\bar{t}$  production. The two top quarks decay into a pair of  $W$  bosons and two  $b$  jets. The cross-section is expected to be dominated by doubly resonant  $t\bar{t}$  production in the Vector Boson Fusion searches of Sections 6 and 7; however, for the search of Section 5, one must also take care to handle the single-top background correctly. The absolute cross-section for the contribution from single top production is presently only known with leading-order uncertainties, but since the search presented in Section 5 normalises the top background using data, it is only necessary to consider its potential impact on the extrapolation from the  $b$ -tagged to the  $b$ -vetoed region. In the estimation of the sensitivity of all channels under study, a sample of 538300 events generated with MC@NLO is used to model this background. Two MadEvent [11–13] samples are used to estimate the importance of the contribution from single-top production in the  $H + 0j$  channel: one contains all matrix elements for  $pp \rightarrow WWbb$ ; the other contains only the doubly-resonant contribution.
- $Z \rightarrow ll$  production. In channels with two electrons or two muons, the direct decays of  $Z \rightarrow ee$  and  $Z \rightarrow \mu\mu$  dominate, but this background can also contribute to  $e\mu$  final states when the  $Z$  decays to a pair of  $\tau$  leptons which both decay leptonically. This background is modeled with a sample of 163200 events generated with PYTHIA in the  $H + 0j$  analysis of Section 5 and with a sample of 38150 events produced using ALPGEN in the  $H + 2j$  analysis of Section 6.
- $W + n$  jets production, with  $n \leq 5$ . This is the dominant background for the lepton-hadron channel; however, it can also play a role in the dilepton channels as a source of fakes. This background is modeled using a sample of 411424 events generated with ALPGEN.

A special subset of this background is  $W + c + n$  jets, with  $n \leq 4$ . The charm production in association with a  $W$  boson through processes like  $gs \rightarrow Wc$  is enhanced, due to the large parton density function of strange sea quarks and the large CKM matrix element  $|V_{cs}|$ . Decays of charm mesons are a potential source of leptons. Lepton isolation cuts are tuned on this kind of background, to reach the necessary rejection against leptons from semileptonic charm- or  $b$ - decays. [14].

- $b\bar{b}$ ,  $c\bar{c}$  and QCD multi-jet. Due to the large cross section of these processes they could be a further source of background. The large amount of CPU power needed makes a Monte Carlo simulation of these backgrounds currently unrealistic. For the dilepton channels the requirement of two leptons and missing transverse energy should reduce these backgrounds to a negligible level.

Table 1 gives an overview of the cross sections of the signal and background samples used in this note. Detailed tables of the Higgs boson cross sections and branching ratios can be found in Ref. [1].

Process	Generator	Cross-section(pb)
$gg \rightarrow H \rightarrow WW$ ( $M_H = 170$ GeV)	MC@NLO	19.418
VBF $H \rightarrow WW$ ( $M_H = 170$ GeV)	PYTHIA/Sherpa	2.853
VBF $H \rightarrow WW$ ( $M_H = 300$ GeV)	HERWIG	0.936
$qq/qg \rightarrow WW$	MC@NLO/Alpgen	111.6
$gg \rightarrow WW$	GG2WW	5.26
$pp \rightarrow t\bar{t}$	MC@NLO	833
$Z \rightarrow \tau\tau$ +jets	PYTHIA/ALPGEN	2015
$W$ +jets	ALPGEN	20510

Table 1: Overview of the Monte Carlo generators and cross sections for the Higgs boson signal and background processes used in this note. The  $W$ +jets cross-section listed is the cross-section per lepton flavor.

### 3 Reconstruction

The final states considered here all include leptons. Section 3.1 briefly describes the lepton selection criteria and other central aspects of the reconstruction used in this note. Then, in Section 3.2, a few important details about jets,  $E_T^{miss}$ , and pile-up are briefly discussed. Note that the results presented in this note were made using version 12 of the ATLAS software, whereas the results on detector performance in Refs. [15] and [16] are based on release 13.

#### 3.1 Leptons

The electron selection consists of the following criteria :

- Electrons are identified using the standard ATLAS criteria described in Ref. [15]. In the  $H + 0j$  ( $H \rightarrow WW \rightarrow e\nu\mu\nu$ ) and  $H + 2j$  ( $H \rightarrow WW \rightarrow \ell\nu qq$ ) channels, tight electrons are required. In the case of the  $H + 2j$ ,  $H \rightarrow WW \rightarrow e\nu\mu\nu$  analysis of Section 6, a sufficiently strong rejection against the  $W$ +jets background can be achieved by applying cuts on the VBF tagging jets that it is possible to use a medium electrons instead.
- A track match is required. The transverse impact parameter significance of the matched track,  $d_0/\sigma_{d_0}$ , is required to be less than 10.
- Candidates are required to be well isolated. Calorimeter isolation in a  $\Delta R$  cone of 0.2 is required to be less than 5 GeV, and  $\Sigma p_T$  of tracks in a cone of  $\Delta R < 0.4$ , excluding tracks from other lepton candidates and tracks with  $p_T < 1$  GeV, is required to be less than 5 GeV.
- Kinematic acceptance:  $p_T > 15$  GeV and  $|\eta| < 2.5$  (The  $p_T$  threshold is larger for the lepton-hadron channel). Electron candidates in the crack region,  $1.37 < |\eta| < 1.52$ , are excluded.

It has been shown that similar isolation criteria can effectively suppress the background from  $W$ +c+jet events, where a second lepton comes from charm decay, to negligible levels.

$W$ +jets is one of the main sources of fake backgrounds for the dilepton channels; it is crucial to achieve a good rejection against this background. The probability for a jet to be misreconstructed as an electron was derived from a  $W(\rightarrow \mu\nu)$ +jets sample which contains no true high  $p_T$  electrons. The average efficiency to reconstruct an electron candidate without isolation cuts in the  $gg \rightarrow H \rightarrow WW$  signal events is  $60.3 \pm 0.5\%$ ; the additional isolation criteria reduce this to  $50.0 \pm 0.5\%$  efficiency. With all cuts,

the average fake rate as determined from  $W \rightarrow \mu\nu + \text{jets}$  events is  $(1.7 \pm 0.2) \times 10^{-4}$  before isolation and  $(6.7^{+1.5}_{-1.3}) \times 10^{-5}$  after isolation.

The muon selection consists of a similar set of cuts :

- Combined muons and best match to an inner detector track [16].
- Calorimeter Isolation based on the *etcone20* variable [16] ( $etcone20 < 2.5$  GeV) and track isolation (in a cone of  $\Delta R < 0.4$ ) as for electrons, but with a different  $p_T$  threshold,  $\Sigma p_T < 3$  GeV.
- Transverse impact parameter significance less than 10.
- $p_T > 15$  GeV and  $|\eta| < 2.5$  (The  $p_T$  threshold is larger for the lepton-hadron channel)

As for the electrons, similar isolation criteria were shown to be effective against the  $W + c + \text{jet}$  background. The performance for muons is better than for electrons. The average efficiency to reconstruct a muon candidate in  $gg \rightarrow H \rightarrow WW$  signal events is  $94.2 \pm 0.1\%$  before isolation cuts and  $77.1 \pm 0.2\%$  after applying cuts. The corresponding fake rate in  $W \rightarrow e\nu + \text{jets}$  events is  $(1.7^{+0.6}_{-0.5}) \times 10^{-5}$  after isolation cuts are applied.

### 3.2 Jets, Missing $p_T$ , and Pile-up

In the  $H + 2j$  searches of Sections 6 and 7, the presence of at least two jets with  $p_T > 20$  GeV and a large difference in pseudorapidity are required. It is frequently the case that at least one of these jets will land in the forward region of the detector. To minimise the effect of calorimeter noise and maximise efficiency for the jets of interest to this study, jets reconstructed from topological clusters are used, rather than jets reconstructed from calorimeter towers [17]. For VBF Higgs boson signal processes the efficiency for jets with a cone size of  $\Delta R = 0.4$  from topological clusters is 94.3% in the central detector region and 95.3% in the forward region. For jets from calorimeter towers the efficiency is significantly lower with 92.4% in the central detector region and 84.1% in the forward region.

All the searches considered in this note make use of analysis techniques that either select or give a large weight to events without additional jets; in either case, events are effectively rejected if they contain extra jets beyond those jets (if any) that are explicitly required by the analysis. Even in the first years of “low-luminosity” data taking at the LHC, analyses will be affected by the pile-up of multiple collisions per beam crossing. Low  $p_T$  QCD interactions (minimum-bias) are present simultaneously to a hard interaction. Such pile-up events will give rise to jet activity that can sometimes cause interesting signal events to be erroneously rejected; in selecting a jet algorithm, it is necessary to consider this effect. Single minimum-bias events have a three times lower probability to be discarded by the central jet veto cut when using jets reconstructed with a cone size of  $\Delta R = 0.4$  instead of jets with a cone size of  $\Delta R = 0.7$ . Furthermore, in the presence of pile-up the jet calibration has to correct for the additional energy that is not from the hard interaction. Due to the well defined jet area, this is much easier done with a cone jet algorithm than with a  $k_t$  jet algorithm.

For the reasons mentioned above, the analyses in this note have used jets reconstructed from topological clusters with a cone algorithm of  $\Delta R = 0.4$  [17]. Jet efficiencies increase with  $E_T$  and are rather stable with  $|\eta|$ . However it should be noted that the efficiency drops at  $|\eta| \geq 4.8$  near the boundary of the forward calorimeter, as expected. Therefore this note uses only jets with  $|\eta| \leq 4.8$ . Jets within a cone of  $\Delta R < 0.4$  of any electron candidate are ignored.

There are other ways to minimise the impact of pile-up; the tracking system of the ATLAS detector is designed to separate the vertices of the different inelastic collisions in an event. Jets built of tracks emerging from the same vertex as the leptons from the Higgs boson decay should be insensitive to pile-up if the vertex reconstruction is working as expected.

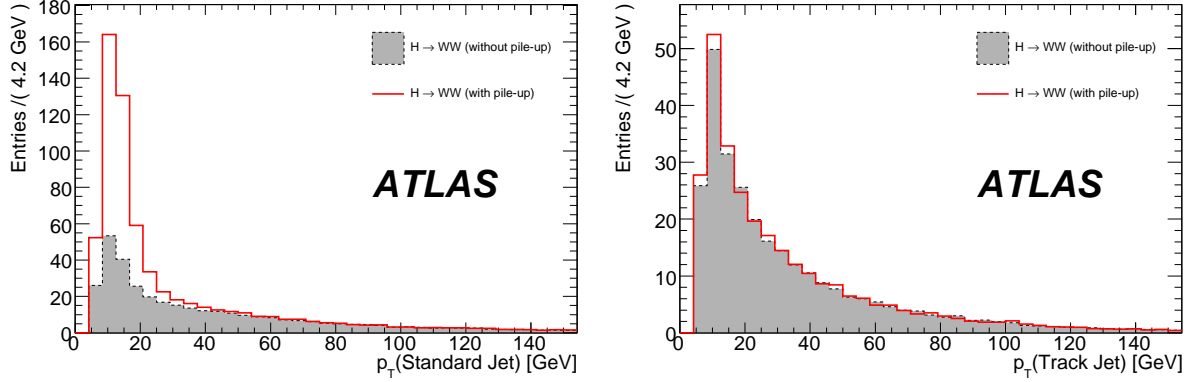

Figure 1: Jet  $p_T$  distributions ( $|\eta| < 2.5$ ) for the  $H \rightarrow WW$  signal sample with (red line) and without (gray filled area) pile-up. Left: Standard jets. Right: Track jets.

While the  $H \rightarrow WW$  searches presented in this note use standard calorimeter jets for the jet veto, it is important to illustrate the potential of track jets. The  $H + 2j$ ,  $H \rightarrow WW \rightarrow e\nu\mu\nu$  analysis has been studied as an example.

Track jets are reconstructed from only those tracks that have  $p_T > 0.5$  GeV and with at least 7 hits in the pixel and semiconductor tracker. The Higgs boson production vertex is taken to be the vertex for which the sum of the transverse energies of the emerging tracks is largest. All tracks that emerge from this vertex and are not associated with an isolated lepton are fed into the standard ATLAS cone  $\Delta R = 0.4$  jet algorithm. Leptons are considered isolated if the sum of the transverse energies of all tracks from the same vertex as the lepton in a cone of  $0.01 < \Delta R < 0.2$  around the lepton is less than 5 GeV.

The independence of the track jets to activity from pile-up is reflected in the jet  $p_T$  distributions in the  $H \rightarrow WW$  signal sample without and with pile-up (pile-up was generated with an average of 2.3 additional events) in Figure 1. The additional  $pp$  collisions in presence of pile-up created additional standard jets at low transverse energies while the multiplicities of track jets are unaffected by pile-up.

A central jet veto cut is constructed using track jets in the acceptance region of the inner detector of  $|\eta| < 2.5$  and standard jets at larger pseudorapidities (up to  $|\eta| < 3.2$ ). The cut on the transverse momentum of the track jets is chosen such that the same rejection efficiency is obtained for  $H \rightarrow WW$  events without pile-up as for the jet veto based on standard jets. This requires a lowering of the  $p_T$  cut from 20 GeV for standard jets to 12.3 GeV for track jets. Table 2 shows the fraction of events passing

	$H \rightarrow WW$		$t\bar{t}$	
	no pile-up	with pile-up	no pile-up	with pile-up
std jets ( $ \eta  < 2.5$ )	$72.0 \pm 1.0$	$63.0 \pm 1.2$	$28.6 \pm 3.4$	$19.7 \pm 3.3$
track jets	$72.0 \pm 1.0$	$73.5 \pm 1.1$	$28.6 \pm 3.4$	$25.9 \pm 3.6$
std jets ( $ \eta  < 3.2$ )	$65.4 \pm 1.0$	$57.0 \pm 1.2$	$24.0 \pm 3.2$	$16.3 \pm 3.0$
combination	$65.8 \pm 1.0$	$65.9 \pm 1.1$	$24.0 \pm 3.2$	$23.1 \pm 3.5$

Table 2: Fraction of events (%) passing the central jet veto

the different options for the central jet veto. The central jet veto based on standard jets is sensitive to pile-up while the track jets show only small sensitivity to pile-up. The combination of the track jet veto in  $|\eta| < 2.5$  and the standard jet veto in  $|\eta| > 2.5$  shows robustness against pile-up.

Figure 2: Left: The log Likelihood Ratio distributions for toy Monte Carlo corresponding to the  $H \rightarrow WW \rightarrow \ell\nu qq$  analysis at  $10 \text{ fb}^{-1}$  for background-only outcomes (red) and signal-plus background outcomes with several values of the Higgs boson mass. Right: The same plot, but for the  $H + 2j$ ,  $H \rightarrow WW \rightarrow e\nu\mu\nu$  analysis.

The performance of the missing transverse momentum reconstruction is strongly affected by the presence of pile-up. In this study, the cell based reconstruction algorithm described in Ref. [18] has been used.

Fortunately, the  $H \rightarrow WW \rightarrow \ell\nu\ell\nu$  searches are not very sensitive to the resolution of  $E_T^{\text{miss}}$ . Since the Higgs boson mass cannot be directly reconstructed in the  $2\ell 2\nu$  final state, a transverse mass is used; although this does have a peak centred around the true value of the Higgs boson mass, the distribution is very broad (several tens of GeV). Therefore a degraded  $E_T^{\text{miss}}$  resolution is unlikely to significantly alter the transverse mass shape unless the degradation is rather severe. The  $H + 2j$  ( $H \rightarrow WW \rightarrow \ell\nu\ell\nu$ ) analysis of Section 6 makes use only of this transverse mass and observables related to the leptons and the jet activity in the event; the  $E_T^{\text{miss}}$  cut in that analysis serves mostly to reject backgrounds like  $Z \rightarrow ee/\mu\mu$  which have no intrinsic  $E_T^{\text{miss}}$ . The  $H + 0j$  analysis of Section 5 does make use of the transverse momentum of the Higgs boson candidate, which is obviously very sensitive to the  $E_T^{\text{miss}}$  resolution; however, that analysis involves a fitting algorithm developed with exactly this concern in mind and includes checks that demonstrate that the algorithm still works reliably in the presence of a degraded  $E_T^{\text{miss}}$  measurement.

In the case of the  $H \rightarrow WW \rightarrow \ell\nu qq$  analysis of Section 7, the  $E_T^{\text{miss}}$  is used in the reconstruction of the Higgs boson candidate's invariant mass. In principle, then, a degraded  $E_T^{\text{miss}}$  resolution does propagate into the Higgs boson mass resolution, and so problems with the  $E_T^{\text{miss}}$  reconstruction are more harmful to the  $H \rightarrow WW \rightarrow \ell\nu qq$  channel than to the dilepton channels. However, for a Standard Model-like Higgs boson with a mass above  $\approx 300 \text{ GeV}$ , the natural width of the Higgs boson tends to become rather large, and the  $E_T^{\text{miss}}$  resolution is again not the primary concern of the analysis.

Mismeasurements of jets and detector inefficiencies can lead to instrumental  $E_T^{\text{miss}}$ . It is very hard to predict such effects without real data and no cuts to reduce instrumental  $E_T^{\text{miss}}$  are currently foreseen.

## 4 Statistical Formalism

The sensitivity estimates presented in this note use a fit-based hypothesis testing procedure. Unless stated otherwise, selection cuts are always independent of the Higgs boson mass hypothesis, no matter how broad the range of masses where the search is sensitive. To take advantage of the discriminating power contained in variables for which the distribution depends significantly on the Higgs boson mass

Selection	Selection cuts	$gg \rightarrow H$	$t\bar{t}$	$WW$	$Z \rightarrow \tau\tau$	$W + jets$
pre-selection	Lepton Selection+ $M_{ll}$	166.4	6501	718.12	4171	209.1
	$p_T^{miss} > 30$ GeV	147.7	5617	505.25	526.3	181.6
	$Z \rightarrow \tau\tau$ Rej.	145.8	5215	485.12	164.2	150.4
	Jet Veto	61.80	14.84	238.35	31.91	76.12
	b-veto	61.56	6.85	237.87	30.76	76.12
signal region	$\Delta\phi_{ll} < 1.575$ , $M_T < 600$ GeV	$50.6 \pm 2.5$	$2.3 \pm 1.6$	$85.4 \pm 2.7$	$< 1.7$	$38 \pm 38$
control region	$\Delta\phi_{ll} > 1.575$ , $M_T < 600$ GeV	$10.9 \pm 1.1$	$4.6 \pm 2.3$	$151.9 \pm 3.6$	$30.8 \pm 4.2$	$38 \pm 38$
b-tagged signal region	$\Delta\phi_{ll} < 1.575$	-	$1.14 \pm 1.14$	-	-	-
b-tagged control region	$\Delta\phi_{ll} > 1.575$	-	$5.71 \pm 2.55$	-	-	-

Table 3: Cut flows (in fb) for  $M_H = 170$  GeV in the  $H + 0j$ ,  $H \rightarrow WW \rightarrow e\nu\mu\nu$  channel. A ‘-’ indicates that the corresponding contribution is ignored in the fit. The  $WW$  background contains the two processes  $q\bar{q} \rightarrow WW$  and  $gg \rightarrow WW$ .

hypothesis or is not precisely predicted by theory, a maximum-Likelihood fit to those variables is used. To perform the hypothesis test itself, a Likelihood Ratio is used,  $\lambda = L_{s+b}/L_{bg-only}$ . The numerator and denominator of this ratio are obtained from separate fits to the data, with the number of signal floating as a free parameter (subject to the constraint  $N_s \geq 0$ ) in the fit for  $L_{s+b}$ , and with the number of signal fixed to zero in the fit for  $L_{bg-only}$ . The sampling distributions of  $\lambda$  at a given luminosity (in the presence of signal and in its absence) are studied by generating pseudo-experimental outcomes and performing the full fit to each outcome.

Throughout this note, when a fit is performed, the Higgs boson mass  $m_H$  is allowed to float as a free parameter in the fit. The resulting significance estimates therefore represent the probability that, in the absence of signal, a background fluctuation anywhere in the allowed mass range would produce an excess at least as significant as the observed excess. This is slightly different from the convention adopted in some other studies, where the significance represents the probability that a background fluctuation would produce an excess that is consistent with a specified mass and at least as significant as the observed excess.

Figure 2 shows two examples of the Likelihood Ratio probability distributions. The left plot shows the sampling distribution of the Likelihood Ratio for the  $H \rightarrow WW \rightarrow \ell\nu qq$  fit discussed in Section 7 (assuming a negligible background from fakes), and the right plot shows the corresponding distributions for the analysis of Section 6.2. A fit to the real data would yield one value of  $\lambda$ ; to obtain a p-value, one would integrate the red distribution in the acceptance region, i.e. from the observed value of  $\lambda$  to infinity. In the absence of data, the expected significance is computed by taking the “observed” value of  $\lambda$  to be the median of the signal-plus-background distribution for a given mass. The expected significance  $Z$  reported here is one-sided, i.e.,  $Z = \sqrt{2}\text{erfc}^{-1}(2p)$ . When the number of pseudo-experimental outcomes in the acceptance region is too small, the background-only Likelihood Ratio distribution is extrapolated with an exponential decay.

Figure 3: Left: transverse opening angle  $\Delta\phi_{ll}$  of the two leptons after preselection cuts. Middle : transverse momentum  $p_T^{WW}$  of the WW system after preselection cuts. Right: transverse mass  $M_T$  for events with  $\Delta\phi_{ll} < 1.575$  and  $p_T^{WW} > 20$  GeV, in a fitted toy Monte Carlo outcome containing a Standard Model Higgs boson with  $M_H = 170$  GeV, after  $10 \text{ fb}^{-1}$  of integrated luminosity. The Likelihood Ratio in this outcome is 30.69, which is typical for this value of  $M_H$  and this luminosity.

## 5 Leptonic $W$ Pair Production with No Hard Jets

The  $H + 0j$ ,  $H \rightarrow WW \rightarrow \ell\nu\ell\nu$  channel has been shown to have a strong discovery potential. [19–22] The basic event selection consists of only a few simple cuts:

- Require that the event has exactly two isolated, opposite-sign leptons (electron or muon) with  $p_T > 15$  GeV.
- To suppress backgrounds from single-top production, backgrounds from dileptonic decays of  $b\bar{b}$  and  $c\bar{c}$  resonances, and lepton pairs from  $b \rightarrow c$  cascade decays, require that the invariant mass  $m_{ll}$  of the leptons is between 12 GeV and 300 GeV.
- Require that the event has  $E_T^{miss} > 30$  GeV
- To suppress backgrounds from  $Z \rightarrow \tau\tau$ , reconstruct the invariant mass of a hypothetical  $\tau$  pair using the collinear approximation [23]. If the energy fractions  $x_\tau^1$  and  $x_\tau^2$  are both positive and the invariant mass of the  $\tau$  pair  $M_{\tau\tau}$  is in the range  $|M_{\tau\tau} - M_Z| < 25$  GeV, the event is rejected.
- To suppress backgrounds from top quark decays, reject events that contain any hard jets with  $p_T > 20$  GeV and  $|\eta_j| < 4.8$ .
- To further suppress the top background, reject events with any jets with  $p_T > 15$  GeV and a b-tagging weight greater than 4.

Table 3 shows the cross-sections in the  $e\mu$  channel for signal and background after these cuts.

The trigger efficiency for signal is sufficiently large for this analysis to be viable. Events are required to pass at least one of the ATLAS single-lepton or double-lepton triggers. The level-1 trigger menus used here are 2EM15I, EM25I, EM60I, MU20, and MU40. For the Level 2 trigger and the event filter, events are required to pass the e25i, 2e15i, e60, or mu20i triggers. Details on the trigger menus can be found in Ref. [24]. For the  $e\mu$  channel considered here the trigger efficiency for L1 is 99.0%; for L2 it is 96.7%, and for the EF it is 95.2% The efficiency is quite high, and the trigger efficiency does not distort the shapes of the kinematic variables of interest in the signal in a significant way. Table 3 does not include the trigger efficiency, but it is taken into account as an overall scale factor for the signal and background when generating toy Monte Carlo to test the fitting algorithm described in the next section and in the calculation of the expected statistical significance for this channel.

After the basic event selection (all cuts from Table 3 including the cut on  $\Delta\phi_{ll}$ ), the signal to background ratio is only  $\approx 1:4$ , but there is still a good deal of discriminating power in the final state. This analysis focuses on three variables:

- the transverse opening angle  $\Delta\phi_{ll}$ ; a cut on this variable exploits differences in the spin correlations in the WW system in the Higgs signal and the WW background,
- the transverse mass  $M_T$ , as defined in Ref. [25],
- the transverse momentum of the WW system,  $p_T^{WW}$ , which tends to be slightly larger for signal than for WW background because gluon-initiated processes tend to have more initial-state radiation than quark-initiated processes.

The distributions of these variables are shown in Figure 3. To make use of the discriminating power of these variables, a maximum-likelihood fit is performed.

### 5.1 Fitting Algorithm

The fit is a 2-dimensional fit of transverse mass and  $p_T^{WW}$  in two bins of the dilepton opening angle  $\Delta\phi_{ll}$  in the transverse plane. [26] The present study considers a fit to only those events with one electron and one muon, since an in-situ background extraction procedure for the  $Z \rightarrow ee/\mu\mu$  background has not yet been studied. After the preselection cuts and the additional requirement that  $M_T < 600$  GeV is applied, the remaining events are separated into two subsamples, one with  $\Delta\phi_{ll} < 1.575$  and the other with  $\Delta\phi_{ll} > 1.575$ . Table 3 shows the cross-sections for the signal and various backgrounds in these two regions. The region with large  $\Delta\phi_{ll}$  (control region) is enriched in background and the region with small  $\Delta\phi_{ll}$  (signal region) is enriched in signal.

The top background is estimated with the help of b-tagged control samples with the same kinematic cuts as the signal-enriched and background-enriched regions. Table 3 includes estimates of the top cross-section in the b-tagged control regions. In the present study, the b-tagging efficiency is assumed to be well-known (i.e., the ratio of cross-sections in the b-tagged and b-vetoed regions is taken from Monte Carlo), and the contamination from processes with only light jets in the b-tagged regions is ignored. The  $t\bar{t}$  cross-section estimates in Table 3 are based on Monte Carlo samples that use MC@NLO to model the top background; even if the b-tagging is well-understood, the ratio of the top cross-section in the b-tagged and b-vetoed regions is sensitive to the treatment of the single-top contribution to the background. Moreover, studies based on fast simulation samples have shown that there are also differences in the shape of the distributions of  $M_T$  and  $p_T^{WW}$  between top background models based on doubly-resonant top production and models that include the singly-resonant and nonresonant processes. (For example, the single-top contribution leads to a larger number of events with large  $M_T$  and small  $p_T^{WW}$ .) Nevertheless, in the present study, standalone fits are performed on the b-tagged control samples before the fit to the b-vetoed regions begins, and the top background in the b-vetoed regions is estimated by extrapolating both the shape and the normalization from the b-tagged region to the b-vetoed region based on ratios obtained from MC@NLO.

The  $Z \rightarrow \tau\tau$  background is normalized and its shape is determined by studying a sample of  $Z \rightarrow \mu\mu$  events taken from real data, where the reconstructed muons are replaced by simulated taus [23]. Two-muon events with a dimuon invariant mass between 82 and 98 GeV are selected, and the same jet veto that is used in the rest of this analysis is applied to the selected events. The effective cross-section after these cuts is roughly 360 pb. The reconstructed muons in the event are replaced with simulated tau leptons, and the remaining event selection cuts are applied. The efficiency of those cuts is about 0.07%, leaving an effective cross-section of roughly 250 fb. To be conservative, the present study assumes that efficiency factors will lower this figure to about 200 fb. A standalone fit to these “data-Monte-Carlo”

events is performed to determine the shape and normalization of the  $Z \rightarrow \tau\tau$  background; in the final fit, the shape parameters are fixed and the normalization is rescaled by a factor that is assumed in this study to be well-predicted. The parameters obtained from the fit to the  $Z \rightarrow \tau\tau$  data-Monte-Carlo control sample are not allowed to float in the main fit.

At the time of this writing, an in-situ determination of fake backgrounds from processes such as  $W$ +jets has not yet been studied. For this study, a fixed probability distribution has been used to represent the fake backgrounds, assuming for the moment that the shape and normalization of fake backgrounds are well-predicted. Because of the limited size of the available  $W$ +jets Monte Carlo sample, there are not enough Monte Carlo events remaining after cuts to provide a prediction of the shape of the transverse mass vs.  $p_T^{WW}$  distribution for  $W$ +jets; the shape of this distribution is therefore taken from a set of events with loosened isolation and shower shape cuts. This treatment ignores any potential systematic uncertainty on the  $W$ +jets background; future studies will attempt to address this in more detail.

Once the fits to the control samples are completed, a simultaneous fit of the two  $\Delta\phi_{ll}$  bins in the b-vetoed region is performed. A few of the parameters that describe the shape of the transverse mass and  $p_T^{WW}$  distributions of the  $WW$  background are allowed to float in the fit. The  $p_T^{WW}$  distributions for the  $WW$  background in the two regions are taken to be the same up to a parabolic distortion factor. The normalizations of the  $WW$  background are free to float independently; however, we add a penalty term of the form  $(R_{fit} - R_{true})^2 / \sigma_R^2$ , where  $R_{fit}$  is the ratio of the best-fit number of  $WW$  background events in the small- $\Delta\phi_{ll}$  region over the number in the large- $\Delta\phi_{ll}$  region,  $R_{true}$  is the Monte Carlo prediction of the ratio taken from the central-value calculation, and  $\sigma_R$  is the uncertainty in the prediction of  $R_{true}$ , taken to be 10%. This value of  $\sigma_R$  is chosen to be larger than the actual variation of  $R$  due to changes in the  $Q^2$  scale definition (about 5%) so that the constraint term does not cause a large bias in the observed value of  $R$ ; such a bias could be expected to lead to a degradation in the sensitivity of the hypothesis test. The value of  $\sigma_R$  has not been optimized; such a study may be performed in the future.

In order to demonstrate the robustness of the fit against systematic uncertainties, toy Monte Carlo has been used to compute the sampling distributions for the Likelihood Ratio in several scenarios where the “true” probability distribution has been distorted to model various sources of systematic error. Seven distorted scenarios are considered: four altered  $Q^2$  scale choices (factorization and renormalization scales raised and lowered by factors of 8), two alternative top background models (based on leading-order  $pp \rightarrow WWbb$  and leading-order  $pp \rightarrow tt \rightarrow WWbb$ ), and one alternative model of all irreducible backgrounds where the  $x$  and  $y$  components of  $E_T^{miss}$  have been independently smeared by 5 GeV each. These alternative models have been derived using fast simulation because large-statistics Monte Carlo samples are needed in order to be sure any change in the shape of the observables is actually due to the systematic uncertainty under study and not merely a statistical fluctuation. In these systematic scenarios, the background contribution from fakes is ignored. Figure 4 shows the Likelihood Ratio distribution for background-only outcomes (upper left) and the distribution of pulls of the fitted Higgs boson mass (upper right) for signal-plus-background outcomes with a true Higgs boson mass of 170 GeV. Both distributions are nearly independent of the systematic distortions.

The lower left plot in Figure 4 shows the linearity of the mass determination as a function of the true Higgs mass. The line shows the mean of a Gaussian fit to the region around the peak of the distribution of best-fit Higgs masses in the toy Monte Carlo sample for the case of nominal detector performance. The green band shows the width of the Gaussian and is a direct measure of the variability of the mass estimate on repetition of the experiment; the error bars show the median fit error. The typical variability of the mass determination at  $10 \text{ fb}^{-1}$  ranges from 5.2 GeV at  $M_H = 130 \text{ GeV}$  to 1.6 GeV at  $M_H = 160 \text{ GeV}$  to 4.2 GeV at  $M_H = 190 \text{ GeV}$ .

Figure 4 also shows the expected significance for an integrated luminosity of  $10 \text{ fb}^{-1}$ . This channel is most promising for Higgs boson masses near the  $WW$  threshold.

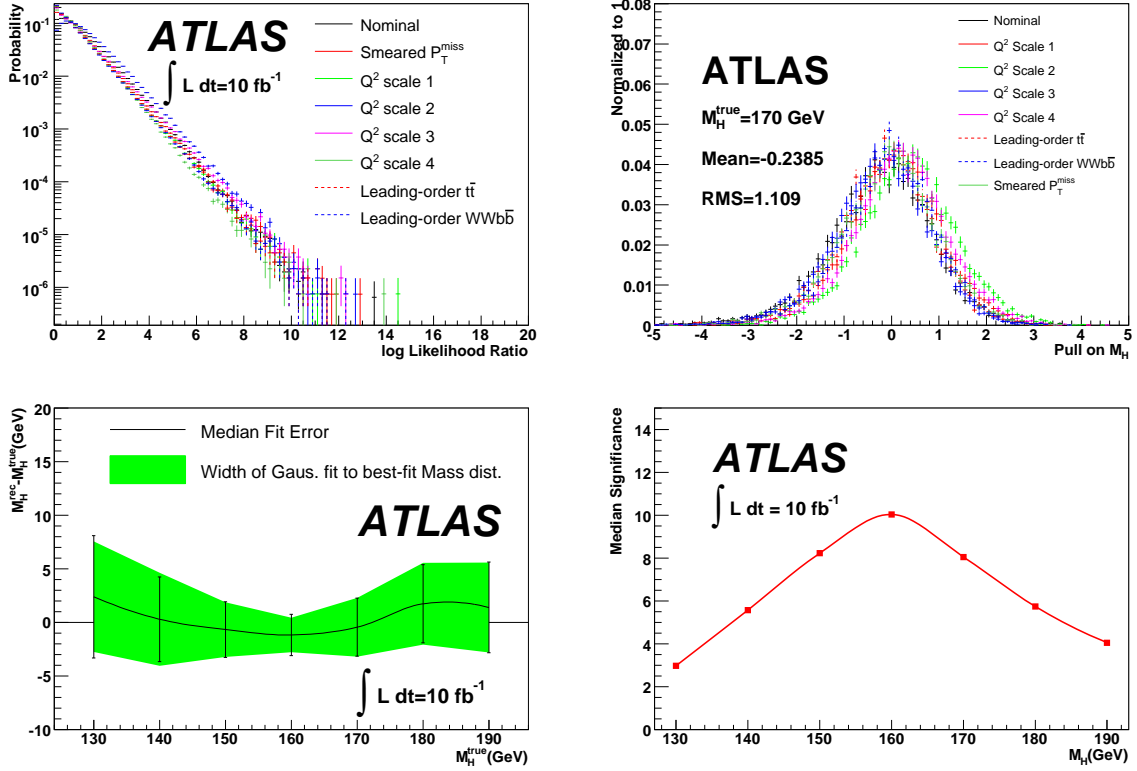

Figure 4: Upper Left: The log Likelihood Ratio distributions for background-only toy Monte Carlo outcomes corresponding to  $10 \text{ fb}^{-1}$  in the  $H + 0j$ ,  $H \rightarrow WW \rightarrow l\nu l\nu$  analysis. Upper Right: The corresponding pull distributions for  $M_H=170$  GeV. Lower Left: The linearity of the mass determination. Lower Right: the expected significance for an integrated luminosity of  $10 \text{ fb}^{-1}$ .

Region	Signal, $M_H = 170$ GeV (fb)	$t\bar{t}$	$WW$	$Z \rightarrow \tau\tau$	$W$ +jets
Signal-like	$28.65 \pm 0.80$	$1.14 \pm 1.14$	$29.35 \pm 1.59$	$< 1.74$	$38 \pm 38$
Control	$1.47 \pm 0.27$	$5.71 \pm 2.55$	$61.13 \pm 2.33$	$4.06 \pm 1.53$	$< 114$
b-tagged	0	$6.85 \pm 2.80$	$0.11 \pm 0.09$	$1.16 \pm 0.82$	$< 114$

Table 4: Cross-sections (in fb) after all cuts for a number-counting analysis with a test mass of  $M_H = 170$  GeV in the  $H + 0j$ ,  $H \rightarrow WW \rightarrow e\nu\mu\nu$  channel.

## 5.2 Cross-check with a Number-Counting Analysis

A number counting analysis of this channel has been performed as a cross-check. The signal region is defined by the basic event selection in addition to the following few additional cuts:  $p_T^{WW} > 10$  GeV,  $M_{ll} < 64$  GeV,  $\Delta\phi_{ll} < 1.5$ , and  $50 < M_T < 180$  GeV. A control region is defined by the requirements  $p_T^{WW} > 10$  GeV,  $80 < M_{ll} < 300$  GeV, and  $\Delta\phi_{ll} > 1.5$ . In order to normalize the top background, it is also useful to define a b-tagged region with similar kinematic cuts:  $p_T^{WW} > 10$  GeV and  $\Delta\phi_{ll} > 1.5$ . Table 4 shows the cross-sections for signal and backgrounds in these regions. Only one of the  $W$ +jets events passes all the selection cuts for the signal-like region; it corresponds to a cross-section of 38 fb. None of the  $W$ +jets events survives in either control region. Because this background is modeled with Alpgen  $W + n$  jets, with  $n \leq 5$ , and because the Monte Carlo was generated with different effective

luminosities for different jet multiplicities, it is not straightforward to compute a meaningful upper bound on the  $W$ +jets cross-section in the control regions. The quoted cross-section is simply three times the cross-section observed in the signal region (which is based on one Monte Carlo event).

The ratios of background cross-sections in the various regions have to come from a theoretical prediction; in a number-counting approach there is no simple way to constrain them with data. A similar background normalization strategy was studied in Refs. [27] and [28]; in Ref. [27], the theoretical error on the ratio of  $WW$  cross-sections in the signal-like region and the control region was 5%, the systematic error on the ratio of the top background cross-sections in the signal-like and  $b$ -tagged regions was 9%, and the uncertainty on the ratio of the top background cross-sections in the control region and the  $b$ -tagged regions was also 9%. These systematic errors have not been re-evaluated in the context of this analysis, nor have the relevant instrumental systematic errors been computed; this cross-check simply uses these values as the systematic uncertainties on the extrapolations.

Using the cross-sections for  $M_H = 170$  GeV in Table 4 and taking into account the additional 95.2% trigger efficiency on signal and background, the luminosity-dependent errors on the normalizations of the control samples (ignoring  $W$ +jets in the Control and  $b$ -tagged regions), and the systematic uncertainties described above, the expected significance of the number-counting analysis (in the Gaussian approximation, for  $\int L dt = 10 \text{ fb}^{-1}$ ) is  $8.5\sigma$ . This figure ignores the error on the  $W$ +jets background prediction; in a future study, it will be important to normalize the  $W$ +jets background using data. In the interest of performing a meaningful comparison with the fit analysis, it is helpful to compute the significance ignoring the  $W$ +jets background altogether:  $10.4\sigma$ . This is comparable to the result from the fit; if the contribution from the  $W$ +jets background is ignored there, the significance is  $8.8\sigma$  at the same luminosity.

## 6 Leptonic $W$ Pair Production with Two Hard Jets

This Section presents the analysis of events where a  $W$  pair is produced in association with two hard jets and both  $W$  bosons decay leptonically. [29–32] In Section 6.1, the main discriminators in this channel are reviewed. For background extraction and significance estimation, two complementary approaches are considered; both of them are fit-based. In Section 6.2, an analysis that uses a Neural Network to combine several jet variables into a single discriminator and fits the Neural Network output and  $M_T$  is presented. This method has the advantage that the correlations among variables related to jets (described in Section 6.1) are naturally taken into account by the Neural Network, and the weak correlations between the jet variables and the lepton variables are largely taken into account by the way the control sample is used in the fit. However, it has the disadvantage that the Neural Network must be trained ahead of time; in principle, this may introduce some model-dependence to the procedure. Ideally, one would like to directly model all kinematic variables in a maximum Likelihood fit; Section 6.3 describes an analysis that takes this approach with a fit of five kinematic variables. This method has the advantage that there is no training stage and therefore has the potential to be more model independent than the analysis of Section 6.2. However, because of the difficulty in constructing a fully correlated probability distribution for a 5-dimensional space, the probability distributions used in the fit of Section 6.3 include only the largest correlations among the kinematic variables and ignore some smaller correlations. It is possible to make some corrections to the shapes of the distributions to model correlations not inherently present in the fit model; Section 6.3 explores the prospects for extracting such corrections from  $b$ -tagged control samples. The combined significance estimate at the end of this note will be based on the analysis of Section 6.2, but further studies of both approaches are needed in order to converge on a final strategy for the analysis of real data.

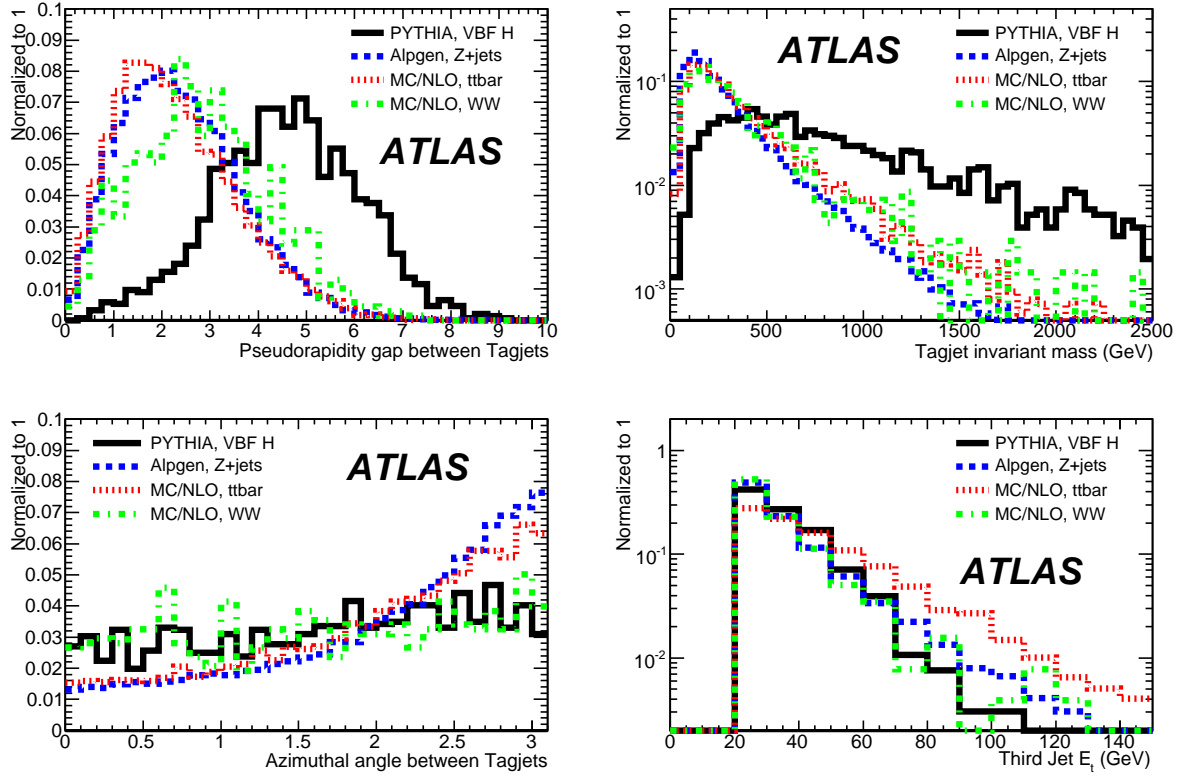

Figure 5: Pseudorapidity gap between tag jets (left top plot), invariant-mass distributions of tag jets (right top plot), azimuthal angle gap between tag jets (left bottom plot) and  $E_T$  of the third jet in VBF  $H \rightarrow WW \rightarrow \mu\nu \mu\nu$  Pythia events ( $m(H)=170$  GeV). A requirement  $\eta_1 \eta_2 \leq 0$  is used in addition to the requirement jet  $E_T > 20$  GeV.

## 6.1 Handles for Suppressing the Top Background

In both of the fit-based approaches under study,  $t\bar{t}$  is the dominant background after the preselection cuts, and in both approaches, similar discriminators are used to suppress it. Two discriminators warrant special attention: jet kinematics, which is discussed in Section 6.1.1, and b-tagging, which is discussed in Section 6.1.2.

### 6.1.1 Jet Kinematics

One of the main advantages of any search for a Higgs in association with two jets is the possibility to suppress QCD backgrounds with cuts on jet kinematics. The Vector Boson Fusion Higgs signal features several distinctive characteristics:

- The two jets arising from struck quarks (often referred to as “tag” jets) tend to be the highest- $p_T$  jets in the event, and they tend to be well-separated in pseudorapidity;
- they tend to have a large invariant mass;
- there is very little jet activity in the region between the two tag jets.

Figure 6: The distribution of leading versus sub-leading jet weights in the events for signal (left plot) and the  $t\bar{t}$  background (right plot). The plots are divided in three regions: (I) where there is a non-default  $b$ -tagging weight for more than one jet, (II) where there is only  $b$ -tagging information for one jet in the event and (III) where there are no jets with  $b$ -tagging information in the event.

Figure 5 shows the distributions of the pseudorapidity gap between the tag jets, their invariant mass, and the  $p_T$  of the third-highest  $p_T$  jet in the event. The figure also shows the distribution of the azimuthal angle between the tagjets,  $\Delta\phi_{jj}$ . It is possible to enhance the discrimination against backgrounds with a cut on  $\Delta\phi_{jj}$ , but in this study no such cut is applied on the grounds that this angle is needed in a measurement of the spin and CP properties of the Higgs boson [33].

Only one Higgs boson mass is shown for the signal process in Figure 5, but it is worth noting that the dependence of these variables on the Higgs boson mass is rather weak. It is also worth noting that Pythia 6.4 predicts a somewhat harder  $p_T$  spectrum for the third jet than Herwig and Sherpa do. This would amount to a difference as large as a few tens of percent in the survival probability if a jet veto cut were applied.

It has been shown in previous studies that hard cuts on the kinematic variables discussed here can provide a strong rejection against the top background [25, 34, 35]. As part of the present study, it has been checked that the high signal-to-background ratio that can be achieved in this channel is not sensitive to degradations arising from detector alignment effects.

### 6.1.2 Rejecting Top with B-tagging

Another effective way to reject a significant fraction of the  $t\bar{t}$  events while retaining a high efficiency for the signal is to apply a veto on events containing jets with high  $b$ -tagging weights. The  $t\bar{t}$  events naturally contain two jets originating from  $b$ -quarks whereas the heavy flavor content in the signal events is limited at tree level to having  $c$  quarks in the tagging jets, and then typically in only one of the two tagging jets. This makes vetoing against events with more than one jet with high  $b$ -tagging weight especially efficient. Figure 6 shows the distribution of leading versus sub-leading jet weights in the events for signal (left plot) and the  $t\bar{t}$  background (right plot). The plots are divided in three regions: I where there is a non-default  $b$ -tagging weight for more than one jet, II where there is only  $b$ -tagging information for one jet in

Cut	Signal (170 GeV)	$t\bar{t}$	$WW$ +jets	$Z \rightarrow \tau\tau$	$W$ +jets
Lepton Selection	30.20	8317	838.96	(2096)	1323
Forward Jet Tagging	17.27	946.6	32.77	79.30	31.83
Leptons Between Jets	16.47	617.8	22.92	55.13	27.91
$Z \rightarrow \tau\tau$ Rejection	15.68	561.8	21.20	39.03	27.91
$p_T^{miss}, M_T, m_T^{lv}$	12.78	425.9	15.28	0	13.96
b-veto	12.67	206.72	-	-	-
signal box, b-jet Veto	$9.28 \pm 0.27$	$28.5 \pm 5.7$	$4.75 \pm 0.30$	-	$4.3 \pm 4.3$
signal box, no b-jet Veto	9.65	114.2	4.99	-	6.07
Control, b-jet Veto	$3.02 \pm 0.15$	$89 \pm 10$	$9.78 \pm 0.43$	-	$7.9 \pm 5.0$
Control, no b-jet Veto	3.13	311.7	10.28	-	7.89

Table 5: Cut flows (in fb) for  $M_H = 170$  GeV in the  $H + 2j, H \rightarrow WW \rightarrow e\nu\mu\nu$  channel. Numbers in parentheses are affected by generator-level filter cuts.

the event and III where there are no jets with  $b$ -tagging information in the event<sup>1</sup>. The fraction of events in each of the three regions is:

- 38% of the events in region I, 48% of the events in region II and 14% of the events in region III for the Higgs signal.
- 85% of the events in region I, 14% of the events in region II and 0.5% of the events in region III for the  $t\bar{t}$  background.

The selection in the leading versus sub-leading jet weights plane was optimized for the highest increase in the number-counting significance after the following cuts have been applied:

- Two leptons,  $p_T > 15$  GeV
- Missing transverse energy  $E_T^{miss} > 30$  GeV
- At least two jets with  $p_T > 20$  GeV and  $|\eta| < 4.8$
- The two jets with highest transverse momentum are required to be in opposite hemispheres, with  $\Delta\eta(jet1, jet2) > 3$
- Require that both leptons are between the two leading jets in pseudorapidity.

Two cuts are applied on the b-tagging weights:

- $weight(jet1) + 0.6 \times weight(jet2) < 3$  for events in region I
- $weight(jet1) < 8$  for events in region II

These cuts provide a strong rejection against the top background and a large acceptance for the Higgs signal.

## 6.2 Two-dimensional Fit

To select the events that are used in the two-dimensional fit, the same preselection cuts that were described in the previous section are applied, plus two additional cuts:

<sup>1</sup>Jets can lack  $b$ -tagging information if they fall outside the acceptance of the inner tracker, or because there are no tracks with high impact parameter significance in the jet.

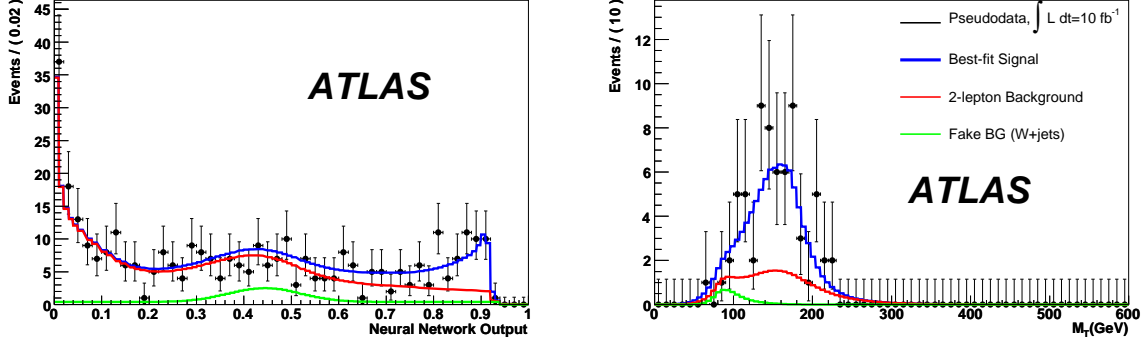

Figure 7: An example fit to a toy Monte Carlo outcome corresponding to  $10 \text{ fb}^{-1}$  of integrated luminosity in the  $H + 2j, H \rightarrow WW \rightarrow e\nu\mu\nu$  channel. The pseudodata contains a Standard Model Higgs boson with a true mass of 170 GeV. Left: The Neural Network output distribution in the signal box, for events with  $50 < M_T < 180 \text{ GeV}$ . Right: The transverse mass distribution for events in the signal box with Neural Network output larger than 0.8. The Likelihood Ratio for this outcome was 22.62, which is typical if the signal model used as truth is derived from a Monte Carlo sample generated with SHERPA.

- To reject backgrounds from  $Z \rightarrow \tau\tau$ , assume that the leptons are coming from  $\tau$  decays and compute  $x_\tau^1$  and  $x_\tau^2$ , the fractions of the tau energies carried by the visible leptons in the collinear approximation. If  $x_\tau^1$  and  $x_\tau^2$  are positive and  $M_{\tau\tau}$  is close to the  $Z$  mass ( $|M_{\tau\tau} - M_Z| < 25 \text{ GeV}$ ), the event is rejected.
- Require that the transverse mass  $M_T$  is between 50 GeV and 600 GeV, and that the transverse mass  $m_T^{ll\nu}$  (as defined in Ref. [25]) is at least 30 GeV.

In this analysis, electrons are selected using the standard ATLAS medium electron selection. The definition of muons, and the isolation cuts applied to both, are the same as in the  $H + 0j, H \rightarrow WW \rightarrow e\nu\mu\nu$  analysis in Section 5.

Events surviving the cuts above are used in the fit; they are partitioned into a signal box and a control region defined by additional cuts on the pseudorapidity gap between the leptons and the dilepton opening angle in the transverse plane. An event lies in the signal box if it has  $\Delta\phi_{ll} < 1.5$  and  $\Delta\eta_{ll} < 1.4$ ; otherwise, it lies in the control region. Table 5 shows the cross-sections for signal and background in these two regions.

The trigger efficiency has been studied in the context of this analysis. The same trigger menus as in the  $H + 0j, H \rightarrow WW \rightarrow e\nu\mu\nu$  analysis are used, and the results are similar: a trigger efficiency of 99.0% after Level 1, 96.8% after Level 2, and 94.5% after the Event Filter. These efficiencies are quite high, and as for the  $H + 0j$  analysis, it has been checked that the trigger efficiency does not significantly change the shape of the most important kinematic variables. Table 5 does not include the trigger efficiency, but it is taken into account as an overall scale factor for signal and background when generating toy Monte Carlo to test the 2-dimensional fit described in the next section.

After the preselection described above, a four-variable Neural Network is used to further enhance the separation between the signal and the background. The inputs to the Neural Network are:

- $\Delta\eta_{jj}$ , the pseudorapidity gap between the tagjets
- $M_{jj}$ , the invariant mass of the tagjets
- $p_T^{\text{veto}}$ , the transverse momentum of the leading non-tag jet in the region  $|\eta| < 3.2$ , and

- $\eta^* = \eta_3 - (\eta_1 + \eta_2)/2$ , the pseudorapidity gap between the tag-tag system and the third jet. It is set to -9 if no third jet is present.

The Neural Network classifies events as signal-like if they have large  $\Delta\eta_{jj}$ , large  $M_{jj}$ , low  $p_T^{\text{veto}}$ , and large  $|\eta^*|$ . Figure 7 shows the Neural Network output and transverse mass distributions in the signal box. The fit is a two-dimensional fit to these two quantities; both the signal model and the background model are uncorrelated product probability density functions (PDFs). The fit does not distinguish among the various types of background.

An in-situ normalization of fake backgrounds has not yet been implemented for this channel. For the present study, a static model has been used to approximate the fake background from  $W$ +jets. The same functional form used for the irreducible backgrounds was fitted to a set of  $W$ +jets Monte Carlo events that pass a loosened lepton selection, and its normalization was scaled to the cross-section obtained with the tighter selection cuts actually used in the analysis. In the present study, none of the parameters governing the shape or normalization of the fake background are allowed to float in the fit; systematic errors on the shape and normalization of the  $W$ +jets background are ignored.

The Neural Network output distribution for the background in the signal box is taken to be the same as the distribution in the control region, but it is multiplied by a linear extrapolation factor. Apart from the slope of this extrapolation factor, all parameters governing the shape of the Neural Network output distribution in the two regions are required to be the same.

A check on the impact of altered jet energy scales on the Neural Network output distributions for signal and background has been performed; changing the jet energy scale by 5% in the region with tracking and 10% elsewhere does not change the Neural Network output shape in a meaningful way. This is not surprising, since the Neural Network inputs are slowly varying functions of the jet energy. Similarly, raising the jet  $p_T$  thresholds from 20 GeV to 30 or 40 GeV to mimic a degraded efficiency for low- $p_T$  jets does not have a large impact on the ratio of the Neural Network output distributions in the signal box and the control regions.

Given the fact that the Neural Network output shape is insensitive to the jet energy scale, one would expect that the ratio of distributions in the signal box and control region would be insensitive to the jet energy scale as well. Other possible sources of uncertainty in the ratio of Neural Network output distributions are underlying event activity and the  $Q^2$  scale uncertainty; these sources of uncertainty have not been checked explicitly at this time. However, it is reasonable to think they might be small because the cuts on jets in the signal box are the same as in the control region and because the distributions of variables related to jets are not strongly correlated to the lepton angular variables. If the uncertainty in the ratio of distributions is sufficiently small, then one can fix the parameter governing the extrapolation factor; if it is too large, one must allow it to float in the fit. In the latter case, it may be possible to constrain it somewhat by looking into a b-tagged control sample; this possibility has been studied in the context of the five-dimensional fit discussed in the next section. All of these possibilities require further study in the context of the two-dimensional fit; this note will simply consider both scenarios: allowing the slope of the extrapolation factor to float in the fit and fixing it to a predetermined value taken from Monte Carlo. In both cases, it is assumed that the transverse mass distributions are well-predicted, and that the Neural Network output distribution is not; in practice this means that the  $M_T$  parameters are set to fixed values while most of the parameters describing the Neural Network output shape are allowed to float in the fit.

The expected significance is shown as a function of the true Higgs mass in Figure 8 for the two treatments of the extrapolation factor considered in this study. The sensitivity is comparable to what was quoted in previous studies of this channel, at least for the case where the extrapolation parameter is constrained to a fixed value.

Figure 8: Left: The Neural Network output distribution for the  $H + 2j, H \rightarrow WW \rightarrow e\nu\mu\nu$  channel in the signal box. Right: The expected significance at  $10 \text{ fb}^{-1}$ . The blue and magenta triangles were computed using a fixed extrapolation.

### 6.3 Five-dimensional Fit

A conceptually simpler but more technically challenging strategy is to directly fit the most important kinematic variables. This section describes such an approach to the  $H + 2j, H \rightarrow WW \rightarrow \ell\nu\ell\nu$  channel.

The selection cuts used in this analysis are similar to those used in section 6.2, with a few slight differences:

- Either two or three jets with transverse momentum  $p_T > 20 \text{ GeV}$  and pseudorapidity  $|\eta| < 4.9$  are allowed.
- The missing transverse momentum  $E_T^{\text{miss}}$  is greater than  $20 \text{ GeV}$ .
- The pseudorapidity gap between the tagjets is required to satisfy  $|\Delta\eta_{jj}| > 2.5$ , and the invariant mass of the tagjets is required to lie in the range  $m_{jj} \in [600, 3000] \text{ GeV}$ .
- A  $b$ -tagged jet is defined as having a displaced vertex significance greater than 4.5.

The values of the Higgs boson mass,  $m_H$ , and the cross section,  $\sigma(VBF H \rightarrow WW)$ , are determined with an unbinned maximum likelihood fit to the distributions of  $x = (M_T, \Delta\phi_{ll}, \Delta\eta_{ll}, \Delta\eta_{jj}, m_{jj})$ , as obtained from the selected data sample. A multidimensional kernel estimation technique [36] has been used to help model the kinematic distributions in the control samples.

Events in the selected data sample are divided into categories based on four properties: the flavors of the reconstructed lepton pair ( $\mu\mu$ ,  $\mu e$ , and  $ee$ ); the number of reconstructed good jets (2jet and 3jet); events with and without a  $b$ -tagged jet (btag and bveto, where a  $b$ -tagged jet is defined as having a displaced vertex significance greater than 4.5); and events that fall into the signal region, ‘sigbox’, having  $|\Delta\phi_{ll}| < 1.5$  and  $|\Delta\eta_{ll}| < 1.4$ , and those that fall outside, into the ‘sideband’ region. The b-vetoed sigbox region is denoted as region 1, the b-vetoed sideband as region 2, the b-tagged sigbox region as region 3, and the b-tagged sideband region as region 4.

Most  $t\bar{t}$  background events contain a  $b$ -tagged jet, whereas most  $WW$  background events fall into the bveto category. The majority of Higgs boson events is expected to be found in physics region 1. Events outside of this region are not considered as signal candidates. These regions are defined to be the background control samples.

For  $t\bar{t}$ ,  $WW$ , and  $H \rightarrow WW$  events, the selected samples are mostly dominated by di-leptonic  $W$  decays. For this reason, the relative fractions of  $\mu\mu$ ,  $ee$ , and  $\mu e$  events ( $f_{\mu\mu}$ ,  $f_{ee}$ ,  $1 - f_{\mu\mu} - f_{ee}$ ) are taken to be identical for background and signal events.

The signal model is obtained from fully simulated Monte Carlo events, and is factorized into four shapes, modelling  $M_T$ ,  $\Delta\phi_{ll}$ ,  $\Delta\eta_{ll}$  and  $(\Delta\eta_{jj}, m_{jj})$  respectively. The signal shape is assumed to be independent of the lepton pair category and the number of good jets per event.

The Higgs boson transverse mass distribution,  $M_T$ , is described with a double-sided exponential, having two different lifetimes, convoluted with a Gaussian. The mean of the Gaussian is interpreted as the Higgs boson mass,  $m_H$ , and is left free in the fit. The left-handed lifetime,  $\tau_L$ , comes from the missing  $z$ -component in the transverse mass calculation. The parameter  $\tau_L$  is a linear function of  $m_H$ , and equals 25 GeV for a Higgs boson mass of 130 GeV, and 45 GeV for a Higgs boson mass of 170 GeV. The right-handed component,  $\tau_R$ , is the result of the non-validity of the approximation  $m_{l\bar{l}} = m_{\nu\bar{\nu}}$  in the definition of  $M_T$ , and is fixed to 20 GeV for all Higgs boson masses. The width of the Gaussian,  $\sigma_{MET}$ , is interpreted as the resolution on the missing transverse energy, and is fixed to 15 GeV.

The distributions of  $\Delta\phi_{ll}$  and  $\Delta\eta_{ll}$  in signal are described with single Gaussians, with means fixed to zero, and widths of  $\sigma_{\Delta\phi} = 1.09$  and  $\sigma_{\Delta\eta} = 0.62$  respectively.

The tagging jet observables  $\Delta\eta_{jj}$  and  $m_{jj}$  in signal are strongly correlated, and are modeled with a 2-dimensional (2D) kernel estimation function.

For these observables, the largest unmodelled correlation is between  $\Delta\phi_{ll}$  and  $\Delta\eta_{ll}$ , and is found to be 14% from the available signal Monte Carlo sample.

The collection of background events in regions 2–4 serves as a data control sample for the determination of: a) the probability density functions, and b) the number of background candidates in physics region 1. The background shape is assumed to be independent of the lepton pair category and number of good jets per event. The shape is factorized into two pieces, describing  $(M_T, \Delta\phi_{ll}, \Delta\eta_{ll})$  and  $(\Delta\eta_{jj}, m_{jj})$  respectively.

The background distribution of  $(M_T, \Delta\phi_{ll}, \Delta\eta_{ll})$  – observables mostly independent of the jet characteristics – is modelled with a 3D kernel estimation function, using the events in physics region 3. A small efficiency correction is applied to the observable  $M_T$ , calculated as the ratio the distributions of  $M_T$  in physics regions 2 and 4, both determined using 1D kernel estimation functions.

Accounting for the hard  $p_T$  spectrum of the  $b$ -tagged jet sample, the distribution of  $(\Delta\eta_{jj}, m_{jj})$  is modelled with a 2D kernel estimation function using the background events in physics region 2. A correction function is applied to  $\Delta\eta_{jj}$ , determined as the ratio the  $\Delta\eta_{jj}$  distributions in physics regions 3 and 4, again determined using 1D kernel estimation functions.

The unmodelled correlations between these observables are found to be smaller than 10%, as obtained from the  $t\bar{t}$  and  $WW$  background Monte Carlo samples.

The number of background events in physics region 1 is partially estimated from the number of background events in categories 2–4. For this we assume the ratio of events in the sideband to sigbox regions ( $f_{\text{sigbox} - \text{sideband}}$ ) to be identical for the btag and bveto categories. Given the ratio of events of physics regions 2 and 4 ( $f_{\text{bveto} - \text{btag}}$ ), determined independently for the 2jet and 3jet samples, estimates for the number of background events in physics region 1 can be obtained. These estimates are expressed as the total number of background events,  $n_{\text{bkg}}$ , and the relative fraction of background event in the 3jet category,  $f_{\text{bkg} - 3j}$ .

Finally, the fitted number of Higgs boson signal events,  $n_H$ , is determined separately for the 2jet and 3jet categories.

### 6.3.1 Toy Monte Carlo Studies

A fit example to approximately  $1 \text{ fb}^{-1}$  of fully simulated Monte Carlo events, including Higgs boson signal events with a mass of 170 GeV, is demonstrated in the left side of Fig. 9. The plot shows the events

Figure 9: Left: The Higgs boson transverse mass distribution for events in the defined physics signal region, corresponding to approximately  $1 \text{ fb}^{-1}$  of data, as obtained from fully simulated Monte Carlo events. The solid (blue) curve is the total fit projection. The background contribution is represented by the dashed (red) curve. Right: The expected statistical sensitivity to Standard Model  $VBF H \rightarrow W^+W^- \rightarrow l^+\nu l^-\bar{\nu}$  decays for  $1 \text{ fb}^{-1}$  of ATLAS data, using the five-dimensional fit of Section 6.3.

Fit parameter	Value	Global corr.	Parameter	Value	Global corr.
$f_{bveto-btag;2jet}$	$0.89 \pm 0.14$	72%	$n_B$	$90.5 \pm 7.4$	93%
$f_{bveto-btag;3jet}$	$3.02 \pm 0.24$	88%	$n_{H;2jet}$	$18.6 \pm 5.5$	25%
$f_{bkg-3jet}$	$0.72 \pm 0.03$	80%	$n_{H;3jet}$	$9.6 \pm 7.9$	38%
$f_{sigbox-sideband}$	$2.64 \pm 0.19$	86%	$\sigma_{MET}$	15000	—
$f_{ee}$	$0.11 \pm 0.01$	34%	$\sigma_{\Delta\phi_{ll}}$	$0.62 \pm 0.03$ (fixed)	—
$f_{\mu\mu}$	$0.47 \pm 0.01$	34%	$\sigma_{\Delta\eta_{ll}}$	$1.09 \pm 0.06$ (fixed)	—
$m_H$	$168 \pm 8$	12%	$\tau_R$	20000 (fixed)	—

Table 6: The free parameters for the five-dimensional fit described in Section 6.3, and their best-fit values for the example toy Monte Carlo outcome in the left side of Figure 9.

in the defined physics region 1, with the total and background fit projections overlaid. Here the signal shape has been obtained from fully simulated Monte Carlo events. The background probability density function has been obtained using kernel estimation from the (Monte Carlo) events in the background control samples.

The corresponding fit results are given in Table 6. The Higgs boson mass found is consistent with the generated value. The total numbers of Higgs boson and background events found are consistent with the input values of 27 and 86 respectively. The fit is most sensitive to Higgs boson events in the 2jet signal region – where most Higgs boson events are expected, and contributions from  $t\bar{t}$  background events are minimal. For Higgs boson masses in the range  $[160, 170] \text{ GeV}$ , the signal to background ratio in this category is approximately 1 : 1. The error on the fitted number of background events in the signal region is found to be 7.4. When not including the estimated number of background event from the background control samples in the fit, the error on the number fitted number of background events doubles. The error on the fitted number of Higgs boson events rises by 25%, and the correlation of the fitted number of Higgs boson events with all other fit parameters – mostly correlated to the number of background events – rises from 25% to 45%. The correlation of the Higgs boson mass with all other fit parameters is 12%.

The statistical properties of this fitting algorithm have been studied with about 15k toy Monte Carlo

outcomes like the one discussed in the previous paragraph. The toy outcomes have been generated with the same number of events seen in, and the shapes obtained from, the fully simulated Monte Carlo signal and background samples remnant after the event selection, corresponding to  $1 \text{ fb}^{-1}$  of data. The mass of the generated Higgs boson sample is varied between 110 and 200 GeV, in steps of 10 GeV. The Higgs boson cross-section is adjusted accordingly [1]. The fit algorithm described above has been performed on each generated pseudo-experiment.

The fitted number of Higgs boson events in the 2jet signal region – most sensitive to the Higgs signal – shows an average bias of less than 0.8 event over the entire generated mass range. Roughly 12 Higgs boson events are needed in this region before a clear signal peak can be picked up by the fitter. The error on the fitted number of 2jet Higgs boson events varies between 3.1 and 5.6 events for no generated Higgs boson events to the maximum cross-section between 160 and 170 GeV respectively.

The average fit error on the Higgs boson mass parameter is about 14.0 GeV in background-only outcomes, or about 9.4 GeV in outcomes containing both background and a 160 GeV Higgs signal with cross-section as given by the Standard Model. In Fig. 9, note that the background distribution, dominated by  $t\bar{t}$  events, peaks at around 160 GeV. Pseudo-experiments with no generated signal events tend to peak at this mass, where statistical fluctuations are largest. For  $1 \text{ fb}^{-1}$  samples, starting from the generated Higgs boson mass of 110 GeV with a value of  $+1\sigma$ , the fit show a decreasing bias in the mass pull distribution, which is consistent with zero at 160 GeV, and becomes  $-1\sigma$  at 200 GeV. The width of the pull is consistent with one in the generated mass range of [150, 190] GeV, and grows for lower cross-section, upto  $1.7\sigma$  at 120 GeV.

The average statistical sensitivity derived from the toy Monte Carlo study is shown in the right side of Figure 9. At  $1 \text{ fb}^{-1}$  of data, the sensitivity to  $VBF H \rightarrow W^+W^- \rightarrow l^+\nu l^-\bar{\nu}$  decays is greater than one for Higgs boson masses greater than 120 GeV. (Below 120 GeV the  $H \rightarrow W^+W^-$  branching ratio becomes too small for this measurement to be effective.) It reaches a maximum of  $2.5\sigma$  at the Higgs boson mass of 160 GeV.

## 7 W Pair Production with Two Hard Jets in the Lepton-Hadron Channel

This section describes the analysis of events where the  $W$  pair is produced in association with two hard jets and one  $W$  boson decays leptonically (with the other  $W$  decaying to jets). [25, 29, 37–42] The dominant backgrounds to this final state are  $W$ +jets and  $t\bar{t}$  production; it is possible that QCD multijets will also play an important role. Because of the large jet multiplicity, there are large theoretical uncertainties in the predicted normalization of the backgrounds, especially for  $W$ +jets and QCD multijets. Therefore, this section will emphasize studies of the signal, the  $W$ +jets background, and the  $t\bar{t}$  background, with discussion of how to normalize the backgrounds given data. Quantitative predictions of the discovery sensitivity will not be included here.

Because there is only one neutrino in the final state, this channel permits a better estimate of the Higgs candidate invariant mass than the dilepton channels. Taken together with the large sensitivity of the dilepton channels for Higgs masses near 160 GeV, this means that the  $H \rightarrow WW \rightarrow \ell\nu qq$  channel is most interesting for the study of Higgs bosons with masses in excess of roughly 250-300 GeV.

The most obvious way to estimate the invariant mass of a  $H \rightarrow WW \rightarrow \ell\nu qq$  candidate is to assume that both  $W$  bosons are on-shell. One can then use the  $W$  mass constraint for the  $W \rightarrow \ell\nu$  system to estimate the  $z$  momentum of the neutrino.<sup>2</sup>

The analysis of this channel uses reconstructed jets to measure the invariant masses of Higgs boson candidates; it is therefore necessary to consider out-of-cone corrections to the jet energies that were not important in the dilepton channels. Eventually, these corrections should be taken from real data;

<sup>2</sup>The  $W$  mass constraint yields a quadratic equation which can have 0, 1, or 2 real solutions. If there are two solutions, the one with smaller  $|p_z^\nu|$  is used; if there is no real solution, the imaginary term is ignored and only the real part is used.

Cut	W+jets	ttbar	Signal ( $M_H = 300$ GeV)
Leptonic $W$ Selection	2353291*	128654	174.27

Table 7: Cross-sections (in fb) for the signal and various backgrounds after successive cuts in the  $H \rightarrow WW \rightarrow lvqq$  channel. A “\*” indicates a number that is biased by generator-level cuts.

however, such a study has not yet been performed. For the present study, the out-of-cone correction from ATLFast-B [43] has been applied to all jets. After applying this correction to the reconstructed jet momenta, the following cuts are applied:

- Leptonic  $W$  selection. The event must contain exactly one hard lepton, with transverse momentum  $p_T > 25$  GeV for electrons and  $p_T > 20$  GeV for muons. It is also required that the missing transverse momentum,  $p_T^{miss}$ , be larger than 30 GeV.
- Hadronic  $W$  selection. Out of all jets with large transverse momentum,  $p_T > 30$  GeV, the two whose invariant mass is closest to the known value of the  $W$  mass are selected. It is required that the reconstructed invariant mass of these two jets be between 64 GeV and 90 GeV.
- Forward Jet Tagging. Select the two jets (excluding those from the  $W$  decay) that have the highest transverse momentum. These are labelled as the “tagging” jets; by construction, they are disjoint from the jets that form the  $W \rightarrow qq$  candidate. Require that they be high- $p_T$  ( $p_T^{j1} > 50$  GeV,  $p_T^{j2} > 30$  GeV), that they lie in opposite hemispheres ( $\eta_{j1} \cdot \eta_{j2} < 0$ ), and that they be well-separated in pseudorapidity ( $|\eta_{j1} - \eta_{j2}| > 4.4$ ).
- Require that the lepton be between the tagjets in pseudorapidity.
- $M_{jj}$ : require that the invariant mass of the two tagging jets be greater than 1500 GeV.
- Central Jet Veto: reject the event if it contains any extra jets (in addition to the two jets from the decay of the  $W$  and the two tagging jets) with  $p_T > 30$  GeV and  $|\eta| < 3.2$ .
- b-jet veto: apply the b-jet veto cuts described in Section 6.1.2.

Trigger Level	Electron Channel	Muon Channel
L1	97.1%	85.3%
L2	94.3%	81.2%
EF	92.4%	79.6%

Table 8: Trigger efficiencies with respect to offline cuts for the H+2j lepton-hadron channel, for a Higgs boson mass of 170 GeV.

- $\Delta\eta_{j1,l}$ : require that the pseudorapidity gap between the leading jet from the decay of the  $W$  and the lepton be no larger than 1.5.
- Reconstruct the mass of the Higgs boson candidate,  $M_{lvqq}$ , by applying the  $W$  mass constraint to the lepton- $p_T^{miss}$  system. The resolution is enhanced by performing a kinematic fit to the mass of the hadronically decaying  $W$ , minimizing the function  $\chi^2 = (M_W^{rec} - M_W^{true})/\Gamma_W + (\Delta E_{j1})^2/\sigma_{j1}^2 + (\Delta E_{j2})^2/\sigma_{j2}^2$ , where  $\sigma$ , the energy resolution for the jets, is given for now by the parameterization used in ATLFAST,  $\sigma/E_j = 0.03 \oplus 0.5/\sqrt{E_j}$  GeV. The left plot in Figure 10 shows the distribution of the Higgs boson candidate invariant mass after all cuts for a representative Higgs boson mass of 300 GeV. The figure includes the mass peak obtained in a few distorted scenarios.

Table 7 shows the cut flow for  $W$ +jets, for  $t\bar{t}$ , and for signal at a representative Higgs boson mass of 300 GeV. At the time of this writing, a detailed estimate of the background from QCD multijet events is not available.

The trigger efficiency for this channel has been estimated, considering only the single-lepton triggers: EM25I, EM60, MU20, and MU40 at Level 1; e25i, e60, and mu20i for Level 2 and the Event Filter. Table 8 shows the trigger efficiency for signal ( $M_H = 170$  GeV) events that pass the offline cuts. Because the present analysis relies only on single-lepton triggers, the trigger efficiency for this channel is not as high as for the two-lepton channels. However, it has been checked that the trigger efficiency does not distort the  $M_{lvqq}$  shape for signal in a meaningful way. At the time of this writing, the trigger efficiency for the backgrounds has not been explicitly computed; in Table 7, the trigger efficiency for background is assumed to be the same as the trigger efficiency for signal.

The control sample for this channel is a region with loosened cuts on  $\Delta\eta_{jj}$  and  $M_{jj}$ . In particular, the event selection is the same as in the signal-like region, except that the pseudorapidity gap between the tagjets is required to be less than 4 instead of larger than 4.4, and the lower bound on the invariant mass of the tagjets is lowered to 500 GeV. Table 7 shows the contributions from the various subprocesses after these cuts are applied. Since both the signal-like region and the control region have a nontrivial contribution from top events, it is necessary to define b-tagged control samples to normalize the top background. These samples have the same kinematic cuts as the signal-like and control regions, but the b-veto cut is reversed. The cross-sections in these two regions are also shown in the table.

The shape of the  $W$ +jets background in the signal-like region is the same as the  $W$ +jets background in the control region to within the available Monte Carlo statistics. Likewise, the top background in the b-tagged region with the same kinematic cuts as the signal-like region has the same shape as the top background in the b-vetoed signal-like region. In fast simulation, there is a small difference between the top background shapes in the control region and the b-tagged region with the same kinematic cuts as the control region, but that distortion is small compared to the statistical errors expected at the luminosities considered here. These statements are robust against a variety of systematic uncertainties, namely changes in the  $Q^2$  scale (a factor of 4 up and down for both top and  $W$ +jets) as well as altered jet energy scales ( $\pm 5\%$  in the region with tracking,  $\pm 10\%$  elsewhere), degraded jet energy resolution (Gaussian smearing to roughly double the resolution), degraded  $E_T^{miss}$  resolution (modeled by smearing the  $x$  and

Figure 10: Left: the reconstructed invariant mass of the  $M_{lvqq}$  system for fully simulated signal Monte Carlo events with a true Higgs boson mass of 300 GeV. The red dashed and black dotted curves show the mass peaks obtained when the jet energy scale is raised and lowered by 7% in the region with  $|\eta| < 2.5$  and 15% elsewhere. The blue dot-dashed curve shows the result obtained when the jet energy resolution is smeared by  $45\%/\sqrt{E}$  in the region with  $|\eta| < 2.5$  and  $63\%/\sqrt{E}$  elsewhere. Middle: A toy Monte Carlo outcome corresponding to  $10 \text{ fb}^{-1}$  of integrated luminosity for the signal-like region of the  $H + 2j$ ,  $H \rightarrow lvqq$  analysis described in Section 7. Here, the background from QCD multijets is assumed to be negligible. Right: the corresponding distribution in the control region.

y components of  $E_T^{miss}$  by 5 GeV each), and  $E_T^{miss}$  reconstruction that has been degraded by artificially inducing a shift of 3% in the reconstructed  $E_T^{miss}$ .

The background is normalized and the signal extracted with the help of a fitting algorithm which implements a simultaneous binned fit in the signal-like region and the main control region in the range  $167 < M_{lvqq} < 1000$  GeV. The fit proceeds in two steps: first, standalone fits of the top background model to the b-tagged regions are performed. All parameters governing the shape of the top background distributions are allowed to float in this fit. After the fits to the b-tagged regions, these parameters are fixed, and the histograms are rescaled by the ratio of cross-sections in the b-tagged and b-vetoed regions to obtain estimates of the top background normalization and shape in both b-vetoed regions.

The main fit is a simultaneous fit of the  $M_{lvqq}$  distribution in the signal-like and control regions. All shape parameters for the  $W$ +jets background are free to float in the fit, but the parameters governing the top background shape and normalization remain fixed. The  $W$ +jets background shape is assumed to be the same in the signal-like region and the control region, but the normalizations in the two regions are independent. Likewise, the signal shape is assumed to be the same in both regions, but the ratio of signal cross-sections is parameterized as a function of Higgs boson mass based on Monte Carlo. Figure 10 shows the result of an example fit to a toy Monte Carlo outcome with a true Higgs boson mass of 300 GeV.

The performance of the fitting algorithm has been evaluated by generating pseudo-experimental outcomes corresponding to a luminosity of  $10 \text{ fb}^{-1}$  with and without true signal events. However, because of the large theoretical uncertainty in the prediction of the  $W$ +jets background and the lack of a precise estimate of the QCD multijet background, an estimate of the expected significance is omitted here.

## 8 Conclusions

The prospects for a search for a Standard Model Higgs boson in the  $WW$  decay mode have been studied, using a realistic model of the ATLAS detector, including effects such as trigger efficiencies, backgrounds from fakes, and realistic misalignments. Three channels have been considered:  $H + 0j$  with  $H \rightarrow WW \rightarrow e\nu\mu\nu$ ,  $H + 2j$  with  $H \rightarrow WW \rightarrow e\nu\mu\nu$ , and  $H + 2j$  with  $H \rightarrow \ell\nu qq$ . In-situ background normalization techniques for all three channels have been proposed, and their effectiveness and robustness has been

Figure 11: Left: The linearity of the mass determination for the combined fit of  $H + 0/2j, H \rightarrow WW \rightarrow e\nu\mu\nu$ . Right: The expected significance at  $10 \text{ fb}^{-1}$ .

demonstrated with detailed toy Monte Carlo studies.

The  $H + 0j, H \rightarrow e\nu\mu\nu$  channel is very promising for Higgs boson masses in the region around the  $WW$  threshold. For other masses, this channel is still very promising, but the analysis is more difficult because of large systematic uncertainties in the background prediction. It has been shown that these uncertainties can be controlled, and that the background can be normalized, with a two-dimensional fit in the transverse mass and the  $p_T$  of the  $WW$  system. With  $10 \text{ fb}^{-1}$  of integrated luminosity, one would expect to be able to reach a  $5\sigma$  discovery with the  $H \rightarrow WW \rightarrow e\nu\mu\nu$  channel alone if there is a Standard Model Higgs with a mass between  $\sim 140 \text{ GeV}$  and  $\sim 185 \text{ GeV}$ . A measurement of the mass of the Higgs boson at this luminosity would have a precision of less than  $2 \text{ GeV}$  for a Standard Model Higgs boson with a mass of  $160 \text{ GeV}$ , or a precision of less than  $4 \text{ GeV}$  for a Standard Model Higgs boson with a mass of  $140 \text{ GeV}$ .

The  $H + 2j, H \rightarrow e\nu\mu\nu$  channel has a smaller event rate than the  $H + 0j$  channel but a similar significance. With  $10 \text{ fb}^{-1}$  of integrated luminosity, one would expect to be able to reach a  $5\sigma$  discovery in the  $H \rightarrow WW \rightarrow e\nu\mu\nu$  channel alone if there is a Standard Model Higgs boson with a mass between  $150 \text{ GeV}$  and  $180 \text{ GeV}$ . A measurement of the Standard Model Higgs boson mass at this luminosity would typically return a precision less than  $\sim 4\text{--}5 \text{ GeV}$  if the Higgs boson mass is  $160 \text{ GeV}$ , or less than  $8 \text{ GeV}$  if the Higgs boson mass is  $140 \text{ GeV}$ .

In the range below  $M_H = 200 \text{ GeV}$ , both of the dilepton channels are important; it is therefore interesting to consider a combined fit of the two. In the combined fit, a shared mass parameter has been used for the two channels, but the signal normalizations have been allowed to float independently to preserve model-independence. Figure 11 shows the linearity of the mass determination and the expected significance of a combined fit of the two dilepton channels as a function of the true Higgs boson mass. As in the other linearity plots in this note, the green band represents the width of a gaussian fit to the region around the peak of the best-fit mass distribution and the error bars show the median fit error. The combined significance for a Standard Model Higgs is above the  $5\sigma$  level for  $M_H$  larger than about  $140 \text{ GeV}$ .

The  $H + 2j, H \rightarrow \ell\nu qq$  channel is most interesting for Higgs masses above  $\sim 250 \text{ GeV}$ . It has been shown that the background normalization can be estimated from data, but it is difficult to make a strong statement about the discovery potential of this analysis until a measurement of the  $W+4$  jets background can be obtained from first data.

# Search for $t\bar{t}H(H \rightarrow b\bar{b})$

## Abstract

For a light Higgs boson, with  $m_H \leq 135$  GeV, the largest decay mode is  $H \rightarrow b\bar{b}$ . Events where the Higgs boson is produced in association with a  $t\bar{t}$  pair manifest a distinct signature due to the presence of two  $W$  bosons and four  $b$  quarks. Topological and kinematical quantities are used to reconstruct the  $t\bar{t}$  system. The identification of an additional  $b\bar{b}$  pair from the Higgs boson decay is used to further reduce the background.

In this analysis we focus on the sensitivity to a light Standard Model Higgs boson with the ATLAS detector in the channel  $t\bar{t}H(H \rightarrow b\bar{b})$  using the semi-leptonic final state with  $30 \text{ fb}^{-1}$  of integrated luminosity. The relevant backgrounds to the channel are investigated and the impact of their associated systematic uncertainties is explored.

## 1 Signal

At the LHC  $t\bar{t}H$  production is dominated (90%) by gluon fusion, as illustrated in Fig. 1. The remaining 10% arises from quark-antiquark interactions. For a Higgs boson mass between 115 GeV and 130 GeV the production cross-section times branching ratio to  $b\bar{b}$  varies between roughly 0.4 and 0.2 pb at leading order. The top quarks decay almost exclusively to  $bW$ , and therefore the various final states can be classified according to the decays of the  $W$  bosons.

The all-hadronic channel is the one with the highest branching fraction, with a value of 43%. Unfortunately, the large QCD multijet cross-section does not allow easy triggering with jets. Only tight requirements on the jet  $p_T$  and on the jet multiplicity could lead to reasonable rates in the first level of the trigger, but these requirements come at the expense of signal efficiency. This is being studied for this final state together with the use of  $b$ -tagging at the second level of the trigger to reduce the jet  $p_T$  threshold.

The fully-leptonic final state analysis is probably the least feasible, despite presenting a simpler signature to trigger on, given the presence of two isolated leptons. The branching fraction (5%) is low and the two neutrinos prevent the reconstruction of the top quarks.

Figure 1: One of the Feynman diagrams for  $t\bar{t}H$  production in the semi-leptonic final state.

The semi-leptonic final state is a good compromise with a branching fraction of about 28% excluding tau leptons. The experimental signature consists of one energetic isolated lepton, a high jet multiplicity with multiple  $b$ -tags, and missing transverse energy from the escaping neutrino, as shown in Fig. 1. The

trigger relies on the presence of the high- $p_T$  lepton. The non- $b$ -tagged jets can be used for reconstructing the hadronically decaying  $W$  boson, decreasing the possible combinatorial permutations.

## 2 Physics backgrounds

The production of  $t\bar{t}$  events is the main background for the  $t\bar{t}H$  process. Given the high jet multiplicity in the signal process ( $\geq 6$  jets), only  $t\bar{t}$  events produced together with at least two extra jets contribute to the preselected data sample. Since most of these extra jets come from the hadronisation of light quarks, this contribution is greatly reduced by asking for four jets to be identified as  $b$ -jets.

Figure 2: Example of Feynman diagrams for the  $t\bar{t}b\bar{b}$  QCD production.

The irreducible background comes from  $t\bar{t}b\bar{b}$  production. This can proceed via QCD or electroweak, (EW), interactions with a total cross-section of the order of 9 pb. Some of the Feynman diagrams involved in the two production mechanisms are shown in Fig. 2 and Fig. 3. While the QCD production cross-section is ten times larger than the EW production, the latter is also important. The two  $b$ -jets not coming from the  $t\bar{t}$  decay have large momenta and also have a total invariant mass which is typically close to the  $Z$  boson mass, and can therefore contaminate the signal region.

Figure 3: Example of Feynman diagrams for the  $t\bar{t}b\bar{b}$  EW production.

The  $t\bar{t}c\bar{c}$  background cross-section is 60% higher than  $t\bar{t}b\bar{b}$  [1], so it could also play an important role. However, it is found upon investigation that due to the  $c$ -jet rejection factor, the  $t\bar{t}c\bar{c}$  background plays a negligible part in comparison with the  $t\bar{t}b\bar{b}$  background. No dedicated sample is therefore simulated for this study. Some  $t\bar{t}c\bar{c}$  events are however present in the inclusive  $t\bar{t}$  +jets sample used.

Several other backgrounds, such as  $W$ +jets,  $tW$  production and QCD multijet production, could also have a non-negligible impact on the analysis. Even though the  $W$  plus two jets inclusive cross-section is about 1200 pb per lepton flavor [2], it has been shown [3] and confirmed in this analysis that the contribution can be reduced to a negligible level if the four  $b$ -tags requirement is applied. This is also true for the less abundant  $tW$  background, which has a cross-section of 9.5 pb [4]. Even when four  $b$ -jets are requested in the event, contamination via QCD  $b\bar{b}b\bar{b}$  production, which has a cross-section of a few hundred nb [5], is still possible. The reconstruction of the  $t\bar{t}$  system allows a certain degree of safety against non-top background. None of these samples are presented in what follows.

### 3 Monte Carlo samples and cross-sections

This study uses the leading order cross-sections for the signal and  $t\bar{t}b\bar{b}$  samples. No calculation has yet been performed for  $t\bar{t}b\bar{b}$  at next-to-leading order, (NLO). This study also uses a  $t\bar{t}$  background, simulated at next-to-leading order. This is the only NLO Monte Carlo sample used, and the only  $t\bar{t}$  large sample available in ATLAS at the time this analysis was performed. No K-factors are applied to the samples simulated at leading order in the significance estimates.

The signal sample is generated for a Higgs boson mass of  $m_H = 120$  GeV with PYTHIA [6] 6.403. The exact generated process was  $pp \rightarrow t\bar{t}HX \rightarrow \ell\nu b q \bar{q}' b\bar{b}X$ , with  $\ell = e$  or  $\mu$ . The factorization and renormalization scales used are identical and are listed in Table 1. The signal and the  $t\bar{t}b\bar{b}$  events are generated with a lepton filter requiring at least one electron or one muon with pseudorapidity  $|\eta| < 2.7$  and transverse momentum above 10 GeV. The leading order production cross-section used is  $\sigma(t\bar{t}H) = 537$  fb [7]. The branching ratios  $H \rightarrow b\bar{b}$  of 67.5% at 120 GeV [7],  $W \rightarrow \ell\nu$  of 10.66% [8], and  $W \rightarrow$  hadrons of 67.6% [8] is applied. Finally the lepton filter efficiency of  $\varepsilon = 0.953$  is also applied. The resulting cross-section is 100 fb.

For both  $t\bar{t}b\bar{b}$  QCD and EW samples, the exact process generated is  $gg \rightarrow t\bar{t}b\bar{b}X \rightarrow \ell\nu b q \bar{q}' b\bar{b}X$ , with  $\ell = e$  or  $\mu$ . Both processes can be initiated by a  $q\bar{q}$  pair, but only the dominant gluon fusion is simulated, with the cross-sections being increased to allow for the  $q\bar{q}$  pair production. For the  $t\bar{t}b\bar{b}$  QCD sample, AcerMC 3.4 [9] is used and interfaced to PYTHIA 6.403 for the simulation of the initial and final state radiation, hadronisation and decay. The  $t\bar{t}b\bar{b}$  EW sample is generated using AcerMC 3.3 and PYTHIA 6.403. The leading order  $t\bar{t}b\bar{b}$  QCD cross-section is  $\sigma(pp \rightarrow t\bar{t}b\bar{b}) = 8.2(gg)(+0.5(q\bar{q}))$  pb and the lepton filter efficiency is  $\varepsilon = 0.946$ . For the  $t\bar{t}b\bar{b}$  EW sample, the leading order cross-section is  $\sigma(pp \rightarrow t\bar{t}b\bar{b}) = 0.90(gg)(+0.04(q\bar{q}))$  pb and the lepton filter efficiency is  $\varepsilon = 0.943$ .

The reducible  $t\bar{t}$  background events are generated with the MC@NLO [10] program, interfaced to HERWIG [11] and Jimmy [12]. The events in this sample correspond to the processes  $pp \rightarrow t\bar{t} \rightarrow (\ell\nu, q\bar{q}')b\ell\nu b$  with  $\ell = e, \mu, \tau$ . The generator versions used are MC@NLO 3.1 and HERWIG 6.510. For the inclusive  $t\bar{t}$  cross-section we use the NLO+NLL calculation of  $\sigma(pp \rightarrow t\bar{t}) = 833$  pb. The  $t\bar{t}$  sample is also produced using a filter requiring one electron or one muon with pseudorapidity  $|\eta| < 2.7$  and transverse momentum above 14 GeV. The  $t\bar{t}$  filter also applies requirements on the jets in the generated events which are reconstructed using a seeded fixed-cone algorithm with a cone size of  $\Delta R = 0.4$  [13], by requiring at least:

- six jets with  $p_T > 14$  GeV and  $|\eta| < 5.2$
- four jets with  $p_T > 14$  GeV and  $|\eta| < 2.7$

The efficiency of this generator filter on inclusive  $t\bar{t}$  events is 0.146.

For the  $t\bar{t}$  sample, about 10% of events are  $t\bar{t}b\bar{b}$  and are removed following the overlap treatment explained in Ref. [14] together with their associated cross-section.

Table 1 summarizes the cross-sections, calculated using the Monte Carlo generators, of the different processes considered for this analysis, together with the corresponding numbers of generated events and the equivalent integrated luminosity. All branching fractions and filter efficiencies are included.

### 4 Analysis overview

The analysis consists of an initial preselection requirement which is applied to the events to ensure that the fundamental physics objects associated with  $t\bar{t}H$  are reconstructed. Following preselection, three different analysis techniques are implemented in order to reconstruct the top quark pairs and the Higgs boson through the identification of their decay products.

Table 1: Summary of the different samples used for the analysis. The cross-sections are taken from the generators and include all branching fractions and filter efficiencies. The fourth column shows the equivalent integrated luminosity, taking into account all corrections (see text). For the scale calculations,  $m_H = 120$  GeV and  $m_t = 175$  GeV are used.  $\max(p_T^2_t, p_T^2_{\bar{t}})$  corresponds to the higher of the two values of  $p_T^2$  when both the top and anti-top quarks are considered.

Process	$\sigma$ (fb)	Events	L (fb $^{-1}$ )	Fact. & Renorm Scale	PDF set
$t\bar{t}H$ (LO)	100	92750	931	$Q^2 = m_t^2 + \max(p_T^2_t, p_T^2_{\bar{t}})$	CTEQ6L1
$t\bar{t}b\bar{b}$ QCD (LO)	2371	98350	42	$Q = m_H/2 + m_t = 235$ GeV	CTEQ6L1
$t\bar{t}b\bar{b}$ EW (LO)	255	24750	97	$Q = m_H/2 + m_t = 235$ GeV	CTEQ6L1
$t\bar{t}$ filtered (NLO)	109487	710321	6.5	$Q^2 = m_t^2 + \frac{1}{2}(p_T^2_t + p_T^2_{\bar{t}})$	CTEQ6M

The identification and association of decay products is directly related to the quality of the reconstructed Higgs boson signal. It mainly suffers from the misassociation of the four  $b$ -tagged jets to the original partons. For this reason, the initial cut-based approach is complemented by two multivariate algorithms, called the pairing likelihood and constrained mass fit.

## 5 Preselection

At the preselection level we require that the event passes the trigger requirement to identify at least one high- $p_T$  lepton (muon or electron) coming from the decay of one of the  $W$  bosons. We then require that the event reconstruction identifies exactly one isolated high- $p_T$  lepton (muon or electron). Vetoing the presence of a second isolated lepton is intended to remove additional sources of background. After the lepton requirements are met, we require at least six calorimeter jets, of which at least four must be loosely  $b$ -tagged jets from the decay of the top quarks and the Higgs boson.

### 5.1 Trigger requirements

The presence of one high- $p_T$  lepton, together with missing transverse momentum, is a distinct signature of  $W$  boson production. These leptons can generally be used to trigger on  $W$  production with high efficiency. A logical OR of the single isolated electron (e22i) [15], high- $p_T$  electron (e55) [15] and single muon (mu20) [16] triggers is used. The inclusion of the e55 trigger is found to improve the efficiency for high- $p_T$  electrons where the e22i trigger efficiency was reduced due to the isolation requirement. Missing energy triggers were not available at the time of writing, but could be used in future analysis.

The trigger efficiency is approximately 82% for the semileptonic top decays for those events which would otherwise pass the offline analysis. This is included consistently in the following sections.

### 5.2 Reconstructed high $p_T$ lepton selection

In this Section we explain the selection criteria used for reconstructed electrons and muons produced in the semi-leptonic decay of the  $t\bar{t}$  system. As previously mentioned, exactly one high- $p_T$  isolated electron or muon must be reconstructed for the event to pass the preselection.

To be considered for the analysis, reconstructed electrons must have transverse momentum  $p_T > 25$  GeV and pseudorapidity  $|\eta| < 2.5$ . Further calorimeter-based cuts are applied to the loose electron [17] definition. An isolation cut is also applied to the candidate electrons in the form of an upper limit of 0.15 on the ratio of the  $p_T$  of the additional tracks inside a cone of size 0.2 in  $\Delta R$ ,  $(\sqrt{\Delta\eta^2 + \Delta\phi^2})$ , around the electron track to the electron  $p_T$ .

Muon candidates are reconstructed using a combination of the Inner Detector and Muon Spectrometer [18]. They must pass the acceptance cuts  $p_T > 20$  GeV and  $|\eta| < 2.5$ . In order to remove poorly reconstructed muons, cuts are applied to the muon track fit quality and its transverse impact parameter, which helps to discriminate against muons generated by the decay of long-lived mesons.

An isolation cut of 0.30 on the ratio between the transverse energy deposited inside a cone of size 0.2 in  $\Delta R$  around the muon track and the muon  $p_T$  is applied.

### 5.3 Jets

To reconstruct the energy of the partons produced in the original collision, calorimeter jets are reconstructed using a seeded fixed-cone algorithm with a cone size of  $\Delta R = 0.4$  [13]. Cuts on  $p_T > 20$  GeV and  $|\eta| < 5.0$  are initially applied. Only events with at least 6 jets are kept for the analysis. All electrons reconstructed as jets are identified and removed from the jet collection according to the electron overlap removal procedure described in Section 5.3.1. Reconstructed muons which are not isolated are combined into jets where applicable (see Section 5.3.3), and only after this step are the jet energies calibrated for residual effects. The jet multiplicity is shown in Fig. 4, calculated after electron overlap removal and the jet  $\eta$  and  $p_T$  cuts.

In the following analyses the concept of ‘correct’ jets is important. This is defined by finding the closest reconstructed jet to each parton, after final state radiation. This match is in  $\Delta R$  space and must be closer than 0.4. A  $W$  or  $H$  boson is correctly matched if both the jets being used are associated to the partons from its decay, while for a top quark the matching refers to the  $b$  quark jet only. Normally ‘correct’ is applied in this note only to one quark or boson at a time.

#### 5.3.1 Treatment of overlaps between jets and electrons

Since most electrons are also reconstructed by the jet algorithm it becomes necessary to identify them in the jet collection in order to avoid double counting. The criteria for the jet-electron overlap removal is the following: each jet matching a well-reconstructed electron (i.e. fulfilling the cuts defined in Section 5.2) within a  $\Delta R$  of 0.2, and for which the ratio of the electron to the jet transverse momenta is greater than 0.75, is discarded from the jet collection. About 4% of the jets in the signal sample are removed by this selection, 99% of them being actual true electrons.

#### 5.3.2 $b$ -tagging

$b$ -jets are identified using the IP3D+SV1 tagger [19], which exploits both the impact parameter of tracks and the properties of an inclusive secondary vertex, using a likelihood approach which leads to a single discriminating variable: the  $b$ -tagging weight. In order to allow for a projected decrease in light jet rejection of approximately 30%, the  $b$ -tagging weight for this study is increased by 0.9 for central jets ( $|\eta| < 2.5$ ) having no associated ( $\Delta R < 0.3$ ) heavy quark or lepton ( $b, c, \tau$ ) in the Monte Carlo simulation history. The  $b$ -tag weight spectrum for  $b$ -,  $c$ -, and light jets in the signal sample is shown in Fig. 4. A cut on the weight defines which jets will be eventually identified as  $b$ -jets in the analysis. The rejection of  $c$ - and light jets versus the  $b$ -jet efficiency, obtained by varying the weight cut, is also shown in Fig. 5. The different samples exhibit very similar behaviour. The rejection for “purified” jets is shown in the bottom row of Fig. 5. Purified jets are those which have no heavy flavor ( $b, c, \tau$ ) quark or lepton within 0.8 in  $\Delta R$ .

In the preselection, a loose set of criteria are initially used to define a sample of jets as a first step to identifying  $b$  jets for the analyses. The requirements are that the jet is in the central region of the detector  $|\eta| < 2.5$ , and has  $b$ -tag weight  $\geq 0$ . If there are fewer than four of these jets, the event is discarded.

The cut-based analysis and the pairing likelihood (Sections 8 and 9) require that there are at least four  $b$ -jets having  $b$ -tag weight  $\geq 5.5$ . The  $b$ -tag weight  $\geq 0$  working point implies a  $b$ -tagging efficiency of about 85% and a rejection of light ( $c$ -) jets of about 8.6 (2.4), whereas the working point at  $b$ -tag weight  $\geq 5.5$  implies a  $b$ -tagging efficiency of about 65% and a rejection of light ( $c$ -) jets of about 60 (6).

Figure 4: Left: Multiplicity of jets, inside  $p_T$  and  $\eta$  acceptance. Right: Distribution of  $b$ -tagging weight for  $b$ -,  $c$ - and light jets in  $t\bar{t}H$  events, using the IP3D+SV1 tagger.

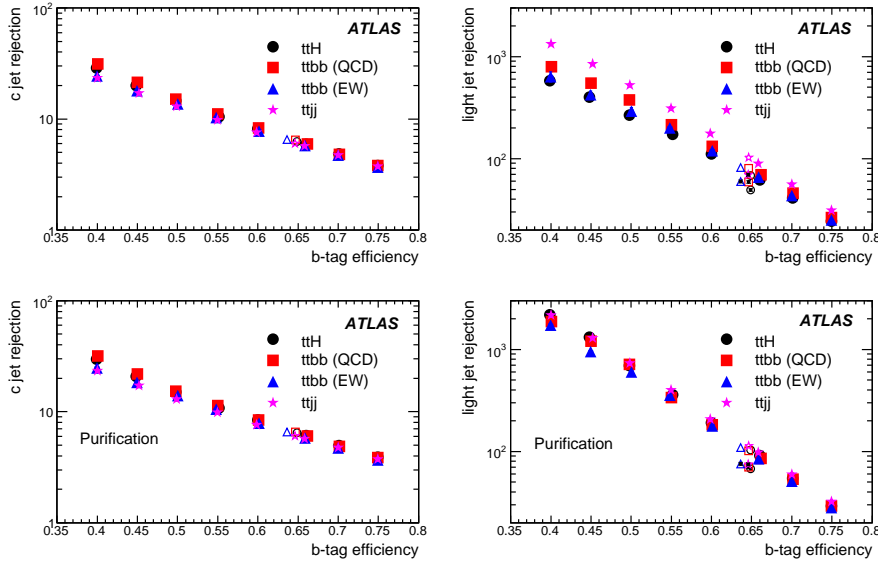

Figure 5: Rejection of light and  $c$ -jets versus  $b$ -tagging efficiency. Red open markers indicate the working point ( $b$ -tag weight  $\geq 5.5$ ) used for the cut-based and pairing likelihood analyses, open markers with a central dot (right plots) represent the performance when the 30% performance degradation is applied. The lower plots show results for purified jets, where no heavier quark existed within a wide cone of  $\Delta R < 0.8$ .

### 5.3.3 Treatment of low $p_T$ muons

About 20% of the time a  $B$ -meson decay cascade gives rise to a muon. With a four  $b$ -jet signature in this channel, these muons, also called *soft muons* are present in almost every event. In order to improve the estimate of the momentum of the original  $b$  quark, these muons must be used to correct the jet four-momenta by adding the muon four-momentum to a jet. Two different algorithms (high and low- $p_T$  [20])

identify the muons, which are required to be within  $\Delta R < 0.4$  of the jet axis. Among the candidates from the high- $p_T$  algorithm which are separated from the selected hard lepton by  $\Delta R > 0.1$ , only the one with the best track quality is considered for addition. All the neighbouring candidates from the low- $p_T$  algorithm are considered for addition, provided they fulfil  $p_T > 4$  GeV and  $p_T < 100$  GeV,  $|\eta| < 2.5$  and chi-squared per degree of freedom  $\chi^2/n < 30$  for the combined fit. In addition, a loose anti-isolation cut is applied, requiring that the energy reconstructed in the calorimeter within a cone of size 0.2 in  $\Delta R$  around the muon track divided by the muon  $p_T$  is higher than 0.1. Table 2 shows that adding low  $p_T$  muons to jets improves both the mean jet  $p_T$  and resolution. Fig. 6 shows that there is also an improvement in the Higgs boson mass and resolution, when the correct jet combination is chosen.

### 5.3.4 Calibration

A Monte Carlo based jet correction has been derived to take into account residual calibrations, *e.g.* out-of-cone effects and neutrinos. The parametrization was derived from full simulation, so that the jet four-momentum is corrected by a flavor dependent rescaling factor which scales all components of the four-momentum. Table 2 shows that for  $b$ -jets, the residual calibration brings the jet and associated parton  $p_T$  into agreement from an offset of 5.4 to  $-0.5$  GeV. Each of the analyses uses the light jet correction for those jets which are assigned to the W boson and corrects the other four jets as  $b$  quark originated. The impact of the calibration on the Higgs boson mass peak where the correct jet combination is chosen is shown in Fig. 6. Both the mass peak location and the resolution are improved.

Table 2: The true parton  $p_T$  minus the measured jet  $p_T$  with and without adding muons and making the out-of-cone correction. The quoted values are the results of a Gaussian fit in the region  $\pm 20$  GeV.

Treatment	Value	No Calibration	Added muons	Calibrated	Both corrections
All $b$ jets	Mean, GeV	$5.7 \pm 0.05$	$5.4 \pm 0.05$	$-0.1 \pm 0.04$	$-0.5 \pm 0.04$
	Sigma, GeV	$10.0 \pm 0.05$	$9.8 \pm 0.05$	$10.2 \pm 0.05$	$10.0 \pm 0.04$
$b$ jets with muons	Mean, GeV	$26 \pm 2.6$	$7.6 \pm 0.2$	$11.4 \pm 0.5$	$2.3 \pm 0.2$
	Sigma, GeV	$18.2 \pm 1.1$	$11.8 \pm 0.2$	$13.6 \pm 0.4$	$12.0 \pm 0.2$
All light jets	Mean, GeV	$2.4 \pm 0.04$	$2.3 \pm 0.04$	$-1.4 \pm 0.04$	$-1.5 \pm 0.04$
	Sigma, GeV	$8.4 \pm 0.04$	$8.4 \pm 0.04$	$8.9 \pm 0.04$	$8.3 \pm 0.04$
Light jets with muons	Mean, GeV	$10.5 \pm 0.9$	$2.4 \pm 0.4$	$7.3 \pm 0.7$	$-1.0 \pm 0.4$
	Sigma, GeV	$11.3 \pm 0.8$	$10.9 \pm 0.5$	$11.5 \pm 0.6$	$10.7 \pm 0.4$

## 5.4 Results of preselection on signal and background

The effect of the event preselection on signal and background samples is illustrated in Table 3. The efficiency for the four  $b$ -tag cut is different in the signal and in the irreducible background because the two additional  $b$ -jets have different  $p_T$  and  $|\eta|$  spectra. The preselection, at a level of four loose  $b$ -tags, removes a large fraction of the signal, but also reduces the backgrounds to a level where they can be handled more easily; for example 98% of the  $t\bar{t}X$  background is removed. It also ensures that the selections are a subset of the requirements placed at generator level. The selected sample has approximately a 0.6% signal component, with a little more than 8% of the background being irreducible  $t\bar{t}b\bar{b}$ . Further tightening the  $b$ -tagging requirement to four jets with weights of at least 5.5 reduces the samples with four  $b$  quarks by a further factor of four while removing 90% of the remaining  $t\bar{t}X$  background.

Figure 6: Effect of adding a reconstructed low  $p_T$  muon to at least one of the  $b$  jets (left), and the effect of jet calibration (right) shown for the Higgs boson mass where the correct jet combination is chosen. Red solid (black open) markers and solid (dotted) line show the mass distribution and fitted values for jets after (before) correction. The effect of the accidental wrong muon matches can be seen in the shape distortion. All distributions are normalized to unity.

Table 3: Cross-sections after each preselection cut for signal and background. The last row shows the further effect of tightening the  $b$ -tag requirements to the level of the final selection in the cut based and pairing likelihood analyses. In the last column the contribution of  $t\bar{t}b\bar{b}$  has been removed. The errors are statistical only.

Preselection cut	$t\bar{t}H(\text{fb})$	$t\bar{t}b\bar{b}(\text{EW})(\text{fb})$	$t\bar{t}b\bar{b}(\text{QCD})(\text{fb})$	$t\bar{t}X(\text{fb})$
lepton	$57. \pm 0.2$	$141 \pm 1.0$	$1356 \pm 6$	$63710 \pm 99$
+ $\geq 6$ jets	$36 \pm 0.2$	$77 \pm 0.9$	$665 \pm 4$	$26214 \pm 64$
+ $\geq 4$ loose $b$ -tags	$16.2 \pm 0.2$	$23 \pm 0.7$	$198 \pm 3$	$2589 \pm 25$
+ $\geq 4$ tight $b$ -tags	$3.8 \pm 0.06$	$4.2 \pm 0.2$	$30 \pm 0.8$	$51 \pm 2$

## 6 Reconstruction of the hadronically decaying $W$ bosons

Reconstructing the  $W$  boson four-momenta is necessary to reconstruct the top quarks. The reconstruction of the hadronically decaying  $W$  boson is done in different ways by the three analyses.

For the cut-based and pairing likelihood analyses (see Sections 8 and 9), the highest four  $b$ -tagged jets (with  $b$ -jet weight  $\geq 5.5$ ) are excluded from the hadronically decaying  $W$  reconstruction, however all other jets are paired to form  $W$  candidates. Figure 7 shows the mass distribution and multiplicity of all  $W$  candidates for the cut-based analysis. Only candidates within 25 GeV of the true  $W$  mass are kept. Even with these cuts the hadronically decaying  $W$  candidate multiplicity is still very high. All jets used to form these  $W$  candidates are calibrated with the light-jet calibration. The likelihood analyses do not require an explicit cut upon this mass as the definition of the likelihood imposes it automatically, but the constrained fit likelihood (Section 10) imposes a requirement that the mass be between 30 and 150 GeV to reduce the number of combinations to be evaluated.

Figure 7: Cross-sections of hadronically decaying  $W$  combinations per event giving candidates within 25 GeV of the true  $W$  mass in the signal sample. (left). Right: Invariant mass spectrum for hadronically decaying  $W$  candidates normalized to unity. The dotted line shows combinations where the jets from the  $W$  are correctly matched.

## 7 Reconstruction of the leptonically decaying $W$ bosons

When reconstructing the leptonically decaying  $W$ , we use the lepton four-momentum as measured in the detector. The neutrino, transverse momentum can be inferred by measuring the imbalance of the transverse energy in the event. This measured quantity is referred to as missing transverse energy.

### 7.1 Neutrino $p_z$ estimation

Once the missing transverse energy is identified with  $p_{TV}$ , the invariant mass of the sum of the lepton and neutrino four-momenta can be constrained to the  $W$  boson mass [21]. Because of the limited measurement resolution on the transverse missing energy, for a significant fraction of events the quadratic constraint equation does not have a real solution. In this case the “ $\Delta = 0$  approximation” can be made by dropping the imaginary part of those solutions with complex roots. Another method (the “collinear approximation”) assumes that the  $W$  boson decay products are produced preferentially in the same direction (due to the large top quark mass boosting the  $W$  boson). For the collinear approximation, one can assume that  $p_{z\ell} = p_{z\nu}$ .

Considering  $t\bar{t}H$  events where one lepton is reconstructed, 72% of the time  $p_{z\nu}$  has real solutions. In this case, both solutions are carried forward into the analyses, and the best performing final state solution is used. For these events the  $p_{z\nu}$  resolution is 19.5 GeV. In the other 28% of cases where there are no real  $p_{z\nu}$  solutions, the  $\Delta = 0$  approximation is used and the  $p_{z\nu}$  resolution is 40 GeV. This performs better than the collinear approximation where the  $p_{z\nu}$  resolution is 54 GeV. The quality of the  $W$ -boson reconstruction can be seen in Fig. 8. For the events where there is no real solution for  $p_{z\nu}$ , the direction and the mass of the  $W$  boson is better represented by the  $\Delta = 0$  approximation.

Since the mass constraint is lost when using the  $\Delta = 0$  approximation (the same would be true for the collinear approximation) there is an actual cut for the reconstructed  $W$  boson mass. The cut-based and pairing likelihood analyses only consider  $W$  candidates having a mass less than 140 GeV, while the constrained fit analysis does not make an explicit requirement on this but the poor  $\chi^2$  will remove extreme cases.

Figure 8: Distributions of  $\Delta R$  between the true and the reconstructed  $W$  boson (left) and of the reconstructed leptonically decaying  $W$  mass (right) for events where a solution for  $p_z$  is found (solid black line) and events where an approximation is used (dotted red for  $\Delta = 0$ , dashed blue for the collinear approximation). All distributions are normalized to unity.

## 8 Cut-based analysis

This section describes the algorithms used to reconstruct the  $t\bar{t}$  system and the Higgs boson. The  $b$ -jets are associated with the leptonically and hadronically decaying  $W$  boson candidates, to build a list of top quark candidates. The combination of  $b$ -jets resulting in the best reconstruction for the top quark candidates is taken as the final choice. It is important to note that the  $b$ -jets themselves satisfy the cut on  $b$ -tag weight  $\geq 5.5$  and that if there are more than four of these jets, then the four with the highest weight are treated as  $b$ -jets. Events where there is no combination giving a satisfactory top quark mass reconstruction are discarded. The two remaining  $b$ -jets are used to form the Higgs boson candidate.

### 8.1 Top-antitop quark system and combinatorial background

In each event, top quarks are reconstructed by pairing two  $b$ -jets with the  $W$  boson candidates in the way which minimizes the  $\chi^2$  expressed as:

$$\chi^2 = \left( \frac{m_{j\bar{j}b} - m_{top}}{\sigma_{m_{j\bar{j}b}}} \right)^2 + \left( \frac{m_{l\nu b} - m_{top}}{\sigma_{m_{l\nu b}}} \right)^2, \quad (1)$$

where  $\sigma_{m_{j\bar{j}b}}$  and  $\sigma_{m_{l\nu b}}$  are the reconstructed mass resolutions estimated in simulated signal events and are 13 and 19 GeV respectively. Only combinations fulfilling  $|m_{j\bar{j}b} - m_{top}| < 25$  GeV and  $|m_{l\nu b} - m_{top}| < 25$  GeV are considered for the  $\chi^2$  calculation. The top quark mass distributions for the chosen combination in the signal sample is shown in Fig. 9. The two remaining  $b$ -tagged jets are used to form the Higgs boson candidates. The mass distribution for all Higgs boson candidates in the signal sample is shown in Fig. 10, and in the same plot the signal and physics background cross-sections are adjacent. Here the difficulty of the analysis is clearly shown, requiring dedicated studies to measure the background normalization and its shape in data.

As a final cut, to discriminate against  $t\bar{t}$  events where no Higgs boson is produced, only events in a mass window of 30 GeV from the nominal Higgs boson mass are used for the final estimation of the cut-based analysis significance.

The effect of the final selection for the cut-based analysis on signal and background samples is shown in Table 4. The selections have reduced the signal by a factor of sixteen from the preselection, but the signal to background has increased from 0.006 to 0.11. The irreducible  $t\bar{t}b\bar{b}$  background is 46% of the total.

Table 4: Accepted cross-section after each successive mass-window selection cut for signal and background in the cut-based analysis. In the last column the contribution of  $t\bar{t}b\bar{b}$  is removed. Errors are statistical only.

cut	$t\bar{t}H(\text{fb})$	$t\bar{t}b\bar{b}(\text{EW})(\text{fb})$	$t\bar{t}b\bar{b}(\text{QCD})(\text{fb})$	$t\bar{t}X(\text{fb})$
$W_{\text{had}} + W_{\text{lep}}$	$2.49 \pm 0.05$	$2.9 \pm 0.2$	$18.2 \pm 0.7$	$22.5 \pm 1.9$
+ $t\bar{t}H$ Higgs	$2.04 \pm 0.05$	$2.2 \pm 0.2$	$14.7 \pm 0.6$	$14.3 \pm 1.5$
+ Higgs boson mass window	$1.00 \pm 0.03$	$0.52 \pm 0.07$	$3.6 \pm 0.3$	$4.9 \pm 0.9$

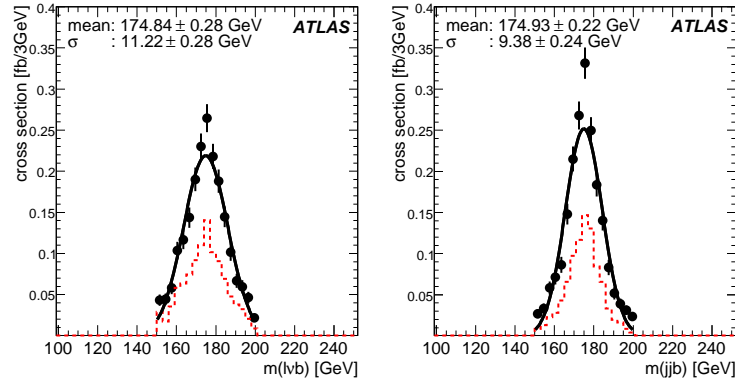

Figure 9: Reconstructed invariant mass spectrum for selected leptonic (left) and hadronic (right) top quark candidates in the signal sample. The dotted red line indicates the candidates formed by assigning the correct  $b$ -jet to the top quark being considered. All distributions are given in cross-section.

Figure 10: Left: Reconstructed invariant mass spectrum for Higgs boson candidates in the signal sample. The dotted red line indicates the candidates formed by assigning the correct  $b$ -jets. Right: Reconstructed invariant mass spectrum for signal and backgrounds after the cut-based selection. All distributions are given in cross-section.

## 9 Pairing likelihood analysis

In the previous Section we used a cut-based approach to identify the top quark decay products. A straightforward improvement to such an approach is to use several discriminating topological distributions combined together in order to build a pairing likelihood. As a first step the analysis considers only top quark properties as likelihood templates. Even though Higgs boson properties could help associating  $b$ -jets, if used, those could lead to bias in the background distributions. A correct combination is obtained when the objects used for the reconstructed variables match the Monte Carlo partons, regardless of whether other objects are correctly associated. On the other hand all the wrongly reconstructed objects are used to form the wrong combination templates. The variables used, shown in Fig. 11, are:

Figure 11: Pairing likelihood templates for top quark topological distributions, derived from the  $t\bar{t}H$  signal sample. Solid lines represent the correct combination while the dotted lines show the combinatorial background in the signal itself. See text for a description of the variables.

- $m_{jj}$ : The invariant mass of the light jets from the hadronic  $W$  decay.
- $m_{jjb}$ : The invariant mass of the hadronic top decay products.
- $m_{lvb}$ : The invariant mass of the leptonic top decay products.
- $\angle(j, j)$ : The angle between the light jets from the hadronic  $W$  decay.
- $\Delta R(jj, b)$ : The distance in  $R$  between the hadronic  $W$  and  $b$  jet from the hadronic top decay.
- $\Delta R(l, b)$ : The distance in  $R$  between the lepton and the  $b$  jet from the leptonic top decay.

The output of the pairing likelihood for the correct and wrong  $b$ -jet combinations is shown in Fig. 12. As shown in this plot, even though the correct distributions are peaked at 1, the wrong combinations still have a large probability of being selected. The only combination used is the one which maximizes the likelihood output. In order to avoid the presence of a large combinatorial contribution a cut on the likelihood output of 0.9 is used to select well-reconstructed events. After this cut,  $b$ -jets are associated to reconstruct the Higgs boson, as shown in Fig. 12, and the two top quarks, shown in Fig. 13. The invariant mass distribution for the selected Higgs boson candidates for signal and backgrounds is shown in Fig. 14.

Figure 12: Left hand side: combinatorial likelihood output for  $t\bar{t}H$  events. Black solid (red dotted) histogram indicates the correct (wrong) combinations. Right hand side: invariant mass for the Higgs boson candidates reconstructed using the maximum likelihood configuration, after applying a cut on the likelihood. Dotted histogram indicates the correct combinations. The differential cross-section is shown in fb.

Figure 13: On the left (right) hand side is shown the leptonic (hadronic) top quark candidates reconstructed invariant mass using the maximum likelihood configuration, after applying a cut on the likelihood output. The dotted histogram indicates the correct  $b$  quark jet for the top quark being considered. The differential cross-section is shown in fb.

A final cut on the reconstructed Higgs boson mass, requiring it to be within 30 GeV of the Higgs boson nominal mass is applied. The event yield for the whole analysis using the pairing likelihood is shown in Table 5. This analysis reduces the signal by a factor thirteen, and produces a sample which has a signal to background ratio of 0.1. The irreducible  $t\bar{t}b\bar{b}$  background increases to 45% of the total.

Table 5: Cross-sections after each selection cut for signal and backgrounds for the pairing likelihood analysis. In the last column the contribution of  $t\bar{t}b\bar{b}$  has been removed. Errors are statistical only.

applied cuts	$t\bar{t}H(\text{fb})$	$t\bar{t}b\bar{b}(\text{EW})(\text{fb})$	$t\bar{t}b\bar{b}(\text{QCD})(\text{fb})$	$t\bar{t}X(\text{fb})$
Leptonic $W$	$3.6 \pm 0.06$	$4.1 \pm 0.2$	$29 \pm 0.8$	$48 \pm 2.7$
+ Best likelihood $> 0.9$	$2.3 \pm 0.05$	$2.5 \pm 0.2$	$16 \pm 0.6$	$19 \pm 1.7$
+ Higgs boson mass window	$1.2 \pm 0.04$	$0.68 \pm 0.08$	$4.6 \pm 0.3$	$6.5 \pm 1.0$

Figure 14: Reconstructed invariant mass spectrum for Higgs boson candidates for signal and backgrounds after pairing likelihood selection. The differential cross-section is shown in fb.

## 10 Constrained fit analysis

An alternative analysis uses a mass-constrained fit to the measured missing energy and jet and lepton four-momenta to help with the jet combinatorics. There are six quarks produced from the top quark and Higgs boson decays, and these are matched to the reconstructed jets. The  $\chi^2$  from this fit is used in a likelihood technique together with kinematic variables,  $b$ -tagging and jet charge. Then, all jet combinations passing loose criteria are tested and the one with the best likelihood is chosen. The analysis starts from the preselection as described in Section 5. The signal events are then separated from background in a second likelihood step.

### 10.1 Mass-Constrained fit technique

The fit varies a scale factor for the four-momenta of the jets and the  $z$  component of the neutrino momentum. Adjustments to the jet momenta and masses through the scale parameters,  $f^i$ , produce accompanying changes in the missing energy and hence in the parameters used in the reconstruction of the leptonically decaying  $W$  as the transverse components of its neutrino are taken to be the missing energy. The longitudinal component of the momentum of decaying  $W$  boson's neutrino  $p_{z\nu}$  is the last fit parameter. The parameters are constrained by the estimated jet errors and by the masses of the top quarks and  $W$  bosons. These later are included as approximate Gaussian  $\chi^2$  contributions calculated using the masses inferred from the current parameters as indicated in the following equation:

$$\chi^2 = \sum_{i=1}^6 \left( \frac{f_{jet}^i - 1}{\sigma_{jet}^i / P_{jet}^{i,initial}} \right)^2 + \frac{(m_W^{lep} - 80.425)^2}{\sigma_W^2} + \frac{(m_t^{lep} - 175)^2}{\sigma_t^2} \quad (2)$$

where the  $W$  and top quark widths  $\sigma_W$  and  $\sigma_t$  are 2.1 and 1.5 GeV respectively.

To simplify the fit, the hadronic top quark and  $W$  are forced to be exactly on mass shell. The scale factor of the higher  $p_T$  jet from the  $W$  is externally varied, while the other two scale factors are calculated to give the correct masses. The momenta of all six jets are varied, but these three are linked. There are therefore five free parameters and not seven. This implies that these two particles are fixed to their nominal masses, while the leptonic top quark and  $W$  are given widths.

The calculation of the momentum of the neutrino from the leptonic  $W$  decay normally has two solutions, as discussed in Section 7. Both of these are used as starting points for the fit, to ensure that it does not find only one local minimum, and the fit with the larger  $\chi^2$  is discarded. If the  $W$  neutrino solutions had complex roots then the real part of these is used as an initial value.

The jet momenta are calibrated as discussed in Section 5.3.4, and the following errors are used in the fit:

$$\sigma_{P_{light}} / P_{light} = 0.988 / \sqrt{p_T} \oplus 0.035 \quad (3)$$

$$\sigma_{P_b} / P_b = 0.888 / \sqrt{p_T} \oplus 0.125 \quad (4)$$

where the momenta are measured in GeV. This form comes from comparing reconstructed jet  $p_T$  with simulated initial quark  $p_T$ ; in other words it includes not only detector effects but also fragmentation. Both light and  $b$ -jet momentum errors are treated as Gaussian distributed; for  $b$  quark jets in particular this is not a good description as the frequent presence of a neutrino gives tails to the measured energy response.

The fit adjusts the momenta of all the jets, including those from the Higgs boson, but the fitted Higgs boson mass is not used in the analysis, as it offers no improvement.

## 10.2 $b$ -tag information

In order to use the  $b$ -tagger output, as described in Section 5.3.2, for a likelihood, the distributions of weights expected for  $b$ -jets and non  $b$ -jets in this environment are required. This is done using jets taken from the signal simulation, where only jets with a parent quark within 0.4 in  $\Delta R$  and no second quark within 0.6 in  $\Delta R$  are used. The ratio of smoothed weight distributions with  $b$ -jet over light flavored jets ( $u, d, s$ ) is shown in Fig. 15.

Figure 15: The  $b$ -tagging likelihood ratio extracted from signal simulation as the ratio of  $b$ -weight distributions for  $b$ -jets and light jets. The degree of smoothing reflects the statistical precision at each point.

In the analysis, four jets are taken to be from  $b$  quarks. For each jet we compute  $\mathcal{L}_b^i$ , the ratio of  $b/light$  for jet  $i$  as shown in Fig. 15. In selecting combinations the sum  $\sum_i \log_{10} \mathcal{L}_b^i$  is taken over the four jets. There is no requirement made on the jets from the  $W$  boson.

## 10.3 Jet charge

The assignment of jets to quarks can benefit from the jet charge measurement as we know the expected charges of the quarks involved. The jet charge is the momentum weighted sum of the charged particle charges within the jet, and it shows some correlation with the initial quark charge. The  $\bar{b}(b)$  quark has only a charge of  $(-)/1/3$ , and furthermore, after hadronisation there are oscillations which reduce the sensitivity, but there is some information.

The analysis requires exactly one high  $p_T$  lepton which has charge  $Q_l$ , and therefore we know the expected charge of both of the  $b$  quarks associated to the top quarks via the relationship  $sign(Q_l) = sign(Q_{t_{lept}}) = -1 \times sign(Q_{t_{had}})$ , and the sum of the charges of the jets from the hadronically decaying  $W$  boson  $Q_{W_{had}} = -1 \times Q_l$ . The measured values of these are then compared with the expectations using a likelihood. The sum of the Higgs boson jet charges is much less sensitive because the expected value is zero, but it is also used.

The jet charge plots in Fig. 16 are calculated using jets from the signal sample. The  $W$  plots are made using only true light jets which were tagged as light jets, and the  $b$  plots only from tagged  $b$ -jets associated with a  $b$  quark. This is to ensure that the jet charge is independent of  $b$ -tag information. The  $W$  wrong combinations distribution has spikes at integral values which generally involve at least one jet outside the tracker acceptance contributing a charge of zero. These are less frequent in the correct combinations which tend to be central. The other distributions reflect  $b$ -tagged jets which must therefore have charged

Figure 16: Left: The jet charge of  $W$  boson candidates, based on the sum of the jet-charges of the two jets signed by the high- $p_T$  lepton. Center: Jet charges of individual  $b$ -jets from top quarks; signed so that those where quark charge agreeing with the lepton charge from  $W$  decay are positive. Right: The magnitude of the sum of the jet charges of the jets assigned to the Higgs boson. Wrong  $b$ -jet combinations have a somewhat flatter distribution. Correct combinations are solid (black) and wrong combinations are dashed (red).

particle tracks. It is assumed that the jet charge information can be calibrated from the plentiful top quark pair events. The normalizations are arbitrary, as they offset every combination equally. The jet-charge is used as  $\mathcal{L}_{\text{jet-charge}} = \mathcal{L}_{q(b)}^{\text{hadronic top}} \times \mathcal{L}_{q(b)}^{\text{leptonic top}} \times \mathcal{L}_{q(W)} \times \mathcal{L}_{q(H)}$ .

#### 10.4 Likelihood analysis for jet assignment

All possible assignments of jets to quarks are evaluated in turn. Those combinations which fail a loose quality requirement are discarded. This quality requirement is that:

- Both of the jets assigned to the Higgs boson must have a  $b$ -likelihood greater than zero. From Fig. 15 that corresponds to a cut of about -2 on the  $b$ -tagging variable.
- Selections on the mass of the  $W$  and top quark which decay to jets. The  $W$  mass calculated from the jets without fitting must lie between 30 and 150 GeV, and the top quark mass between 100 and 250 GeV. Note that the jet energy correction factor applied depends upon whether or not the jet is considered to originate from a  $b$  quark in this hypothesis.
- Total  $b$ -likelihood greater than 8. This is the sum of the log-likelihoods of the four jets which are assigned to  $b$ -jets; this roughly corresponds to the mean  $b$ -weight of the jets being 4 or greater.

In the preselected signal sample there are a mean of 5811 combinations to be tested per event, but the above quality requirement reduces this to 233; a considerable saving in time. 90% of the preselected signal events have at least one combination passing the above requirements.

Events which pass these selections are processed by the  $t\bar{t}H$  fitting code. Correct or wrong combinations are then used to define a likelihood ratio.

The elements of that likelihood ratio are as follows:

- The  $\log_{10}$  of the  $\chi^2$  from the fit.

Figure 17: Left: The  $\chi^2$  of the fit. Center:  $\text{jet} \cdot \text{top}|_{\min}$ . The cosine of the minimum angle between top quarks and their daughter jets. Correct combinations have more collimated tops. Right: The  $t_b^{\text{lept}} \cos \theta^*$ . The decay angle in the rest frame of the leptonically decaying top quark of the  $b$ -jet relative to the top quark direction in the lab frame. Correct combinations are solid (black) and wrong combinations are dashed (red).

- $\text{jet} \cdot \text{top}|_{\min}$ : The minimum cosine of the angle between the top quarks and any of their four jets in the  $t\bar{t}H$  center of mass frame.
- $t_b^{\text{lept}} \cos \theta^*$ : The decay angle in the rest frame of the leptonically decaying top quark of the  $b$ -jet relative to the top quark direction in the lab frame.
- $t_b^{\text{lept}} \Delta R$ : the distance in  $\Delta R$  space between the lepton and the  $b$  quark assigned to the same top quark.
- $|\eta|^{\max}$ : The maximum  $|\eta|$  of the considered jets. Jets from the  $t\bar{t}H$  system tend to be more central than those from the underlying event.
- $\cos \theta_{H\text{-jet}}^*$ : Measured in the Higgs boson rest frame, this is the cosine of the angle between the higher  $p_T$  of the two jets from the Higgs boson and the boost applied to shift from the lab frame to the Higgs boson rest frame.
- $m_t$ : The hadronic top quark mass before the fit is performed.

The variables are displayed in Figs. 17 and 18 for correct and wrong combinations. In this case ‘correct’ implies that all six quarks are correctly assigned. Fig. 19 shows how each variable would perform if used individually to separate correct and incorrect pairings. For each variable combinations are selected by the likelihood ratio found using that variable alone. The Fig. shows the fraction of wrong pairings which would be accepted as a function of the fraction of correct ones. The fit  $\chi^2$  is the most powerful single variable over much of Fig. 19, but the masses of the hadronic top quark and  $W$  work well at high efficiency while  $\text{jet} \cdot \text{top}|_{\min}$  is also rather powerful. Clearly the variables have correlations, and these are taken into account by evaluating the likelihood in a 3D space defined by the three variables under study. This explicitly includes the correlations, but is limited by the simulation statistics required to populate the space. The combination of  $\chi^2$ ,  $\text{jet} \cdot \text{top}|_{\min}$  and  $t_b^{\text{lept}} \cos \theta^*$  was adopted as the most powerful set of three variables found.

Figure 18: Left: The distribution of distances,  $\Delta R$ , between the lepton and the  $b$  quark from the leptonic top quark. Center: The maximum  $|\eta|$  of any jet in the combination being tested. Correct combinations are more central. Right: The reconstructed mass of the hadronically decaying top quark, before any fit is performed. Correct combinations are solid (black) and wrong combinations are dashed (red).

Figure 19: The performance of a range of possible variables if they are used individually to find the correct quark-jet pairing in a  $t\bar{t}H$  event. For a given efficiency for selecting the correct pairing (x axis), what fraction of the incorrect pairings will also be chosen (y axis). The line labelled null shows the effect of selecting combinations at random.

The remaining variables were tested to see whether their addition as uncorrelated likelihood contributions made a significant improvement, and those that did were included. The final likelihood is defined as follows:

$$\begin{aligned} \mathcal{L}_{pairing} = & \log \mathcal{L}_{\log \chi^2, \text{jet} \cdot \text{top}|_{\min}, t_b^{\text{lept}} \cos \theta^*}^{3D} + \log \mathcal{L}_{t_b^{\text{lept}} \Delta R} + \log \mathcal{L}_{|\eta|_{\max}} \\ & + \log \mathcal{L}_{\cos \theta_{H-\text{jet}}^*} + \log \mathcal{L}_{m_t} + \log \mathcal{L}_{b\text{-tag}} + \log \mathcal{L}_{\text{jet-charge}} \end{aligned} \quad (5)$$

The combination which produces the largest likelihood for each event is adopted. The quality of the chosen combination is examined in Section 11.

### 10.5 Signal and background separation

The separation of signal from background is again done using the likelihood technique. There are two rather different backgrounds considered: the  $t\bar{t}j\bar{j}$  component for which  $b$ -tagging is the primary tool and the ‘irreducible’  $t\bar{t}b\bar{b}$  background which differs from the signal only in kinematic ways, which can be exploited to give some separation. The variables used to separate signal and background are:

- $\mathcal{L}_{pairing}$ : From combinatorics.
- $\Sigma_i \log_{10} \mathcal{L}_b^i$ : Sum of the log-likelihoods of the four jets used as  $b$ ’s in the combination chosen.
- $\Sigma_{b\text{-tag}}^H$ : The sum of the  $b$ -tagging weight of the two jets from the Higgs boson.
- $\Delta\eta(H, \text{top})^{\min}$ : The difference in  $\eta$  between the Higgs boson and the closer top quark.
- $\cos(tH)^{\max}$ : The higher of the two angles between top quarks and Higgs boson in the center of mass of the  $t\bar{t}H$  system.
- $H_p$  in C.o.M: The Higgs boson momentum in the center of mass frame of the  $t\bar{t}H$  system.
- $\cos \theta_{H-\text{jet}}^*$ : As defined in Section 10.4.

Figure 20: Left: Distributions for signal and backgrounds of the likelihood used to find the combinatorics solution. Center: The sum of the  $b$ -tag likelihoods of the four jets used as  $b$ ’s in the chosen combination. There was cut at 8 in the combinatorics preselection. Right: The sum of the  $b$ -tags of the jets associated to the Higgs boson. This variable removes  $t\bar{t}j\bar{j}$  more than  $t\bar{t}b\bar{b}$ . Histograms are filled for every event where there is a successful fit. In all histograms, the sum of the individual histograms is shown. They are stacked to indicate relative contributions.

## HIGGS – SEARCH FOR $t\bar{t}H(H \rightarrow b\bar{b})$

Figure 21: Left: The maximum cosine of the angle between either top quark and the Higgs boson when boosted into the  $t\bar{t}H$  center of mass frame. Center: The momentum of the Higgs boson candidate in the center of mass frame. Note that the true Higgs bosons have a lower momentum than the background. Right: The  $\cos\theta^*$  of the higher  $p_T$  of the jets from the Higgs boson. This tends to be more central for signal events. In all histograms, the sum of the individual histograms is shown. They are stacked to indicate relative contributions.

Figures 20 and 21 show the data used to produce the likelihood ratio for most of the variables. The backgrounds fall into two basic classes - the  $t\bar{t}j\bar{j}$  and the  $t\bar{t}b\bar{b}$ , and to deal with these two 3D likelihoods are defined. The first includes the three quantities which contain  $b$ -tagging information:  $\mathcal{L}_{\text{pairing}}, \Sigma_i \log_{10} \mathcal{L}_b^i, \Sigma_{b\text{-tag}}^H$ . These are all powerful but are highly correlated and therefore benefit from a correct treatment of those correlations. The second is  $\cos(\theta_H^{\max}), H_p, \cos\theta_{H\text{-jet}}^*$ , which carries discrimination based on event kinematics. It too has important correlations. These likelihoods are combined as if independent, with one further likelihood, derived from  $\Delta\eta(H, \text{top})^{\min}$ , added as well. All the likelihoods have been smoothed so that the expected fluctuations are below 10%, and there is therefore little over-training, as separate test and training samples are maintained.

The distributions used to define the likelihood are constructed using all events for which a constrained fit was made, and all the components are normalized to the cross-sections at that stage. The signal separation likelihood is:

$$\mathcal{L}_{s/b} = 1/3 \left( \log \mathcal{L}_{\text{pairing}, \Sigma_i \log_{10} \mathcal{L}_b^i, \Sigma_{b\text{-tag}}^H}^{3D} + \log \mathcal{L}_{\Delta\eta(H, \text{top})^{\min}} + \log \mathcal{L}_{\cos(\theta_H^{\max}), H_p, \cos\theta_{H\text{-jet}}^*}^{3D} \right) \quad (6)$$

The factor of 3 makes this an average, rather than a sum, and is there purely for convenience. Note that there is nothing in this definition to prefer correctly paired signal events.

Figure 22 shows the distribution of the final likelihood. It is generally dominated by  $t\bar{t}j\bar{j}$  events, but at the largest likelihood values the  $t\bar{t}b\bar{b}$  and signal events are more prevalent. It can be seen that any  $t\bar{t}H$  analysis will be selecting a tail of the signal, and controlling this will be important. The signal to background ratio, within the mass window, rises to about 25%, and any rise above that is in a region affected by lack of simulation statistics.

The final choice of working point will depend upon the details of the systematic error evaluation. The tighter the selection on the likelihood the higher the signal to background ratio but the smaller the samples in data and simulation; the latter is an important consideration.

The maximum significance which might be expected in a measurement (evaluated as  $s/\sqrt{b}$ ) ignoring all systematic uncertainties, is obtained by cutting at a log likelihood of -4.44. This would yield a significance of  $2.78\sigma$ , but at low purity. Reducing the mass range by requiring that the candidate has a mass within the range 90 to 150 GeV does not appear to improve the results when systematic errors are not considered.

# HIGGS – SEARCH FOR $t\bar{t}H(H \rightarrow b\bar{b})$

Figure 22: Left: The total signal separation likelihood. The top figure shows all events while the bottom shows only those within a Higgs boson candidate mass window of 90 to 150 GeV. Right: The integrated version of the lower left plot, so the total event rates passing any cut can be seen. The bottom half of this plot is the signal to background ratio implied.

If an arbitrary ten per cent error on the background level is assumed then the significance for this cut, evaluated as  $s/\sqrt{b + (\delta b)^2}$ , decreases to below  $0.5\sigma$ , while the highest significance is around  $1.8\sigma$  for a cut at  $-4.05$ . This is shown numerically in Table 6, where the expected event rates are shown for three different cut values. No final choice is really possible without complete evaluation of systematic errors, but  $-4.2$  with the mass window cut applied does seem to be a plausible working point. The statistical significance for this selection is  $2.18\sigma$ . At this point the signal is reduced by a factor of twelve from the preselection, but signal to background ratio has become  $0.125 \pm 0.01$ . The irreducible  $t\bar{t}b\bar{b}$  background has increased to 50% of the total.

Table 6: The accepted cross-sections for signal and the main backgrounds at various stages of the analysis. The  $t\bar{t}j\bar{j}$  cross-section suffers from limited statistics.

Selection	$t\bar{t}H(\text{fb})$	$t\bar{t}b\bar{b}(\text{EW}) (\text{fb})$	$t\bar{t}b\bar{b}(\text{QCD}) (\text{fb})$	$t\bar{t}X (\text{fb})$
Initial Sample	100	255	2371	109487
Pass preselection	16	23	198	2589
Fit quality requirements	14	20	165	1584
$\mathcal{L}_{s/b} > -4.40$	4.9	5.1	35	58
$\mathcal{L}_{s/b} > -4.20$	2.5	2.3	13.9	11.9
$\mathcal{L}_{s/b} > -4.10$	1.4	0.96	7.11	4.5
Mass window 90 to 150 GeV.				
$\mathcal{L}_{s/b} > -4.40$	$2.3 \pm 0.07$	$1.4 \pm 0.17$	$10.8 \pm 0.7$	$22 \pm 3.1$
$\mathcal{L}_{s/b} > -4.20$	$1.3 \pm 0.05$	$0.62 \pm 0.12$	$4.6 \pm 0.5$	$5.3 \pm 1.5$
$\mathcal{L}_{s/b} > -4.10$	$0.71 \pm 0.04$	$0.23 \pm 0.07$	$2.5 \pm 0.35$	$2.2 \pm 1.0$

The distribution of the masses of the candidates can be seen in Fig. 23, at a cut of  $\mathcal{L}_{s/b} > -4.2$ . The right hand side of Fig. 23 shows details of the mass distribution for signal only.

Figure 23: The mass distribution after cutting at  $-4.2$  in  $\mathcal{L}_{s/b}$ . Left: All samples, showing the contributions stacked. The signal distribution is also shown separately at the bottom. Right: Signal only, the dashed (red) line equals events where the correct jets from the Higgs boson are selected.

## 11 Comparison between the three analysis techniques

The performance of the cut-based, pairing likelihood and the constrained fit analyses in terms of purity versus selection efficiency can be seen in Fig. 24. For the likelihood analyses, the different working points are obtained by varying the final cut on the likelihood discriminant. In the case of the cut-based analysis, the same variation is achieved by loosening or tightening the mass-window cuts on the hadronically decaying  $W$  and the reconstructed top quarks. For this section the efficiency is defined as the selection efficiency relative to the total events simulated. The purity is defined in terms of the correctness of the assignment of  $b$ -jets used to reconstruct the final objects. For instance, one has a *pure* hadronic top quark when the  $b$ -jet matches the true  $b$  parton from the top quark decay, regardless of whether the same happens for the hadronic  $W$  boson decay products.

Fig. 24 clearly shows the increase of performance when using more information (likelihood) than just the mass of the reconstructed particles (cut-based).

The chosen working points are indicated with solid markers on Fig. 24. Those points have not been optimized in terms of statistical significance, because of a lack of statistics for the  $t\bar{t}X$  background and because due consideration of the systematic errors should also influence the decision. However, the significance does not change much with the choice of the cut on the pairing likelihood output since this likelihood is not designed to discriminate signal from physics background events.

The ability of the three analyses to correctly identify objects in the event is compared in Table 7. The likelihood-based assignments perform noticeably better than the cut-based analysis. The signal efficiency and statistical significance are also improved.

## 12 Background Shapes

The success of this analysis relies on the accurate knowledge of the background level and shape. Monte Carlo predictions are affected by large systematic uncertainties, as the background rejection depends critically also on the jet flavor composition. For this reason it is mandatory to develop methods to measure background directly from real data.

Figure 24: Comparison of the purity of reconstructed  $b\bar{b}$  invariant mass before the final mass window cut versus selection efficiency for the cut-based, the pairing likelihood and the constrained fit analysis. The solid markers show the selected working points.

Table 7: A comparison of quality criteria for the three analyses at their working points. The mass window of 90 to 150 GeV is only applied for the last two rows.

	Cut Based	Pairing likelihood	Constrained fit
$b$ jet from Hadronic top correct	$44.4 \pm 1.1\%$	$49.2 \pm 1.1\%$	$51.0 \pm 1.5\%$
$b$ jet from Leptonic top correct	$50.5 \pm 1.2\%$	$57.4 \pm 1.1\%$	$56.2 \pm 1.5\%$
Higgs boson jets correctly chosen	$29.4 \pm 1.0\%$	$34.0 \pm 1.0\%$	$32.0 \pm 1.4\%$
Four $b$ quarks correct	$23.3 \pm 1.0\%$	$27.5 \pm 1.0\%$	$27.1 \pm 1.3\%$
Higgs boson mass peak resolution, GeV	$22.8 \pm 1.6$	$20.1 \pm 1.1$	$22.3 \pm 2.1$
Signal Efficiency	$2.04 \pm 0.05\%$	$2.32 \pm 0.05\%$	$2.49 \pm 0.07\%$
Signal to background	$0.110 \pm 0.014$	$0.103 \pm 0.014$	$0.123 \pm 0.019$
$s/\sqrt{b}$ , $30\text{fb}^{-1}$	1.82	1.95	2.18

One important result of the present study is that the Higgs boson candidate mass spectrum depends weakly upon the  $b$ -tagging working point. This is shown in Fig. 25, which reports the difference in  $b\bar{b}$  invariant mass shape for the  $t\bar{t}b\bar{b}$  and  $t\bar{t}$ +jets processes after applying the pairing likelihood analysis with the loose and tight  $b$ -tagging requirement as defined in Section 5.3.2

The complete determination of the background shape from data depends crucially on the relative contributions of the  $t\bar{t}b\bar{b}$  and  $t\bar{t}$ +jets distributions, which in turn depends on the strength of the  $b$ -tagging cut applied. The  $b\bar{b}$  invariant mass can be studied for a  $b$ -tag requirement, the “medium  $b$ -tag”, between the loose and tight, such that the possible presence of signal can be still neglected. We choose a medium working point corresponding to a  $b$ -tagging weight cut of 3, such that the ratio of the contribution of  $t\bar{t}b\bar{b}$  with respect to  $t\bar{t}$ +jets goes from 11% to 30%, with a signal contamination of less than 3%.

One strategy contemplated is to use the  $t\bar{t}b\bar{b}/t\bar{t}$ +jets fraction coming from the Monte Carlo prediction and the total number of events from the data to normalize the Monte Carlo at the loose working point where the signal level is less than 1%. Using the Monte Carlo jet flavor composition and the ratio of the  $b$ -,  $c$ - and light jet efficiencies ( $\epsilon_{b,c,\text{light}}^{\text{medium}}(p_T, \eta)/\epsilon_{b,c,\text{light}}^{\text{loose}}(p_T, \eta)$ ) at the loose and medium working

points, it is then possible to predict the shape and normalization at the medium working point.

The data reduction when moving the  $b$ -tag quality from “loose” to “medium” is explained by the ratio of the  $b$ -tag efficiencies at these two working points applied to the  $t\bar{t}b\bar{b}$  and  $t\bar{t}$ +jets data. With a  $50 \text{ pb}^{-1}$  data sample, the  $b$ -tagging efficiency of  $b$ - and  $c$ -jets will be known with an accuracy of 5% [19], while the rejection of light quark jets will be measured with a 10% uncertainty. We expect a significantly more accurate knowledge of the  $b$ -tagging performance with a data sample of approximately  $30 \text{ fb}^{-1}$ . This will allow the measurement of the background level of  $t\bar{t}b\bar{b}$  and  $t\bar{t}$ +jets as a function of the  $b\bar{b}$  invariant mass for the loose and medium  $b$ -tagging working points. These measurements can be used to verify and tune with data the background prediction given by the Monte Carlo simulation, which will be used to extrapolate the event yield expectation of known processes when the  $b$ -tag quality is moved from “medium” to “tight”. This extrapolation can be monitored, and eventually further corrected, by looking at the comparison with the measured data outside the mass window, where the number of signal events expected is small (about 4%). If necessary, this procedure can be extended by asking for three  $b$ -tagged jets to further constrain the background composition and its shape and absolute normalization, to achieve the 5% systematic uncertainty necessary for the analysis of this processes.

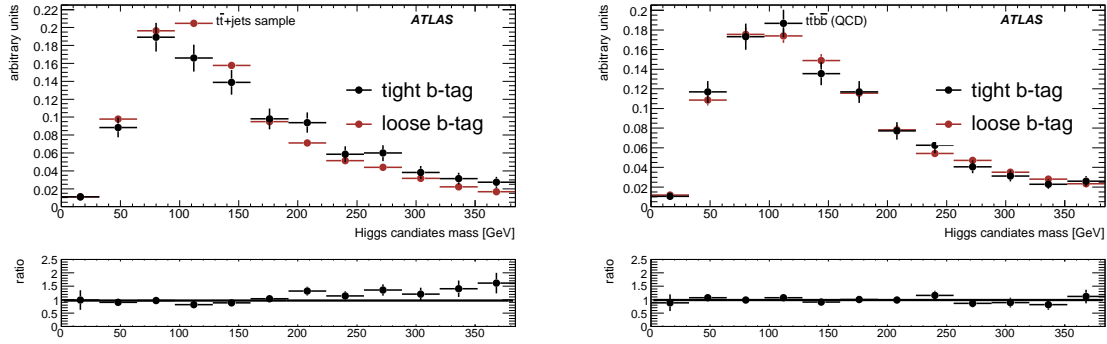

Figure 25: Ratio of the invariant mass spectrum for Higgs boson candidates after combinatorial likelihood analysis and using a loose and tight cut on the  $b$ -tag weight. Left hand side:  $t\bar{t}$ +jets, right hand side:  $t\bar{t}b\bar{b}$ . The signal region shows very consistent behaviour.

### 13 Systematic uncertainties

The evaluation of systematic uncertainties, especially in the background level, is of vital importance in this analysis. Unfortunately it has not yet been brought to a satisfactory level and a robust method to infer background shapes and normalization from data, vital for this channel, still needs to be developed. Following the estimation of systematic uncertainties due to the standard detector effects, Table 8 shows the various contributions for all three analyses. It is noticeable how important the jet uncertainties are for both signal and background. Indeed the knowledge of the jet energy and of the  $b$ -tagging performance have a crucial impact on the kinematic quantities used for the reconstruction of the  $t\bar{t}$  system and for the correct identification of the  $b$ -jets used for the analysis. Large fluctuations on the background estimations arise due to the lack of statistics for the  $t\bar{t}X$  sample, giving rise to a relative statistical error up to 20%.

While the theoretical uncertainties for the signal and background normalization are quite large, their impact can be reduced by making direct measurements. This is certainly the case for the  $t\bar{t}$  cross-section, where the theoretical uncertainties associated with the NLO+NLL calculation are around 12% [14] while with only  $100 \text{ pb}^{-1}$  of data, a direct measurement of the cross-section for the semileptonic final state using  $b$ -tagging could be performed with a much smaller error [22]. The  $t\bar{t}b\bar{b}$  background is only calculated at LO, the cross-section calculation has a strong scale dependence, a factor 4 when changing

from  $Q_{QCD}^2 = \hat{s}$  to  $Q_{QCD}^2 = \langle p_T^2 \rangle$  [9]. Even though the signal cross-sections used for this work are LO, NLO calculations are already available with a theoretical uncertainty including errors coming from parton distribution functions of the order of 15-20% [23] (compared to the 100-200% uncertainty of the LO cross-section).

Table 8: Effect of the various systematic uncertainties on the signal and background efficiencies.

Source		Cut-based		Likelihood		Constrained fit	
		signal	background	signal	background	signal	background

### 13.1 Effect of pile-up on signal

The portion of the semi-leptonic  $t\bar{t}H$  signal sample used here is simulated a second time, but with the anticipated effects of pile-up and cavern background included. It is important to stress that the same generated events are used as input for both pile-up and non pile-up samples. The pile-up actually applied to the events is that expected for running at instantaneous luminosity  $\mathcal{L}$  of  $10^{33} \text{ cm}^{-2} \text{ s}^{-1}$ .

The effect of pile-up on the preselection of events (applicable to all three analyses) is shown in Table 9, and as can be seen, the effect of the trigger requirement is the most significant.

Table 9: The effect of pile-up on the samples at successive stages of preselection with relative efficiencies.

Quantity \ Sample	$t\bar{t}H$ $\sigma$ (fb)	
	No pile-up	pile-up
Starting Sample Generated	100	100
Pass Trigger (e22i, e55, mu20)	65 (65%)	62 (62%)
One high- $p_T$ Lepton	56 (87%)	53 (86%)
$\geq 6$ jets ( $p_T > 20$ GeV, $ \eta  < 5$ )	36 (64%)	34 (64%)
$\geq 4$ central $b$ -jet candidates, ( $ \eta  < 2.5$ & $b$ -jet weight $> 0$ )	16 (45%)	15 (44%)
<b>Preselected</b>	<b>16 (45%)</b>	<b>15 (44%)</b>

The distribution of the number of high  $p_T$  leptons in the events before preselection is shown in Fig. 26 for the pile-up and non pile-up samples. They are very similar, suggesting that the electron and muon reconstruction are not significantly affected by pile-up; however the trigger requirement reduces the number of events with pile-up available to the rest of the preselection.

Figure 26: High  $p_T$  lepton multiplicity ( $e^\pm, \mu^\pm$ ) for pile-up and non pile-up samples (before preselection).

Figure 27: Jet multiplicity (before preselection) for pile-up and non pile-up samples. The cuts  $p_T < 20$  GeV and  $|\eta| < 5$  are applied to the individual jets.

Figure 28:  $b$  jet multiplicity (after preselection) for pile-up and non pile-up samples. The cuts  $p_T < 20$  GeV,  $|\eta| < 2.5$  and  $b$ -jet weight  $> 5.5$  are applied to the individual jets.

Figure 29: Reconstructed Higgs boson mass peak ( $m_{bb}$ ) for pile-up and non pile-up samples.

Figure 27 shows the jet multiplicity before preselection. It can be seen that the number of events having exactly 6 jets is reduced by approximately 10%, and the number of events having more than 7 jets is increased. The net effect will be an increase in the combinatorial background, though the extra jets will typically have a low  $p_T$ .

For the cut-based and pairing likelihood analyses, candidate  $b$ -jets are designated as those jets lying in the central region of the detector ( $|\eta| < 2.5$ ), with  $p_T > 20$  GeV and  $b$ -jet weight  $> 5.5$ , however, if there are more than four of these then the jets with the highest  $b$ -jet weights are used.

The number of  $b$ -jets in the events both with and without pile-up after the other preselection cuts are applied can be seen in Fig. 28, where there is a reduction in the number of events having the requisite four  $b$ -jets.

The extent of the reduction in events at the various stages of the cut-based analysis is shown in Table 10. The most pronounced difference comes from the reduction in the number of  $b$ -jets, and the net

effect of pile-up is a  $\sim 12\%$  reduction in the number of events where it is possible to reconstruct a Higgs particle, as shown in Fig. 29. This effect will also manifest itself in the backgrounds, since they all have either two or four  $b$ -quarks. The most interesting background pile-up study would now be with the  $t\bar{t}j\bar{j}$  sample, since this relies on mis-tagging of light jets to create a physics background, however this is beyond the scope of this study which only examines the signal.

It should be noted that in the course of this study, the  $b$ -jet efficiency and light-jet rejections were studied, however no visible differences were observed. This can be explained by the fact that even a 1% drop in efficiency from 50% to 49% causes almost an 8% drop in events having four  $b$ -jets.

Table 10: The extent of the reduction in events for pile-up and non pile-up samples for the cut-based analysis with relative efficiencies in parentheses. The harshest reduction comes from the four  $b$ -jet requirement.

Quantity \ Sample	$t\bar{t}H$ $\sigma$ (fb)	
	No pile-up	pile-up
Preselected events	16.0	14.8
$\geq 4$ $b$ -jets ( $b$ -jet weight $> 5.5$ )	3.7 (23.1%)	3.2 (21.5%)
Had & Lep $W$ inside mass-window	2.5 (66.4%)	2.1 (66.8%)
$t, \bar{t}$ -quarks rec. in mass-window	2.0 (81.6%)	1.8 (83.1%)

## 14 Significance estimates

The number of remaining events in the Higgs boson mass window (30 GeV around the nominal Higgs boson mass) have been used to compute a crude estimate of the statistical significance for this channel with  $30 \text{ fb}^{-1}$ . For such a channel in which the signal and backgrounds are very alike, this naive estimate is not the most relevant figure of merit, but it is still useful to compare analyses. For the cut-based analysis, a significance of 1.8 is achieved with signal to background ratio of approximately 0.11. It is worth noting that the addition of the low  $p_T$  muons to jets and the residual jet calibrations performed in Sections 5.3.3 and 5.3.4 improved the cut-based analysis significance by 0.3. With the pairing likelihood approach the significance is 1.95 for a signal to background ratio of 0.1. Finally the constrained fit likelihood gives 2.2 (1.7) for a signal over background value of 0.12 (0.14), obtained with a cut on  $\mathcal{L}_{s/b}$  of -4.2 (-4.1). Figure 30 shows the total significance  $S/\sqrt{B + (\Delta B)^2}$  as a function of the systematic error on the background ( $\Delta B$ ) for the different analyses. As is shown in the Fig., only a background uncertainty level below 10% allows exploitation of the statistical power of the mass constrained fit analysis with respect to the cut-based analysis, and even less for the case the pairing likelihood. Even for a robust analysis such as the cut-based approach, the large systematic uncertainties estimated in Table 8 provide a clear indication that a data driven background estimation is necessary.

## 15 Conclusion

We performed a baseline sensitivity study for the detection of a Standard Model Higgs boson decaying to  $b\bar{b}$  when produced together with a  $t\bar{t}$  pair. After the definition of a common preselection, three different techniques are used, all aimed at the reconstruction of the  $t\bar{t}$  system. The first one is based on the reconstruction of the top quark and  $W$  candidate masses (cut-based analysis). The second one (pairing likelihood analysis) uses a more complete description of the kinematic properties of the  $t\bar{t}$  system to build

Figure 30: Comparison of the total significance as function of systematic uncertainties ( $\Delta B$ ), for the cut-based, the pairing likelihood and the constrained fit analysis. Markers indicate the significance corresponding to the background uncertainty estimated in Table 8.

a likelihood discriminant and isolate the jets coming from the Higgs boson decay. The third approach (constrained fit) uses the known masses and jet errors as constraints to produce a combinatoric likelihood, and a second likelihood to separate signal from background. While the cut-based analysis is certainly the most stable one, relying only on the reconstructed invariant masses of the top quark candidates, it also performs worse with respect to the other two likelihood based analyses. On the other hand, these likelihood based analyses can be used successfully only after all kinematical variables are well understood together with their correlations. Although beyond the scope of this work, the use of more advanced multivariate techniques is foreseen to reduce both the combinatorial and physics background.

The statistical significance obtained for the three approaches was 1.82 for the cut-based, 1.95 for the pairing likelihood and 2.18 for the constrained mass fit at signal-to-background ratios of 0.11, 0.10 and 0.12 respectively. All the analyses suffer drastic reduction in significance as the overall systematic uncertainty increases. The most important individual uncertainties are those for the jet energy scale and  $b$ -tagging efficiency.

From this study emerges the necessity of a strong  $b$ -tagging algorithm which is important not only to suppress the  $t\bar{t}$ +jets physics background but also to help reduce the combinatorial background by improving the hadronically decaying  $W$  reconstruction. It is also clear that the combinatorial background, responsible for the dilution of the Higgs boson mass peak, needs to be further reduced, possibly using multivariate techniques, in order to improve the statistical significance of the channel. Improvements in the mass peak resolution would also enhance the ability of a shape analysis from two perspectives; firstly it would be easier to select a signal-depleted region for any shape fits, and secondly the mass peak itself would become more pronounced.

The results presented in this work can be compared with a previous ATLAS study [3] performed using fast simulation with a parametrized  $b$ -tagging efficiency which had a higher performance than the one used here and also used PYTHIA in order to simulate the  $t\bar{t}$ +X background. It resulted in a significance of 1.9 and 2.6 respectively for the cut-based and likelihood analyses. The results presented in this note can also be compared with a recent CMS study [24] reporting a significance of 1.8 for the electron channel and 1.6 for the muon channel, in both cases for an integrated luminosity of  $60 \text{ fb}^{-1}$ . While a detailed comparison between the two experiments is not attempted in this work, it is noteworthy that the jet energy resolution quoted the CMS paper could be a key factor in explaining the improved

sensitivity seen by ATLAS for this channel.

The measurement of the background normalization from data is vital for this channel. Subsequent studies must be performed in this regard. Further methods of extracting shape information from data must also be developed, in particular, the extraction of the signal in the presence of a *quasi-signal-like* background as is exhibited in the invariant mass plots at the ends of the analyses. The shape information and any estimate of the significance obtained from it could be used in conjunction with the counting experiment information to improve the overall significance.

# Study of Signal and Background Conditions in

$t\bar{t}H, H \rightarrow WW^{(*)}$  and  $WH, H \rightarrow WW^{(*)}$

## Abstract

In this note we present Monte Carlo studies of the associated Standard Model Higgs boson production in the  $t\bar{t}H$  and  $WH$  channels with the decay  $H \rightarrow WW^{(*)}$ . These channels are intended to provide information on the Higgs boson's couplings. We study the two- and three lepton final states in  $t\bar{t}H$  and three lepton final states in  $WH$ , based on the full ATLAS detector simulation.

## 1 Introduction

The discovery and subsequent study of the Higgs boson is one of the main aims of the Large Hadron Collider (LHC) at CERN. The possible mass range of the Standard Model Higgs boson is bounded by the lower limit set at LEP of 114 GeV and reaches to about 1000 GeV [1]. The ATLAS experiment will use all possible channels to extract information on it, because comparing the rates in the different channels will allow information on the couplings to be extracted.

The sensitivity of ATLAS to a Higgs boson produced in gluon fusion or via vector boson fusion and decaying to  $W$  quark pairs has been discussed elsewhere in this volume [2]. This note contains the results of studies of the Higgs boson in the same decay mode but produced in association with either top quarks, ( $t\bar{t}H, H \rightarrow WW^{(*)}$ ), or a  $W$  boson ( $WH, H \rightarrow WW^{(*)}$ ). The cross-sections for these processes are significantly lower than for inclusive Higgs production, and the additional activity makes them more complex to reconstruct, but the presence of extra signatures gives more possibilities for the reduction of the background.

This note explores techniques to exploit these signatures, and the signal and background conditions are studied in both channels. A full simulation of the ATLAS experiment is employed to estimate these, which represents an improvement over the fast simulation used in previous studies of  $t\bar{t}H$  [3] and  $WH$  [4, 5]. The marginal production rates and numerous background sources, many with large cross-sections, make this analysis difficult, and both the background and signal need to be established in some detail. Nevertheless, if the background can be well estimated, then for integrated luminosities of several tens of  $\text{fb}^{-1}$  measurements should be possible.

The backgrounds considered in detail here arise from the inclusive  $t\bar{t}$  process, from  $t\bar{t}$  produced in association with gauge bosons, and from gauge bosons produced inclusively or in pairs. Unfortunately, it has not been possible to model all the relevant backgrounds with a complete simulation at the statistical level required; this is true for example of inclusive QCD multijet events. Section 2 describes the considered signal and background processes. Sections 3 and 4 give the details of  $t\bar{t}H$  and  $WH$  analysis accordingly. Section 5 discusses the results, including the signal-to-background ratio that can be achieved in these two channels.

## 2 Signal and background Monte Carlo samples

Signal and background were produced with various generators, through a realistic ATLAS detector simulation based on the GEANT 4 package [6].

## 2.1 Signal generation

Events with a Higgs boson decaying to a  $W$  pair produced in association with a  $t\bar{t}$  pair or with a  $W$  boson can be searched for at hadron colliders by requiring the presence of lepton pairs ( $\ell = e, \mu$ ).

In particular, for the two-lepton final states, like-sign leptons are selected; this allows a strong reduction of the large background produced by the  $Z$  or  $t\bar{t}$  leptonic decays. In order to improve the efficiency of the Monte Carlo data sample production, generated events were filtered before their processing through the ATLAS detector simulation.

For the  $WH$  channel, only events with three leptons in the final state were selected. These leptons had to pass loose  $\eta$  and  $p_T$  cuts.

Samples of  $t\bar{t}H$  with at least two leptons were generated and filtered for different Higgs boson masses between 120 and 200 GeV using the PYTHIA 6.4 generator [7]. Results obtained with these samples were normalized to the Next-to-Leading Order (NLO) cross-sections and branching ratios reported in Ref. [1]. Only the  $m_H = 170$  GeV mass point was studied for the  $WH$  channel, where signal events were generated with the MC@NLO program [8].

Table 1 summarizes the most important characteristics of the signal samples used for this note.

Table 1: Signal samples generated for the  $t\bar{t}H$  and  $WH, H \rightarrow WW^{(*)}$  analyses.

Process	$m_H$ [GeV]	$\sigma_{tot}$ (NLO) [fb]	Final states	Generator	$\sigma \times BR \times \epsilon_{filter}$ [fb]	$N(\text{events})$
$t\bar{t}H$	120, 130, 140	669, 534, 431	$t\bar{t}H \rightarrow 4W$ (2L)	PYTHIA 6.4	3.60, 6.25, 8.51	$\sim 40k$ per $m_H$

$WH$	170	511	$WH \rightarrow WWW$ (3L)	MC@NLO	3.42	80k

## 2.2 Background samples for $t\bar{t}H, H \rightarrow WW^{(*)}$

The main backgrounds for the  $t\bar{t}H, H \rightarrow WW^{(*)}$  final states are  $t\bar{t}$ ,  $t\bar{t}W$ ,  $t\bar{t}Z$ ,  $t\bar{t}t\bar{t}$  and  $t\bar{t}b\bar{b}$ . Single top events have been neglected. Jets from QCD production and  $WZ$  production processes are also sources of background. However, lepton identification with isolation and a jet multiplicity requirement are expected to reject a large fraction of these. The background from QCD multijet production has not been properly estimated so far and it is hoped that the selection requirements reduce it to an acceptable level.

A special MC@NLO sample is filtered for a pair of like-sign or more than two leptons with a  $p_T > 13$  GeV and  $|\eta| < 2.6$  at the generator level. It results in a filter acceptance of 0.0384. In addition, when there are three or more generated leptons, events with oppositely charged leptons from  $W$  bosons falling into a special domain ( $p_T \geq 30$  GeV and  $||\eta| - 1.5| \leq 0.2$  for electron,  $p_T \geq 15$  GeV and  $||\eta| - 1.25| \leq 0.2$  for muon) were rejected. This results in a small bias, analysis dependent.

The  $Wb\bar{b}$  sample was produced by the ALPGEN generator with only leptonic  $W$  boson, a generator level filter led to an additional 0.02 acceptance, and a 2.57 K-factor [6] was also included. Leading order  $t\bar{t}W + jets$  samples were produced with ALPGEN [9]. The minimum  $p_T$  for the additional jets was 15 GeV, while the maximum  $|\eta|$  was 6.0. The generated jets were also required to be separated by a distance  $\Delta R = \sqrt{\Delta\eta^2 + \Delta\phi^2}$  larger than 0.4. MLM matching [9] was performed to avoid double counting of additional jets.

Samples of  $t\bar{t}Z$ ,  $t\bar{t}t\bar{t}$ ,  $t\bar{t}b\bar{b}$  and  $t\bar{t}b\bar{b}$ (EW) were produced with the leading order generator ACERMC [10]. The  $t\bar{t}Z$  events are normalized to the total cross-section recently calculated at NLO [11], while other ACERMC samples are normalized to LO. In the  $t\bar{t}Z$  sample, the decay  $Z \rightarrow \ell\ell$  was forced. The  $t\bar{t}b\bar{b}$ (EW) sample contains the electroweak contribution to the production of  $t\bar{t}b\bar{b}$ . For both  $t\bar{t}b\bar{b}$  samples, the final

states containing four  $b$ -jets, two light jets and a lepton (muon or electron) were generated. Table 2 summarizes the characteristics of all background samples relevant for the  $t\bar{t}H$  analysis.

Table 2: The samples used to estimate the background contribution in the  $t\bar{t}H, H \rightarrow WW^{(*)}$  analysis.  $\mathcal{L}$  denotes the effective integrated luminosity available from Monte Carlo statistics.

### 2.3 Background samples for $WH, H \rightarrow WW^{(*)}$

The  $t\bar{t}$  and  $Wb\bar{b}$  samples as given in Table 2 are used also in this analysis. For the irreducible diboson  $WZ/ZZ$  backgrounds only the fully leptonic decays were considered; this was done with the MC@NLO generator. The ALPGEN  $t\bar{t}W+0$  jet sample described in Section 2.2 was analyzed to account for the  $t\bar{t}W$  background and as it gives a negligible accepted cross-section the samples with additional jets were not considered. The huge  $W$ +jet background was generated with HERWIG [12] and was normalized to the NLO production cross-section [6] with a filter applied, requiring at least one electron (muon) with  $p_T \geq 10$  GeV and  $|\eta| \leq 2.7$  ( $p_T \geq 5$  GeV and  $|\eta| \leq 2.8$ ).

An overview of all background samples used for the  $WH$  analysis is given in Table 3.

Table 3: List of background samples for the  $WH$  analysis.  $\mathcal{L}$  denotes the effective integrated luminosity available from Monte Carlo statistics.

Process	Generator	$\sigma_{tot}$ [fb]	$\sigma \times BR \times \varepsilon_{filter}$ [fb]	$N(\text{events})$	$\mathcal{L}$ [ $\text{fb}^{-1}$ ]
$t\bar{t}$ no all-hadronic	MC@NLO	833000	450000	440k	0.98
$t\bar{t}$ pre-filtered	MC@NLO	833000	32000	350k	10.9
$WZ$	MC@NLO 3.10	47760	750	36k	48

## 3 Selection of the $t\bar{t}H, H \rightarrow WW^{(*)}$ two and three-lepton final states

In this study, the high  $p_T$  single lepton trigger is used for the  $t\bar{t}H$  two-lepton (2L) events and three-lepton (3L) analyses, with a trigger efficiency larger than 96% for both channels at offline selection level. Cut-based analyses were performed, based on the standard ATLAS reconstruction of a medium quality electron [13], combined muons [14], and cone size of  $\Delta R = \sqrt{\Delta\eta^2 + \Delta\phi^2} = 0.4$  (cone-0.4) tower jets [15].

Signal data sets for nine Higgs boson masses in the range between 120 and 200 GeV were analysed. In the following, numbers will be given mainly for the most promising Higgs boson mass of 160 GeV including cut flow information for the 120 and 200 GeV mass points.

### 3.1 Event selection in $t\bar{t}H, H \rightarrow WW^{(*)}$

The event selection is based on the analysis of final states with at least two reconstructed leptons and jets; from now on we refer to this analysis as “basic selection”. Each lepton or jet is required to have transverse momentum  $p_T > 15$  GeV and to lie in the pseudorapidity region  $|\eta| < 2.5$ . Finally, two-lepton (2L) events are required to have at least six reconstructed jets, while events with three leptons (3L) must have at least four jets.

The 2L(3L) selection retains 36.1% (35%) of the Higgs boson events with  $m_H = 160$  GeV, while reducing the various backgrounds (see Tables 4 and 5).

For both selections, further suppression of the main background sources can be done by isolation. The isolation criteria require that the transverse energy deposited in the calorimeter around the lepton in a cone size  $\Delta R = 0.2$  be below 10 GeV (calorimeter isolation), the maximum  $p_T$  of extra tracks reconstructed in the Inner Detector around the lepton track in a cone size  $\Delta R = 0.2$  be below 2 GeV (tracker isolation) and the angular separation  $\Delta R_{lep-clj}$  between the lepton and the closest jet be greater than 0.2 for an electron or 0.25 for a muon (cone isolation). This is referred to as “standard isolation” and it allows the reduction of the  $t\bar{t}$  background by more than a factor of 10 (170) in the 2L (3L) analysis. The  $t\bar{t}Z/t\bar{t}W$  backgrounds are suppressed by a factor 2 ( $t\bar{t}Z$ , 2L) to 5 ( $t\bar{t}W + 2\text{jets}$ , 3L).

Further reduction of the  $t\bar{t}$  background in the dilepton final state can be achieved by requiring exactly two like-sign isolated leptons. This requirement suppresses the large  $t\bar{t}$  processes with two leptonic  $W$ -decays, as well as the contribution from the  $t\bar{t}Z$  process.

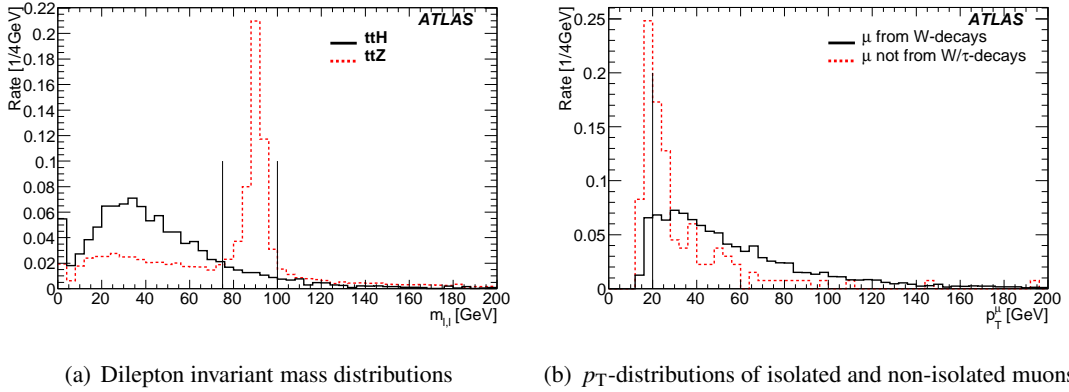

Figure 1: (a) Dilepton invariant mass distributions in  $t\bar{t}H$  (2L) and  $t\bar{t}Z$  and (b)  $p_T$ -distributions of muons passing the loose isolation criteria. The solid distribution shows electrons from  $W$  decays in the 160 GeV signal sample, the dotted distribution shows muons in  $t\bar{t}$ , which could not be matched to a generator-level muon from a  $W$ - or  $\tau$ -decay. All distributions are normalized to unity.

In both final states,  $t\bar{t}Z$  can be suppressed further by an explicit  $Z$ -veto: events that contain a lepton pair of opposite charge and same flavour with an invariant mass between  $75 \text{ GeV} < m_{\ell\ell} < 100 \text{ GeV}$  are rejected. This veto includes all leptons passing the selection criteria and loose  $p_T$ -cut, here set to 6 GeV. The dilepton invariant mass distributions in  $t\bar{t}H$  and  $t\bar{t}Z$  are shown in Figure 1(a). The  $Z$ -veto decreases the  $t\bar{t}Z$ -contribution roughly by 75%, while 98% of the signal survive in the 2L analysis. In the 3L case, 83% of the signal events pass the  $Z$ -veto, while 80% of the  $t\bar{t}Z$  contribution is suppressed.

At this stage of the 2L selection, 73% of the remaining  $t\bar{t}$  events have at least one muon from a semi-leptonic heavy quark decay, while the fraction of events with electrons of this origin is only 20% (identification of electrons embedded in jets is more difficult than that of muons).

Further rejection of these muons from  $t\bar{t}$  events is achieved by requiring the reconstructed muon  $p_T$

to be larger than 20 GeV, as leptons from heavy quark decays tend to be softer than leptons from  $W$  decays (see Figure 1(b)). After this cut, the fraction of events with at least one muon from semileptonic decay versus the one with at least one electron from semileptonic decay is respectively 46% and 41% .

The detailed cut flows, with the corresponding accepted cross-sections, are listed in Tables 4 and 5. From now on the “basic selection” is quoted with the filter efficiency allowed for. In the  $2L$  analysis we have used the special MC@NLO $t\bar{t}$  sample described in Section 2.2 and a small bias has been computed at various stages of the cut flow. The different values have been found to be compatible and a correction of  $1.15 \pm 0.10$  has been applied in the  $t\bar{t}$  line in Table 4. In the  $3L$  analysis the standard MC@NLO $t\bar{t}$  sample has been used, and therefore no correction has been applied.

In both cases, the largest background contribution is expected from  $t\bar{t}$  events. The accuracy of the MC prediction of the total background expectation is limited by the available statistics and by the intrinsic accuracy of the simulation tools. In the case of  $t\bar{t}$  the basic cross-section error is large, but the ALPGEN predictions for higher additional jet multiplicities suffer from even larger uncertainties. There may also be background contributions from  $W$  bosons with multijets which have not been reliably estimated or QCD multijet production or other sources which it has not been possible to simulate.

Table 4: Cut flow and expected cross-sections [fb] for the  $t\bar{t}H$  ( $2L$ ) analysis. The errors presented are statistical only. Some backgrounds, such as  $W$ +jets,  $b\bar{b}$  and  $t\bar{t}jj$  have not been included.

### 3.2 Projective likelihood estimator for electron isolation

A projective likelihood estimator, called IsolationLikelihood [13], was developed in the course of the  $t\bar{t}H, H \rightarrow WW^{(*)}$  ( $2L$ ) analysis. Alternative to the standard isolation, this tool is meant to combine the separation power of several isolation variables into a single, more powerful one. It uses the likelihood

ratio method to reject electrons from semi-leptonic heavy quark decays using a different set of isolation variables than those described in Ref. [13]:

- The additional transverse energy deposited in a cone of size  $\Delta R = 0.2$  around the electron cluster.
- The sum of the  $p_T^2$  of all additional tracks measured in a  $\Delta R = 0.2$  cone around the electron cluster.
- The transverse impact parameter significance  $|Ip|/\delta(Ip)$  of the electron.

In addition, the “cone isolation” cut is also used as in the standard isolation analysis.

When tuned to give the same electron isolation efficiency obtained with standard isolation in the  $t\bar{t}H$  analysis, the IsolationLikelihood allows a higher rejection of non isolated electron background by a factor 1.5 to 4, as shown in Figure 2. Using this projective likelihood estimator could suppress the  $t\bar{t}$  background from  $7.4 \pm 1.1$  pb to  $5.7 \pm 1.0$  pb, while keep the same signal and other backgrounds selection efficiencies. It shows a potential improvement of this analysis which could be adopted at a small increase in complexity, but it has not been used in this document.

Figure 2: Non-isolated electron rejections vs. signal efficiencies obtained by the IsolationLikelihood estimator for four different  $p_T$  and  $\eta$  intervals. The large points mark the working point of the standard isolation cuts for comparison and indicate the size of the error bars, which are not shown for the curves.

## 4 WH analysis

Only the three lepton final state,  $W(H \rightarrow WW^{(*)}) \rightarrow 3(l\nu)$  is described below. The analysis of the larger cross-section dilepton final state, which has an important  $W + jet$  background is currently ongoing.

The basic selection requires three leptons that satisfy the lepton identification criteria, i.e. medium electron [13] and standard muon [14]. The lepton  $p_T$ -thresholds were set to 35 GeV for the leading and 15 GeV for the other lepton. As seen from Fig. 3(a) the cut on the leading lepton reduces the backgrounds much more than the signal. The presence of these leptons also ensures that any signal is efficiently recorded by the ATLAS trigger system

In addition to a 6 GeV calorimeter isolation and a 0.25 cone isolation as described in Section 3.1,  $p_T^{track}/p_T^{lepton} \leq 0.05$  were forced, where  $p_T^{track}$  is of the track with maximal  $p_T$  in a cone of  $\Delta R=0.2$  (0.3) around the muon (electron). Furthermore, a cut on the lepton three-dimensional impact parameter  $I_{3D}/\sigma_I \leq 2.5$  was employed to reject leptons from bottom quarks.

In order to reduce the  $WZ$  background, a  $Z$  veto is applied by requiring that no opposite sign and same flavor lepton pair has an invariant mass between mass 65 and 105 GeV (Fig. 3(b)). In addition only events with  $E_T^{\text{miss}} \geq 30$  GeV were kept. To further reduce the backgrounds, we ask the sum of the  $p_T$  of all the jets (which were preselected above 20 GeV from cone-0.7 tower jets [15]) to be smaller than 120 GeV, as seen in Figure 3(c).

For additional rejection of  $t\bar{t}$  and  $t\bar{t}W$ , events having at least one jet fulfilling a loose  $b$ -tag [16] are removed. In order to exploit the spin correlations in the  $H \rightarrow WW^{(*)}$  signal, the minimum angular separation ( $\Delta R$ ) between lepton pairs is required to be in the range of  $[0.1 \sim 1.5]$  (so called “H-S cut”).

(a) Lepton  $p_T$

(b) lepton-lepton invariant mass

(c) Jet  $p_T$ -sum

Figure 3:  $p_T$ -distribution for the leading leptons in the  $WH(3L)$  signal,  $t\bar{t}$ ,  $WZ$ ,  $t\bar{t}W$  and  $W$ +jet-production(a), invariant mass of all the lepton pairs (b) and sum of the  $p_T$  of all jets (c) for the  $WH(3L)$  signal and the relevant backgrounds. All these plots are done after loose cut.

Table 6 summarises the cross-sections after the cut flow described above. The filtered MC@NLO  $t\bar{t}$  sample described in Section. 2.2 has been used here. In order to take into account the bias introduced by this sample, a correction of  $2.36 \pm 0.6$  has been applied. The background rate from  $W$  bosons with multijets, QCD multijet production or other sources, which have not yet been possible to simulate, have their contribution still under study. The errors on the background are, at this stage, much larger than the size of the expected signal.

## 5 Discussion

### 5.1 Uncertainties in the analyses

Several systematic uncertainties affect the results presented in this paper. There are theory uncertainties associated to the the choice of the Parton Distribution Functions (PDFs), to the choice of the renormal-

Table 6:  $WH$  (3L) cut flow and corresponding cross-sections. The errors presented are statistical only; systematic uncertainties are also important. Some backgrounds, such as  $WWW$ , single top and  $t\bar{t}Z$  have not been included.

	Input [fb]	Basic sel.	Isolation	Z-veto	$E_T^{\text{miss}}$	H-S	( $b$ -) jet veto
$WH$ (3L)	5.04	1.18	0.62	0.53	0.47	0.36	$0.31 \pm 0.02$
$WZ$	750.	165.5	1.41	0.74	0.63	0.21	$0.10^{+0.08}_{-0.06}$
$t\bar{t}$	833000.	3564.3	6.45	6.11	5.10	1.02	$0.34^{+0.70}_{-0.3}$
$ZZ$	72.5	34.5	0.13	0.06	0.013	0.008	$0.005 \pm 0.001$
$t\bar{t}W$	61.1	1.35	0.22	0.21	0.19	0.07	$0.003^{+0.005}_{-0.003}$
$Wb\bar{b}$	66721.	3.1	-	-	-	-	-
$W \rightarrow e\nu + \text{jets}$	$2.05 \cdot 10^7$	17.6	-	-	-	-	-
$W \rightarrow \mu\nu + \text{jets}$	$2.05 \cdot 10^7$	27.6	-	-	-	-	-
<b>Total background</b>							$0.45 \pm 0.70$

ization and factorization scales, to the description of the initial and final state radiation and to the model used to simulate the heavy quark fragmentation. In order to evaluate the size of these uncertainties, the theory parameters above mentioned have been varied within intervals corresponding to sensible choices. Concerning the PDFs, the MRST2000-LO set was used at the place of the CTEQ6L1.

For the  $t\bar{t}H$  analysis, the theory uncertainties have been found to induce a 9% change of the signal cross-section, dominated by the PDF choice. The impact to the  $t\bar{t}$  process, which is the most important source of background to this signal, has been found to be 12% in Ref. [6]. An additional 5%, found in study of the signal process, associated to the uncertainty of the initial and final state radiation, has been included in quadrature, giving an overall 13% uncertainty on the total cross-section. However, the background sample is dominated by  $t\bar{t}$  with extra jets, and the uncertainty on this rate is of order a factor two. For  $WH$ , the PDF uncertainty was found to be less than 5%, and energy scale uncertainty even smaller [17]. Including these effects and others (ISR,FSR) we get a total theoretical uncertainty of 9%.

The effect of experimental systematic uncertainties has been also investigated. The main sources of these uncertainties are represented by the knowledge of the integrated luminosity, the energy scale and the energy resolution of electrons, muons and jets, as well as the tag efficiency of  $b$ -jets and the rejection of light quarks. The level of these uncertainties and the impact on the overall event selection is presented in Tables 7 and 8. Pile-up events will decrease the detector performance and the impact needs to be properly addressed in future studies. However, the relatively low jet transverse momentum threshold of 15 GeV in the  $t\bar{t}H$  analyses may be sensitive to this. The overall systematic uncertainty expected in the  $t\bar{t}H$  analysis is 10% (10%) for the 2L (3L) signal and 15% (18%) for those backgrounds which have been quantified. In the case of the  $WH$  analysis the overall systematic uncertainty is about 10% for the signal, and about 20% for those background systematics which have been estimated. In each case the total background uncertainty is much larger than this at present.

## 5.2 Conclusion

The  $t\bar{t}H, H \rightarrow WW^{(*)}$  and  $WH, H \rightarrow WW^{(*)}$  processes have been studied using two- and three-lepton final states. The signal and main backgrounds have been estimated using a full GEANT based simulation of the detector. The estimated accepted cross-sections in fb of signal and background for these processes are 1.9:10 ( $t\bar{t}H$  2L), 0.8:3.4 ( $t\bar{t}H$  3L) and 0.3:0.4 ( $WH$  3L) respectively. The signal is small and clear distinguishing features such as resonance peaks have not been established. The backgrounds are larger and their uncertainties have not been fully controlled. The analysis is therefore very challenging.

Accurate estimations of the background level using large simulation samples (made with more efficient simulation packages) as well as direct measurements using control samples from real LHC data are essential if a good signal significance is to be reached. For example the production of  $W$  bosons with

# Discovery Potential of $h/A/H \rightarrow \tau^+\tau^- \rightarrow \ell^+\ell^-4\nu$

## Abstract

This note describes a study of the discovery potential for the supersymmetric Higgs bosons  $h/H/A$  in proton-proton collisions at a center-of-mass energy of 14 TeV in final states with  $\tau$  lepton pairs with the ATLAS detector at the LHC. The Higgs bosons are produced in association with  $b$  quarks and decay into a  $\tau\tau$  final state where both  $\tau$  leptons decay leptonically. The signature of Higgs bosons with masses between 110 and 450 GeV is analyzed and the discovery potential is assessed. The analysis is based on an integrated luminosity of  $30\text{fb}^{-1}$ .

All results are obtained using full simulation of the ATLAS detector. No pile-up or cavern background has been considered in this analysis. In addition a procedure for estimating the shape and the normalization of the irreducible  $Z \rightarrow \tau^+\tau^-$  background from data is investigated. The discovery potential as a function of  $m_A$  and  $\tan\beta$  is shown for the  $m_h^{\text{max}}$  MSSM benchmark scenario.

## 1 Introduction

In the Minimal Supersymmetric Standard Model (MSSM), the minimal extension of the Standard Model, two Higgs doublets are required, resulting in five observable Higgs bosons. Three of them are electrically neutral ( $h$ ,  $H$ , and  $A$ ) while two of them are charged ( $H^\pm$ ). At tree level their properties like masses, widths and branching fractions can be predicted in terms of only two parameters, typically chosen to be the mass of the CP-odd Higgs boson,  $m_A$ , and the tangent of the ratio of the vacuum expectation values of the two Higgs doublets,  $\tan\beta$ .

In the MSSM the couplings of the Higgs bosons to fermions and bosons are different from those in the Standard Model resulting in different production cross-sections and decay rates. While decays into  $ZZ$  or  $WW$  are dominant in the Standard Model for Higgs boson masses above  $m_H \sim 160$  GeV, in the MSSM these decay modes are either suppressed like  $\cos(\beta - \alpha)$  in the case of the  $H$  (where  $\alpha$  is the mixing angle of the two CP-even Higgs bosons) or even absent in case of the  $A$ . Instead, the coupling of the Higgs bosons to third generation fermions is strongly enhanced for large regions of the parameter space. The decay of the neutral Higgs bosons into a pair of  $\tau$  leptons therefore constitutes an important discovery channel at the LHC. The production of the Higgs bosons can proceed via two different processes: gluon-fusion or production in association with  $b$  quarks.

In this note, the discovery potential of neutral MSSM Higgs bosons, produced via associated production with  $b$  quarks and decaying into a pair of  $\tau$  leptons in ATLAS at the LHC is discussed. Only  $\tau$  lepton decays into electrons and muons are considered here. Higgs bosons in the mass range between 110 and 450 GeV are analyzed for an integrated luminosity of  $30\text{fb}^{-1}$ . Both the shape and the normalization of the  $Z \rightarrow \tau\tau$  background which is dominant for low Higgs boson masses are estimated from  $Z \rightarrow \mu\mu$  and  $Z \rightarrow ee$  events in data. The results are interpreted in the  $m_h^{\text{max}}$  scenario as a function of the two parameter of the model,  $m_A$  and  $\tan\beta$  [1]. Studies concerning the semileptonic and the fully hadronic final state are not included in this note. These studies are ongoing and will be published separately.

This note is organized as follows. In Section 2 the signal and background processes are introduced and their cross-sections are discussed. In Section 3 the analysis is discussed. After a description of the selection, a procedure to estimate the shape and the normalization of the irreducible  $Z \rightarrow \tau^+\tau^-$  background from data is detailed before the discovery potential in the  $m_A - \tan\beta$  plane is assessed. In Section 4 the results are summarized.

## 2 Signal and background processes

### 2.1 Higgs boson production

The production mechanism of Higgs bosons in the MSSM is discussed in the introductory section of this chapter. The Higgs boson masses, their production cross-section and their branching fraction into a pair of  $\tau$  leptons are summarized in Table 1.

Table 1: Masses, cross-sections for  $b$ -associated production, and branching fractions into the  $\tau^+\tau^-$  final state for Higgs bosons in the  $m_h^{\max}$  scenario and for  $\tan\beta = 20$ .

Mass / GeV			$\sigma_{h/H/A}^{\text{associated}}/\text{fb}$			$\mathcal{B}(h/H/A \rightarrow \tau^+\tau^-)/\%$		
A	H	h	A	H	h	A	H	h
110	129.8	109.0	314810	7579	310707	8.9	9.1	8.9
130	134.2	124.7	189602	92897	99992	9.1	9.2	9.0
160	160.8	128.0	97480	93102	6650	9.4	9.5	8.4
200	200.5	128.4	45685	45095	2188	9.6	9.7	7.5
300	300.4	128.6	10312	10253	979	8.2	9.5	6.3
450	449.8	128.6	2019	2035	723	6.1	6.2	5.7

The theoretical uncertainty on the inclusive production cross-section, i.e. without imposing any requirements on the  $p_T$  of the  $b$  jets at generator level, is estimated taking into account contributions from the scale uncertainty and from the uncertainty on the parton distribution functions. The scale uncertainty is obtained from Ref. [2] as a function of the mass of the Higgs boson. The contribution from the Parton Density Functions (PDFs) is estimated by exchanging MRST2002 for MRST2004 parton distribution functions. Since the cross-sections obtained with MRST2004 are smaller than that with MRST2002 they are considered conservative. Therefore, half of the difference observed with this variation is taken as a systematic uncertainty.

The total uncertainty on the cross-section, obtained by adding the PDF and scale uncertainties in quadrature, is displayed in Fig. 1 as a function of the Higgs boson mass  $m_A$ . For Higgs boson masses as low as  $m_A = 100$  GeV the total theoretical uncertainty is of the order of 20%. This uncertainty decreases to values below 10% for  $m_A = 400$  GeV. For low Higgs boson masses the contribution from the scale uncertainty dominates over that from the parton distribution functions while for high Higgs boson masses the situation is reversed.

### 2.2 Background processes

The following background processes are relevant and have been considered in this analysis (for details see Ref. [3]).

- $Z \rightarrow \ell\ell$ : The Drell-Yan production of  $Z$  bosons and their subsequent decay into a pair of leptons constitutes an important source of background. The production cross-section has been calculated to NNLO accuracy and was found to be  $\sigma_{Z \rightarrow \ell\ell} = (2015 \pm 60)\text{pb}^1$ .

Events with the  $Z$  boson decaying to a pair of  $\tau$  leptons constitute an irreducible background. In particular for low Higgs boson masses, due to the limited invariant mass resolution in the  $\tau^+\tau^-$  final state this background is problematic and needs therefore to be estimated directly from data.

- $t\bar{t}$  production: The cross-section for this process has been calculated at NLO+NLL accuracy and was found to be  $\sigma_{t\bar{t}} = (833 \pm 100)\text{pb}$ . This background is dominant for Higgs boson masses beyond  $m_A = 200$  GeV.

<sup>1</sup>The cross-section is given for a cut on the invariant mass of the lepton pair of  $m_{\ell\ell} > 60$  GeV.

Figure 1: Systematic uncertainty on the signal cross-section for associated Higgs boson production as a function of  $m_A$ . The dashed line corresponds to the contribution from the scale uncertainty, the dash-dotted line to that introduced by the uncertainty on the parton distribution functions, and the solid line is the sum of both contributions added in quadrature.

- **W+jets production:** The production cross-section for this process has been calculated at NNLO accuracy and was found to be  $\sigma_{W+\text{Jets}} = 20510 \text{ pb}$ . This dataset was complemented by a  $Wb\bar{b}$  sample whose cross-section has been calculated to NLO accuracy ( $\sigma_{Wb\bar{b}} = 176.9 \text{ pb}$ ).

### 2.3 Event generation

The Monte Carlo samples have been generated using the SHERPA [4], PYTHIA [5], HERWIG [6], ALPGEN [7], and MC@NLO [8] Monte Carlo generators. Except for SHERPA, all external matrix element generators are interfaced to HERWIG to produce the parton shower. The  $\tau$  leptons are decayed using either SHERPA or TAUOLA [9]. Initial and final state radiation of photons is simulated using PHOTOS [10]. Event filters have been applied for all processes in order to increase the event generation efficiency. Details on Monte Carlo simulation are given in Ref. [3].

## 3 Analysis of the exclusive lepton lepton final state

The experimental signature consists of two leptons from the  $\tau$  decays and missing transverse energy,  $\cancel{E}_T$ , due to the neutrinos from the  $\tau$  decays. At least one jet tagged as coming from a  $b$  quark is required in the event and therefore the  $b$  quark associated production is dominant here.

### 3.1 Preselection

The preselection cuts are grouped into ‘Trigger Selection’, ‘ $b$ -Tagging’, ‘Lepton Selection’, and cuts related to the reconstruction of the invariant mass of the Higgs boson.

**Trigger selection:** An isolated muon (electron) with transverse momentum of at least 20 GeV (25 GeV) or two isolated electrons with  $p_T \geq 15 \text{ GeV}$ , or one electron with  $p_T \geq 15 \text{ GeV}$  and a muon with  $p_T \geq 10 \text{ GeV}$  are required.

**$b$ -Tagging:** Since the Higgs boson is produced in association with  $b$  quarks, at least one jet has to be identified as coming from a  $b$  quark in order to suppress backgrounds from processes involving light

quarks. Jets are reconstructed using a cone algorithm with radius  $\Delta R = 0.4^2$ , and a  $b$ -tagging weight of  $\geq 3$  is required in order for the jet to be labeled as coming from a  $b$  quark [11].

**Lepton selection:** Electrons are required to have  $p_T \geq 10$  GeV, be within  $|\eta| < 2.5$  and pass the medium electron selection [12]. No isolation criteria are applied. Muons are reconstructed using the algorithm described in Ref. [13]. A minimum  $p_T$  of 10 GeV and  $|\eta| < 2.5$  are required. An isolation cone of opening angle  $\Delta R = 0.2$  around the muon track is used with a maximum  $E_T$  of 6 GeV deposited in the calorimeters. Two leptons of opposite charge are required if the event is to be considered for further analysis. In case more than two leptons fulfill the above requirements the lepton pair with the highest scalar sum of  $p_T$  is selected.

**Collinear approximation:** The invariant mass of the Higgs boson candidate is reconstructed using the collinear approximation [14]. In this approximation the masses of the particles involved in the decay of the  $\tau$  lepton are small compared to their momenta, so that the direction of the  $\tau$  lepton can be approximated by the direction of its observed visible decay products. The method assumes furthermore that the missing energy observed in the event is entirely due to neutrinos from the  $\tau$  lepton decays. In addition the Higgs boson is required to have some amount of transverse momentum. If that is not the case the two  $\tau$  leptons from the Higgs boson decay are back-to-back. An accurate reconstruction of the transverse momenta of the  $\tau$  leptons is not possible in that case and the resolution of the invariant mass of the  $\tau$  pair will be poor. Neglecting the masses of all leptons, the invariant mass of the Higgs boson candidate can be reconstructed via

$$m_{\tau^+\tau^-} = \frac{m_{\ell\ell}}{\sqrt{x_1x_2}}. \quad (1)$$

The quantity  $x_i = p_{T\ell_i}/p_{T\tau_i}$  is the fraction of the  $\tau$  lepton momentum carried by its visible decay products. They are calculated from  $\cancel{E}_T$  in the event and the transverse momentum of the visible leptons. For this calculation  $\cancel{E}_T$  is decomposed into two components, each of them pointing along the direction of the charged decay products of the  $\tau$  lepton. This fraction is required to be within physical bounds ( $0 < x_i < 1$ ). In order for the solution to be numerically stable a cut on the angle between the visible decay products of the  $\tau$  lepton of  $\Delta\phi_{\ell\ell} < 3$  is imposed. This also improves the invariant  $m_{\tau\tau}$  resolution.

The accepted cross-section for the above preselection is detailed in Table 2 for the signal and the dominant background contributions.

Table 2: Cross-section in fb passing the preselection criteria as described in the text. The numbers for the signal samples are given assuming  $\tan\beta = 20$ .

Process	Trigger	Lepton Selection	1 or 2 jets	> 0 b-tags	Coll. Approx
$m_A = 110$ GeV	1837.6	1154.8	628.6	175.7	118.4
$m_A = 130$ GeV	1511.8	971.6	544.6	172.1	115.7
$m_A = 160$ GeV	987.4	656.4	374.9	119.1	80.8
$m_A = 200$ GeV	497.9	340	199.3	63.9	44.9
$m_A = 300$ GeV	139.4	98.8	60.2	20.4	13.9
$m_A = 450$ GeV	25.3	18.3	11.2	3.7	2.4
$t\bar{t}$	255114	48045.9	7804.8	5479	1096.2
$Z \rightarrow \tau\tau$	47026.8	27654.4	14053.2	665.1	440.6
$Z \rightarrow ee$	1.4 E6	797747	421393	16197.8	2848.4 <sup>3</sup>
$Z \rightarrow \mu\mu$	1.3 E6	704275	345491	16811.5	3223.4 <sup>3</sup>
W+Jets	17.2 E6	91042.8	44612.4	1537.5	122.4 <sup>3</sup>

<sup>2</sup>The radius  $\Delta R$  of the cone is defined as  $\Delta R = \sqrt{\Delta\phi^2 + \Delta\eta^2}$

<sup>3</sup>Results were obtained using cut factorization.

### 3.2 Event selection

Figure 2: Invariant  $m_{\tau^+\tau^-}$  distribution for a Higgs boson of mass  $m_A = 130$  GeV (left) after preselection cuts. The width has been determined by a fit of a single Gaussian to the peak region of the distribution. The right-hand plot shows the  $m_{\tau^+\tau^-}$  distribution as a function of the  $p_T$  of the Higgs boson.

Cuts on kinematic variables have been optimized in an iterative procedure in order to maximize the statistical significance  $S/\sqrt{B}$  for a potential Higgs boson signal. Since the composition of the background depends on the signal mass hypothesis, this has been done separately for each mass point. In addition, the optimization has been done separately for the  $ee$ ,  $\mu\mu$ , and for the mixed  $e\mu$  final states.

The following variables are considered: To suppress background from  $t\bar{t}$  production only events with less than three jets are selected. The invariant dilepton mass  $m_{\ell\ell}$  has to be well below  $m_Z$  in order to suppress  $Z \rightarrow ee$  and  $Z \rightarrow \mu\mu$  events. Since there are neutrinos from the  $\tau$  decays in the event, missing transverse energy is required in the event. The transverse momentum of the jet tagged as coming from a  $b$  quark has to be above a certain value which depends on the Higgs boson mass under study. Requirements on the maximum  $p_T$  of the leading lepton as well as on that of the lepton-lepton system  $p_{T,\ell\ell}$  are imposed. In addition, the angle  $\Delta\phi$  between the two leptons is restricted. The cut values and the accepted cross-section for a Higgs boson mass of  $m_A = 130$  GeV are given in Table 3.

The resolution of the  $m_{\tau^+\tau^-}$  distribution using the collinear approximation for a Higgs boson of mass  $m_A = 130$  GeV is illustrated in Fig. 2 (left) after applying preselection cuts. The width as extracted from a fit of a single Gaussian to the peak region is  $\sigma = 25$  GeV compared to the natural width of a Higgs boson of that mass between less than 100 MeV up to a few GeV depending on  $\tan\beta$ . The  $m_{\tau^+\tau^-}$  distribution versus the  $p_T$  of the Higgs boson is illustrated on the right-hand side of Fig. 2, showing that the invariant mass resolution improves with  $p_T$  of the Higgs boson.

### 3.3 Selection results

The accepted cross-sections after all cuts for different Higgs boson masses and the various backgrounds are summarized in Table 4 for  $\tan\beta = 20$ . The reconstructed  $\tau\tau$  invariant mass distributions are displayed in Fig. 3 for all masses considered. The vertical solid lines mark the mass window defined as  $m - 1.65\sigma < m_{\tau^+\tau^-} < m + 2\sigma$  where  $\sigma$  denotes the invariant  $m_{\tau^+\tau^-}$  resolution for a given mass hypothesis as determined from Monte Carlo simulations. All candidate events falling inside this mass window are used to calculate the significances for a Higgs boson signal.

In the low mass range, the invariant mass resolution is of the order of 25 GeV. A potential signal for a Higgs boson is nearly indistinguishable from the irreducible  $Z \rightarrow \tau^+\tau^-$  background which dominates in this mass range over the contribution from  $t\bar{t}$  processes, which contribute at the (10–20)% level. This

makes it necessary to estimate the shape and the normalization of the  $Z \rightarrow \tau^+\tau^-$  background directly from data. A procedure has been developed and will be discussed in detail in Section 3.5.

Table 3: Accepted cross-section in fb for optimized cuts for  $m_A = 130$  GeV and  $\tan\beta = 20$ . The values of the cuts applied are stated for the  $ee/\mu\mu$  (upper row) and  $e\mu$  (lower row) subchannels. In case only one number is given it applies to all leptonic subchannels.

Table 4: Accepted cross-section for all Higgs boson mass hypotheses analyzed. The cross-section in fb for signal and background after all selection cuts is given (except for the cut on the mass window) for  $\tan\beta = 20$ .

	$H \rightarrow \tau^+\tau^-$	$t\bar{t}$	$Z \rightarrow \tau^+\tau^-$	$Z \rightarrow e+e^-$	$Z \rightarrow \mu^+\mu^-$	$W+\text{jets}$
$m_A = 110$ GeV	$34.4 \pm 2.9$	$24.0 \pm 5.1$	$62.1 \pm 6.1$	$1.9 \pm 3.0$	$2.7 \pm 3.3$	$8 \pm 11$
$m_A = 130$ GeV	$28.4 \pm 2.6$	$19.7 \pm 4.6$	$22.1 \pm 3.6$	$1.8 \pm 2.9$	$2.0 \pm 2.8$	$12 \pm 12$
$m_A = 160$ GeV	$18.7 \pm 1.2$	$39.3 \pm 6.6$	$8.4 \pm 2.2$	$1.4 \pm 2.5$	$2.0 \pm 2.9$	$1.8 \pm 4.9$
$m_A = 200$ GeV	$10.9 \pm 0.6$	$28.4 \pm 5.6$	$5.4 \pm 1.8$	$2.0 \pm 3.1$	$2.1 \pm 2.9$	$3.7 \pm 7.0$
$m_A = 300$ GeV	$2.7 \pm 0.1$	$32.8 \pm 6.0$	$3.0 \pm 1.3$	$0.4 \pm 1.4$	$1.7 \pm 2.6$	$5.8 \pm 8.8$
$m_A = 450$ GeV	$0.50 \pm 0.03$	$50.2 \pm 7.4$	$1.8 \pm 1.0$	$0.4 \pm 1.4$	$0.3 \pm 1.1$	$4.1 \pm 7.3$

In the medium mass range, the contributions from  $Z \rightarrow \tau^+\tau^-$  events and from  $t\bar{t}$  processes become equally important. The mass resolution for signal events is now of the order of  $(30 - 40)$  GeV leading to a broad structure which is indistinguishable from that of background events.

In the high mass range ( $m_A = 300$  to  $450$  GeV), the cross-section for the signal process decreases rapidly. The invariant mass resolution for signal events is between  $(50 - 80)$  GeV so that a discovery with an integrated luminosity of  $\mathcal{L} = 30 \text{ fb}^{-1}$  in this channel will not be possible.

### 3.4 Systematic uncertainties

In order to assess the impact of systematic uncertainties, each of these has been applied in turn and the impact on the result of the analysis is evaluated. The uncertainties assumed on the energy and momentum resolution of muons, electrons, photons, and jets are conservative estimates assuming non-optimal performance of the corresponding algorithms at the beginning of data taking.

1. For muons the uncertainty on the reconstructed  $p_T$  is  $\sigma(1/p_T) = (0.011/p_T \otimes 0.00017)$  with  $p_T$

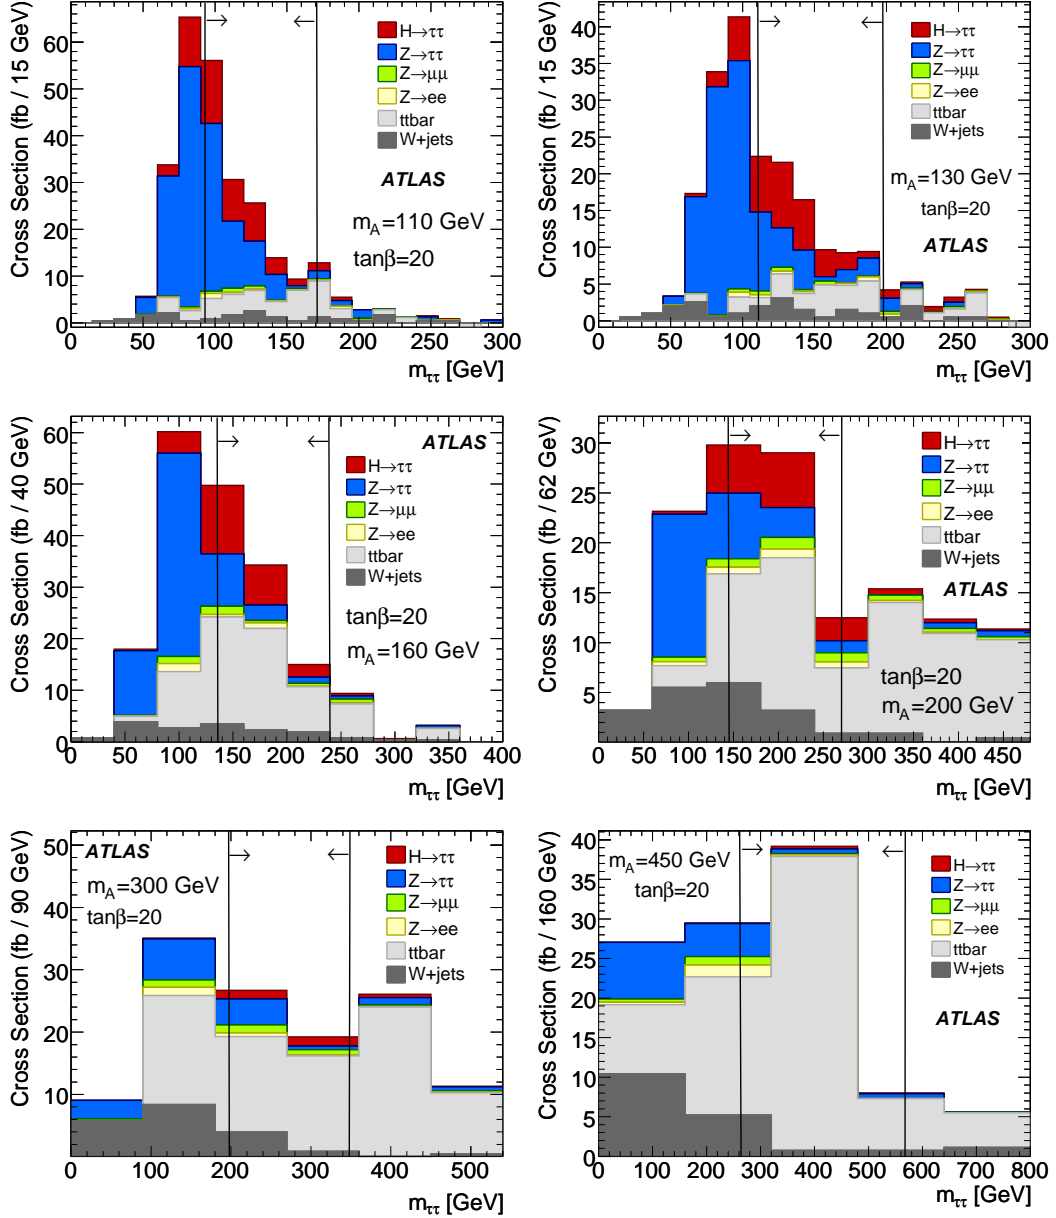

Figure 3: Invariant  $m_{\tau^+\tau^-}$  distribution for signal and background events. The distributions are shown after all selection cuts with the nominal masses and  $\tan\beta$  values as indicated in the plots. The vertical lines indicate the mass window used for calculating the signal significance.

Table 5: Effects of systematic uncertainties as described in the text for different Higgs boson masses for  $\tan\beta = 20$ . The effects of the systematic uncertainties considered are listed in percent. The total uncertainty is obtained by adding the individual contributions in quadrature.

given in GeV. The uncertainty on the energy scale is estimated to be  $\pm 1\%$ , and that on the reconstruction efficiency is assumed to be  $1\%$  and flat in  $p_T$ .

2. For electrons and photons the uncertainty on the reconstructed  $E_T$  is  $\sigma(E_T) = 0.0073 \cdot E_T$ . The uncertainty on the energy scale is estimated to be  $\pm 0.5\%$ , and that on the reconstruction efficiency is assumed to be  $0.2\%$  and being flat in  $E_T$ .
3. For jets with  $|\eta| < 3.2$  ( $|\eta| > 3.2$ ) the uncertainty on the jet energy scale is taken to be  $\pm 3\%$  ( $\pm 10\%$ ) and the jet energy resolution is assumed to be  $45\%\sqrt{E}$  ( $63\%\sqrt{E}$ ).
4. For the  $b$ -tagging a degradation of the tagging efficiencies of  $5\%$  is taken as systematic uncertainty. For the  $Z$ +light jets background an uncertainty on the rejection rate of  $\pm 10\%$  is assumed.

A detailed description of the sources of systematic uncertainties can be found in [3]. The impact of the systematic uncertainties on the number of signal and  $t\bar{t}$  background events<sup>4</sup> inside the mass window is summarized in Table 5 for Higgs boson masses between  $m_A = 110$  and  $450$  GeV. A sample of  $48M$   $t\bar{t}$  events from fast simulation has been used for these studies. The  $Z \rightarrow \tau\tau$  background in this analysis is estimated from sidebands in data as described in the next Section. The number of events from  $Z \rightarrow \mu\mu$  and  $Z \rightarrow ee$  processes after all selection cuts is small compared to that from  $t\bar{t}$ . Their contribution to the total systematic uncertainty is small compared to that from  $t\bar{t}$  processes.

### 3.5 Estimation of $Z \rightarrow \tau^+\tau^-$ shape and normalization from data

Figure 4: Distribution of the invariant dilepton mass  $m_{\ell\ell}$  (left). The shaded area illustrates the distribution from  $Z \rightarrow \mu\mu$  events, and the solid line that from signal events. The contribution from  $Z \rightarrow \tau^+\tau^-$  and  $t\bar{t}$  events is illustrated by the dashed and dotted lines, respectively. The cut on the invariant  $\ell\ell$  mass is indicated by the solid vertical lines. The distribution of  $p_T^{\text{miss}}$  in the calorimeter for  $Z \rightarrow \mu\mu$  and  $Z \rightarrow \tau\tau \rightarrow \mu\mu + X$  events (right). All plots shown are after preselection cuts.

As discussed above the estimation of the shape and the normalization of the irreducible  $Z \rightarrow \tau^+\tau^-$  events from data is of great importance in particular for low Higgs boson masses where this background is dominant. Procedures to estimate both the shape and the normalization of  $Z \rightarrow \tau^+\tau^-$  events from data are needed. This procedure is based on  $Z \rightarrow \mu\mu$  and  $Z \rightarrow ee$  events selected from a sideband region which is free of Higgs boson events, in contrast to the signal region. The method proceeds in three steps:

<sup>4</sup>The impact on the number of  $Z \rightarrow \tau^+\tau^-$  events is not listed here since this background is estimated from data.

1. As a first step, a pure sample of  $Z \rightarrow \mu\mu$  or  $Z \rightarrow ee$  events is selected from a sideband region as described below.
2. The shape of the  $m_{\tau\tau}$  spectrum is estimated by adapting the four-momenta of the muons such that they appear like coming from  $Z \rightarrow \tau\tau$  events.
3. The normalization of the  $Z \rightarrow \tau\tau$  background is estimated from a double-ratio comparing the number events found in data and in Monte Carlo in the sideband region as well as in the signal region.

This procedure is described in detail below.

### 3.5.1 Definition of signal and sideband regions

Events of the type  $Z \rightarrow ee$  and  $Z \rightarrow \mu\mu$  are selected from a sideband region (called region B) with very high purity and with an event topology similar to that from  $Z \rightarrow \tau^+\tau^-$  events in the signal region (called region A). The following cuts are applied in order to select  $Z \rightarrow ee$  and  $Z \rightarrow \mu\mu$  events in region B:

- The invariant mass of the lepton-lepton system is required to be within  $75 \text{ GeV} < m_{\ell\ell} < 100 \text{ GeV}$ , where  $\ell\ell$  is either a  $ee$  or a  $\mu\mu$  final state.
- At least one jet identified as coming from a  $b$  quark has to be found in the event.
- The number of jets allowed in the event has to be less than three.

The main cut defining region B is that on the invariant lepton-lepton mass. A distribution illustrating the cut on  $m_{\ell\ell}$  is displayed in Fig. 4 (left) showing the large amount of  $Z \rightarrow \mu\mu$  events selected by the cuts above that only have a small contamination of events coming from  $t\bar{t}$  processes and events containing Higgs boson decays. The number of events from  $Z \rightarrow ee$  and  $Z \rightarrow \mu\mu$  is around 500000 for an integrated luminosity of  $30 \text{ fb}^{-1}$  and thus much larger than the number of  $Z \rightarrow \tau\tau$  events expected in the signal region. The purity of the  $Z \rightarrow \mu\mu$  ( $Z \rightarrow ee$ ) control sample in region B after all cuts mentioned above is 99.1% (97.9%) with a contribution of 0.04% (0.05%) of events from the signal process<sup>5</sup> with the remainder coming from  $t\bar{t}$  processes.

### 3.5.2 Estimation of the $Z \rightarrow \tau^+\tau^-$ shape from data

The method of estimating the shape of  $Z \rightarrow \tau^+\tau^-$  events from data is based on the assumption that in the calorimeter this type of events is indistinguishable from that of type  $Z \rightarrow \mu\mu$ . This method has been proven to work in a vector boson fusion  $H \rightarrow \tau^+\tau^-$  analysis [15].

The muons are minimum ionizing particles and their energy deposit in the calorimeter only weakly depends on their momentum. Therefore, the missing energy signatures of both types of events in this detector component are very similar as illustrated on the right-hand side of Fig. 4. Altering the energy of muons in  $Z \rightarrow \mu\mu$  events so that they correspond to those from  $Z \rightarrow \tau^+\tau^- \rightarrow \mu\mu + 4\nu$  events leads to identical distributions of  $p_{T,\mu}$ ,  $p_{T,\text{miss}}$  and  $m_{\tau^+\tau^-}$  for both classes of events. The following procedure is adopted:

- Three dimensional reference histograms from  $Z \rightarrow \tau^+\tau^- \rightarrow \mu\mu + 4\nu$  events from Monte Carlo in region A are created. The following variables calculated in the  $Z$  rest frame are used:

---

<sup>5</sup>A Higgs boson mass of  $m_A = 130 \text{ GeV}$  and  $\tan\beta = 20$  is assumed here. The contamination of Higgs boson events is even smaller for the other signal masses considered in this analysis.

1. The absolute value of the Gottfried-Jackson angle  $\xi$  between the  $Z$  boson and the negatively charged muon.
  2. The energy of the muon with  $\cos \xi > 0$ .
  3. The energy of the muon with  $\cos \xi < 0$ .
- The components of the momentum vector of the muons in  $Z \rightarrow \mu\mu$  events from region B are altered in a way that they match those from  $Z \rightarrow \tau^+\tau^- \rightarrow \mu\mu + 4\nu$  events using the above reference histogram:

$$p_{i,\text{altered}} = \frac{p_i}{|\vec{p}|} \cdot E_{\mu,\text{altered}}. \quad (2)$$

For each event, the angle  $\xi$  is calculated and then new energies for the muons are chosen randomly from the reference histogram. After applying this procedure, the muon momenta are boosted back into the lab frame.

- The missing energy in the event is re-calculated according to the new muon momenta:

$$\vec{p}_{T,\text{miss,altered}} = \vec{p}_{T,\text{miss}} - \sum_{\mu} p_{T,\text{altered}} + \sum_{\mu} p_{T,\text{old}}. \quad (3)$$

A comparison of  $p_{T,\text{miss}}$ , of  $x_1 \cdot x_2$  from the collinear approximation and of the invariant  $m_{\tau^+\tau^-}$  mass from altered  $Z \rightarrow \mu\mu$  in comparison with  $Z \rightarrow \tau^+\tau^- \rightarrow \mu\mu + 4\nu$  events is shown on the left-hand side, middle and right-hand side of Fig. 5, respectively. Good agreement within the statistical uncertainties of the samples used is observed.

Figure 5: Comparison of the  $p_{T,\text{miss}}$ ,  $x_1 \cdot x_2$ , and  $m_{\tau\tau}$  spectra for events of type  $Z \rightarrow \mu\mu$  and  $Z \rightarrow \tau\tau$ . Good agreement within the statistical uncertainties is observed.

The same shape as extracted from region B using  $Z \rightarrow \mu\mu$  events to estimate  $Z \rightarrow \tau\tau \rightarrow \mu\mu + X$  events in region A is also used for  $Z \rightarrow \tau\tau \rightarrow ee + X$  and  $Z \rightarrow \tau\tau \rightarrow \mu e + X$  events. As shown in Figure 6, the  $m_{\tau\tau}$  shapes are identical within statistical uncertainties justifying this procedure.

### 3.5.3 Estimation of the background normalization from data

In order to estimate the number of background events from the  $Z \rightarrow \tau^+\tau^-$  background process for this analysis, the same definition of the sideband region has been used as described above.

The number of  $Z \rightarrow \tau^+\tau^-$  background events in the signal region A can then be obtained by re-weighting the number of events found in data in region B by the predicted ratio of the number of events found in Monte Carlo in region A relative to that found in region B. In order for this method to be valid, the following two conditions have to hold:

$$\frac{(Z \rightarrow \ell\ell)_{\text{Data}}^B}{(Z \rightarrow \ell\ell)_{\text{MC}}^B} = \frac{(Z \rightarrow \tau^+\tau^- \rightarrow \ell\ell + 4\nu)_{\text{Data}}^B}{(Z \rightarrow \tau^+\tau^- \rightarrow \ell\ell + 4\nu)_{\text{MC}}^B} \quad (4)$$

Figure 6: Comparison of the  $m_{\tau\tau}$  shape for  $Z \rightarrow \tau\tau \rightarrow \mu\mu + X$ ,  $Z \rightarrow \tau\tau \rightarrow ee + X$ , and  $Z \rightarrow \tau\tau \rightarrow \mu e + X$  events. Good agreement is observed within the statistical uncertainties of the samples used.

$$\frac{(Z \rightarrow \ell\ell)_{\text{Data}}^{\text{B}}}{(Z \rightarrow \ell\ell)_{\text{MC}}^{\text{B}}} = \frac{(Z \rightarrow \tau^+\tau^- \rightarrow \ell\ell + 4\nu)_{\text{Data}}^{\text{A}}}{(Z \rightarrow \tau^+\tau^- \rightarrow \ell\ell + 4\nu)_{\text{MC}}^{\text{A}}}, \quad (5)$$

where the first condition means that  $Z \rightarrow \ell\ell$  events behave like  $Z \rightarrow \tau^+\tau^- \rightarrow \ell\ell + 4\nu$  events, and when combined with the second it implies that  $Z \rightarrow \tau^+\tau^- \rightarrow \ell\ell + 4\nu$  events in region A and in region B behave identically.

The calculation of the number of events from the  $Z \rightarrow \tau^+\tau^-$  process in data is performed in bins of  $p_T$  of the leading lepton vs. the  $p_T$  of the subleading lepton with a bin size of  $2 \times 2 \text{ GeV}^2$  which was found to give unbiased results in previous Monte Carlo based studies [16]. This ensures that the method is less dependent on the differences in  $p_T$  in the signal and the sideband region. Once events from real data are available the method has to be validated and the influence of a possible difference between data and the Monte Carlo prediction on the results has to be checked.

This procedure also allows to easily take into account differences in acceptance and trigger efficiencies by simply applying the appropriate factors to the reweighting procedure. The number of  $Z \rightarrow \tau^+\tau^- \rightarrow \ell\ell + 4\nu$  events in region A is then given by

$$(Z \rightarrow \tau^+\tau^- \rightarrow \ell\ell + 4\nu)_{\text{Data}}^{\text{A}} = \sum_{i,j} \frac{((Z \rightarrow \tau^+\tau^- \rightarrow \ell\ell + 4\nu)_{\text{MC}}^{\text{A}})_{ij}}{((Z \rightarrow \ell\ell)_{\text{MC}}^{\text{B}})_{ij}} \cdot ((Z \rightarrow \ell\ell)_{\text{Data}}^{\text{B}})_{ij}, \quad (6)$$

where  $i$  and  $j$  indicate the corresponding bin in  $p_T$ . The statistical uncertainty on this method is calculated according to Gaussian error propagation. The method has been tested using two independent Monte Carlo samples, one to fill the reference histogram and one to test the reweighting procedure. Good agreement within statistical uncertainties between the expected number of events in region A and that actually found was observed.

The application of this method is straight forward for the  $ee$  and the  $\mu\mu$  final state. For the  $e\mu$  final state the procedure has to be adapted since there are no  $Z \rightarrow e\mu$  decays. In order to estimate the number of background events in that case, events from  $Z \rightarrow ee$  and  $Z \rightarrow \mu\mu$  processes are used. Additional correction factors are applied to account for the differences in trigger efficiencies and selection efficiencies in that case.

### 3.5.4 Systematic uncertainties of the background estimation procedure

Table 6: The effects of systematic uncertainties on the calculation of the normalization.

Uncertainty Effect	Value	Systematic Uncertainty
Muon resolution	$\sigma\left(\frac{1}{p_T}\right) = \sqrt{\left(\frac{0.011}{p_T}\right)^2 + 0.00017^2}$	0.16 %
Muon energy scale	$\pm 1\%$	1.35 %
Muon efficiency	$\pm 1\%$	0.7 %
Electron resolution	$\sigma(E_T) = 0.0073 \cdot E_T$	1.9 %
Electron energy scale	$\pm 0.5\%$	0.85 %
Electron efficiency	$\pm 0.2\%$	0.1 %

The impact of the systematic uncertainties on the estimation of the number of background events from  $Z \rightarrow \tau^+\tau^-$  processes as described in Section 3.4 has been evaluated. The uncertainties on jet energy scale and jet resolution, as well as on the  $b$  tagging efficiency are expected to be negligible since the same effects would apply to the signal region as well as to the sideband region. The remaining contributions to the systematic uncertainty on the background estimation procedure are coming from the energy scale, efficiency and resolution connected with the electrons and muons in the final state. These contributions as expected in  $30\text{fb}^{-1}$  of data are summarized in Table 6.

In addition, systematic uncertainties due to the different acceptances and trigger efficiencies for the  $Z \rightarrow ee/\mu\mu$  samples from the sideband region compared to  $Z \rightarrow \tau\tau \rightarrow ee/\mu\mu/e\mu + X$  samples in the signal region need to be taken into account. Since the reweighting of events is done as a function of the  $p_T$  of the leading and the subleading lepton, these are easy to apply. Since this analysis is aimed at an integrated luminosity of  $30\text{fb}^{-1}$ , it is assumed that by then these uncertainties are evaluated to a very high precision.

The overall systematic uncertainty has been evaluated to be 2.6% by dividing the available MC events into two independent samples. This uncertainty has been taken into account for the final results.

### 3.5.5 Summary of the background estimate from data

Both methods described above are now combined to estimate the  $Z \rightarrow \tau\tau$  background and thereby the significance of a possible Higgs boson signal in the low mass region. First, the number of events of type  $Z \rightarrow \tau^+\tau^-$  is estimated using the method described in Section 3.5.3. Then, the shape of this background is determined as described in Section 3.5.2. The background is then subtracted from the  $m_{\tau^+\tau^-}$  distribution.

## 3.6 Results and discovery potential

The discovery potential for the  $h/H/A \rightarrow \tau^+\tau^- \rightarrow \ell\ell 4\nu$  channel is now assessed. All sub-channels, i.e.  $ee$ ,  $e\mu$  and  $\mu\mu$  are combined to calculate the significance of a Higgs boson signal. A mass window  $m - 1.65\sigma < m_{\tau^+\tau^-} < m + 2\sigma$  is applied to calculate the final significance where  $\sigma$  denotes the invariant mass resolution of the Higgs boson signal of the corresponding mass.

The shape and the normalization of the  $Z \rightarrow \tau^+\tau^-$  background is estimated from the sideband region in data as described in Section 3.5. There is no corresponding procedure available yet for the  $t\bar{t}$  background so that all experimental systematic uncertainties are taken into account for all calculations below. Theoretical uncertainties are treated separately. The significance of a potential Higgs boson signal in the

Figure 7: The five  $\sigma$  discovery potential (left) and the 95% exclusion limit (right) as a function of  $m_A$  and  $\tan\beta$ . The solid line represents the main result of the analysis. The dashed lines indicate the discovery potential and exclusion limit including an addition 10% uncertainty on the  $t\bar{t}$  cross-section. The bands represent the influence of the systematic uncertainty on the signal cross-section.

given mass window is calculated as

$$\text{Sign.} = \frac{S}{\sqrt{N_{t\bar{t}} + (\Delta_{\text{sys}}^{t\bar{t}})^2 + N_{Z \rightarrow \tau\tau} + (\Delta_{\text{sys}}^{Z \rightarrow \tau\tau})^2 + N_{W \rightarrow \ell\nu} + (\Delta_{\text{sys}}^{W \rightarrow \ell\nu})^2 + N_{Z \rightarrow ee} + N_{Z \rightarrow \mu\mu}}}, \quad (7)$$

where  $S$  is the number of signal events,  $N_{t\bar{t}}$  and  $\Delta_{\text{sys}}(t\bar{t})$  are the statistical and systematic uncertainties on the  $t\bar{t}$  background. The quantities  $N_{Z \rightarrow \tau^+\tau^-}$  and  $\Delta_{\text{sys}}(Z \rightarrow \tau^+\tau^-)$  are the statistical and systematic uncertainties on the  $Z \rightarrow \tau^+\tau^-$  background, respectively. The term in the denominator is dominated by the contribution from  $t\bar{t}$  events; the contributions from  $N_{Z \rightarrow ee}$  and  $N_{Z \rightarrow \mu\mu}$  and their corresponding systematic uncertainties are negligible.

The discovery potential and the 95% exclusion limit in the  $m_h^{\text{max}}$  scenario as a function of  $\tan\beta$  and  $m_A$  and for an integrated luminosity of  $30\text{fb}^{-1}$  is displayed in Fig. 7 on the left-hand side and right-hand side, respectively. The uncertainty on the signal cross-section is indicated as bands in the plots. The calculation of the significance includes both statistical and experimental systematic uncertainties on the background. The uncertainties on the background cross-sections are not taken into account in the main results since they are assumed to be measured with high precision at the time of the analysis. However, since the cross-section for the  $t\bar{t}$  background might not be measured at high precision in the region of phase space relevant to this analysis, the discovery potential including a 10% uncertainty on that background is displayed in addition (dashed line).

The discovery potential for Higgs bosons is shown in Fig. 8 as a function of  $\tan\beta$  for various  $m_A$  values, and in Fig. 9 as a function of  $m_A$  for various  $\tan\beta$  values.

## 4 Conclusion

In this note a study of the discovery potential for the supersymmetric Higgs bosons  $h/H/A$  in proton-proton collisions at a center-of-mass energy of 14 TeV with the ATLAS detector at the LHC has been presented. The final state  $h/H/A \rightarrow \tau^+\tau^-$  in  $b$  quark associated production has been investigated with at least one jet identified as coming from a  $b$  quark and with both  $\tau$  leptons decaying leptonically.

A significant improvement for the discovery potential can be achieved if this channel is combined with the  $\ell$ -had and had-had channel, where one  $\tau$  lepton decays leptonically (either electron or muon)

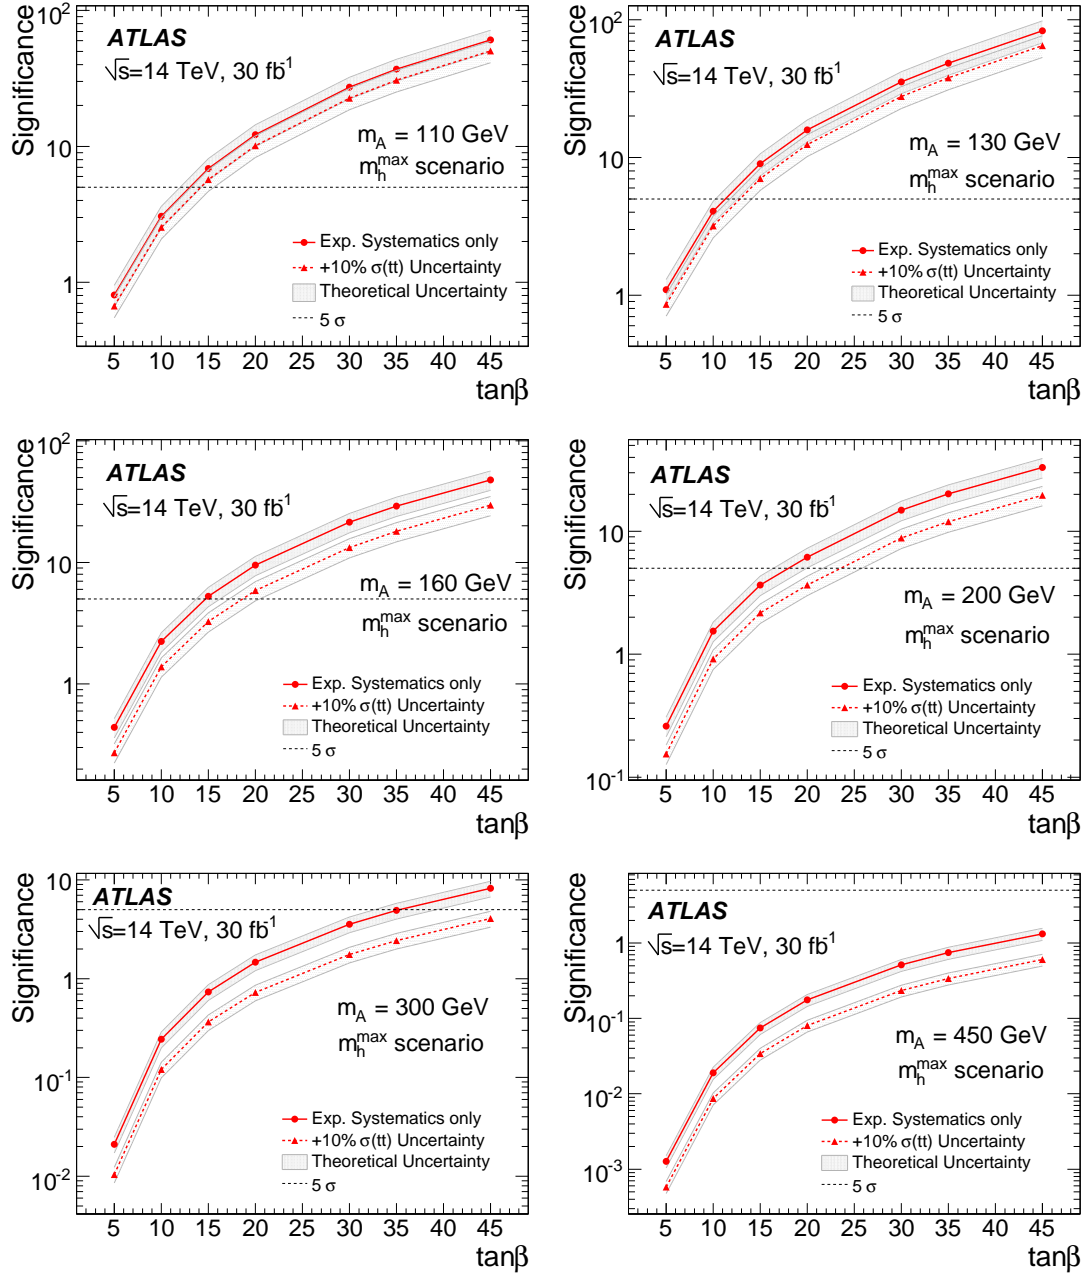

Figure 8: The discovery potential as a function of  $\tan\beta$  and for Higgs boson masses as indicated in the plots. The solid lines indicate the discovery potential including experimental systematic uncertainties. The dashed lines indicate the discovery potential including an additional systematic uncertainty on the  $t\bar{t}$  cross-section. The bands indicate the impact of the systematic uncertainty on the signal cross-section.

Figure 9: The discovery potential as a function of  $m_A$ . The solid lines indicate the discovery potential including experimental systematic uncertainties for  $\tan\beta$  values as indicated in the plots. The dashed lines indicate the discovery potential including an additional systematic uncertainty on the  $t\bar{t}$  cross-section of 10%. The bands indicate the impact of the systematic uncertainty on the signal cross-section.

and one hadronically, or both  $\tau$  leptons decay hadronically [17].

# Search for the Neutral MSSM Higgs Bosons in the Decay Channel $A/H/h \rightarrow \mu^+ \mu^-$

## Abstract

Motivated by the high muon momentum resolution and identification efficiency achievable with the ATLAS detector, the observability of  $A/H/h \rightarrow \mu^+ \mu^-$  channel is explored. The high experimental resolution in this decay mode compensates to some extent for the suppression of the branching ratio, with respect to the  $A/H/h \rightarrow \tau^+ \tau^-$  decays. The analyses are performed in the Higgs mass range from 100 to 500 GeV. Two main analysis strategies are applied - the search for the dimuon final states resulting from the direct  $A/H/h$  production is combined with the search for the associated  $b\bar{b}A/H/h$  production mode.

The studies are optimized for the early stage of data taking up to an integrated luminosity of  $30 \text{ fb}^{-1}$ . All results are obtained combining the fast and the full simulation of the ATLAS detector with the nominal detector layout and the trigger efficiencies included. In addition, dedicated data samples are produced to study the impact of the pile-up and cavern background on the analysis performance. The estimation of the background contribution from the experimental data and the contribution of theoretical and experimental uncertainties are also addressed. The discovery potential is shown in the  $m_A$ - $\tan\beta$  plane in context of the  $m_h^{\text{max}}$  MSSM benchmark scenario.

## 1 Introduction

In the framework of the Standard Model, the observability of the Higgs boson in the decay channel  $H \rightarrow \mu^+ \mu^-$  is very unlikely, since the branching ratio for the Higgs decay into muons is very small and the backgrounds from several Standard Model processes are large. As opposed to the Standard Model predictions, the decay of neutral MSSM Higgs bosons  $A$ ,  $H$  and  $h$  into two muons is strongly enhanced in the MSSM for large values of  $\tan\beta$  and can be used either as a discovery channel or for the exclusion of a large region of the  $m_A$ - $\tan\beta$  parameter space (see Ref [1]).

Compared to the dimuon channel, the  $A/H/h \rightarrow \tau^+ \tau^-$  decays have a substantially larger branching ratio which scales as  $(m_\tau/m_\mu)^2$  and thus provide a promising discovery signature, as discussed in Ref [2]. Nevertheless, the  $\tau$  identification represents an experimental challenge. The  $\mu^+ \mu^-$  final state, on the other hand, has the advantage of a very clear signature in the detector. Furthermore, a full reconstruction of the Higgs boson final state is possible, which allows for a direct mass measurement. The dimuon channel provides for the most accurate Higgs boson mass measurement.

In this note, the potential for the discovery of the neutral MSSM Higgs bosons is evaluated in the dimuon decay channel. The study concentrates on the region of  $(m_A - \tan\beta)$  plane with  $m_A > 110 \text{ GeV}$  and intermediate  $\tan\beta$  values between 10 and 60, which is still uncovered by the current experimental limits [3, 4]. A detailed study of the ATLAS discovery potential for this channel has been recently performed in the low mass region below 130 GeV [5]. The study includes also higher Higgs boson masses up to 400 GeV.

In Section 2, the relevant production and decay rates of the MSSM Higgs boson are briefly discussed in the context of the  $m_h^{\text{max}}$  LHC scenario [6], as well as the production mechanisms of the major background processes. In Section 3, the Monte Carlo simulation and data samples used for the analysis are described. Section 4 provides a short description of the detector performance obtained from the simu-

lation, related to the reconstructed particles which will be present in the final state. The event selection criteria, the resulting efficiency of the signal selection and the corresponding background rejection shall be described in Section 5. Discussion of the systematic uncertainties is presented in Section 6. Section 7 describes the methods for the estimation of different background contributions from the real data. The obtained results are finally represented by the discovery contours in the  $(m_A - \tan\beta)$  plane (see Section 9). The note concludes with Section 10.

## 2 Signal and background processes

In this Section, the properties of the signal shall be briefly described, as well as the background processes relevant for the MSSM Higgs boson searches in the dimuon final state at the LHC.

### 2.1 Signal production and decays

The characteristic production and decay properties of all MSSM Higgs bosons are determined at tree-level by the values of the two free parameters  $\tan\beta$  and the mass  $m_A$  of the  $A$  boson. These properties have been calculated at NNLO with the Feynhiggs 2.6.2 package [7] in the  $m_h^{max}$  scenario, as summarized in Ref [1].

The direct  $gg \rightarrow A/H/h$  production via the gluon-gluon fusion is an analogue to the Standard Model Higgs boson production. This process is important in the region of low  $\tan\beta$  values (below 10), where the Higgs bosons couple most strongly to up-type quarks. For larger values of  $\tan\beta$ , the rate of the  $b\bar{b}A/H/h$  Higgs production in association with b-quarks becomes dominant, due to the enhanced couplings to the b-quarks.

There are two approaches to calculate the signal rates for the associated  $b\bar{b}A/H/h$  production mode. In the first approach, the production cross-section for the  $gg \rightarrow b\bar{b}H$  process has been calculated at NLO in Ref [8, 9]. This calculation is most reliable in the case where both outgoing b-quarks have a high transverse momentum (above  $\sim 15$  GeV). The inclusive cross-section without any cut on the transverse momenta of the b-quarks is less accurate, due to additional collinear logarithms which appear in the calculation due to the presence of low-momentum b-quarks. An alternative approach is the calculation of the inclusive cross-section for the  $b\bar{b} \rightarrow H$  process, for which the collinear logarithms can be absorbed in a parton density function for the b-quarks and resummed to all orders of perturbation theory [10, 11]. This later calculation has been implemented in a parametrized way into the Feynhiggs package, which was finally used for the evaluation of the signal cross-sections, as mentioned previously.

The different higher-order calculations mentioned above have been extensively compared in Ref [12]. The two approaches agree within uncertainties. For the  $gg \rightarrow b\bar{b}H$  calculation, the uncertainty related to the variation of the renormalization and the factorization scale amounts to 20-30%. For the  $b\bar{b} \rightarrow H$  calculation, which is used for the analysis, the scale uncertainty is much smaller, less than 10%. However, it should be noted that the uncertainty on the b parton density function has not been included here. In order to estimate this pdf-uncertainty, a calculation of the  $b\bar{b} \rightarrow H$  cross-section is performed with two different parton density functions, MRST2002 and MRST2004. The observed difference of  $\sim 14\%$  is taken as the estimate of the pdf-uncertainty. Adding the 10% scale uncertainty to this in quadrature, the total theory uncertainty for the signal is estimated to be  $\sim 17\%$  for  $H$  boson masses up to 500 GeV.

The production cross-section of  $H$  and  $A$  bosons increases approximately quadratically with increasing  $\tan\beta$ , while the  $h$  boson production is  $\tan\beta$ -dependent only for  $m_A < 130$  GeV. Also the branching ratio of  $H$  and  $A$  boson decays into  $\mu^+\mu^-$  pairs become enhanced with increasing values of  $\tan\beta$ . The  $h$  boson decay is rather insensitive to the two mentioned parameters. The increase of the cross-sections and branching ratios with  $\tan\beta$  make the  $A/H/h \rightarrow \mu^+\mu^-$  decay channel a promising Higgs signature in MSSM.

Additionally, the signal is enhanced due to the mass degeneracy of the neutral Higgs bosons. For  $A$  boson masses  $m_A < 130$  GeV, the  $h$  and  $A$  bosons are degenerate in mass, while the heavy  $H$  boson mass is rather constant ( $\sim 130$  GeV). In case of  $m_A \approx 130$  GeV, all three bosons have very similar masses. For  $m_A > 130$  GeV, the  $h$  boson mass reaches its maximum value of  $\sim 130$  GeV, independent of the  $A$  boson mass, while the  $A$  and  $H$  bosons become degenerate in mass. Thus the signal can be observed as the sum of all two or three degenerate mass states.

## 2.2 Background processes

The processes with two muons in the final state, which give a major background contribution in the searches for the  $A/H/h$  signal are depicted in Figure 1.

Figure 1: Tree-level Feynman diagrams of the dominant background processes with two isolated muons in the final state: a) Drell-Yan  $Z$  boson production, b)  $Z$  boson production in association with jets, c)  $t\bar{t}$  production and d)  $ZZ$  and  $WW$  production.  $q$  is a general symbol for  $u$  and  $d$  quarks, while  $Q$  stands for the  $b$  and  $c$  quarks.

The dominant background process with a very large production rate of  $\sim 1$  nb is the Drell-Yan  $Z$  boson production, with subsequent  $Z$  decay into two muons. The invariant dimuon mass peaks at the  $Z$  resonance, such that the search for the  $A/H/h$  becomes unfeasible for the Higgs masses below 100 GeV. Even for the higher Higgs boson masses, the tail of the  $Z$  resonance still provides an overwhelming background. The Drell-Yan background can be suppressed by requiring the presence of one or more additional b-jets, originating from the associated  $b\bar{b}A$  production. The major backgrounds remaining after this requirement are the  $Z$  boson production in association with the light jets or b-jets and the  $t\bar{t} \rightarrow (W^+b)(W^-\bar{b}) \rightarrow (\mu^+\nu b)(\mu^-\nu\bar{b})$  background. The  $t\bar{t}$  background can be distinguished from the signal by a higher jet activity and a large missing energy caused by the neutrinos from  $W$  decays. Additional background from  $WW$  and  $ZZ$  diboson productions is expected to be small, due to the much lower production rates.

### 3 Data samples

Two different Monte Carlo generators are used for the signal production. PYTHIA 6.4 [13] has been used to generate the direct  $gg \rightarrow \phi \rightarrow \mu\mu$  and associated  $gg \rightarrow b\bar{b}\phi \rightarrow b\bar{b}\mu\mu$  processes (where  $\phi = A, H, h$ ). The SHERPA [14] event generator (version 1.0.9) combines all three associated production mechanisms,  $gg \rightarrow b\bar{b}\phi$ ,  $bg \rightarrow b\phi$  and  $b\bar{b} \rightarrow \phi$ , in a coherent way without double-counting. This is accomplished by the CKKW algorithm [15] for the matching of the parton showers to the quark emission from the matrix elements. Both generators provide leading-order cross-sections, which have been rescaled to the Feynhiggs NNLO values. The studies at the D0 experiment [16] have shown that the differential SHERPA distributions are in a good agreement with the real data and can simply be normalized to the previously described inclusive higher-order cross-sections. The comparison of the samples produced by the two generators will be described in Section 6.1. A generator filter requiring at least two muons with  $p_T > 5$  GeV and  $|\eta| < 2.7$  is applied to each event for all signal data samples, after the showering and before writing out the events into permanent storage. The background samples are listed in Table 1, together with the corresponding NLO cross-sections. The details of the cross-section computation can be found in Ref [17]. In addition to already mentioned generators, the MC@NLO 3.1 [18] and AcerMC 3.4 packages [19] have been used for the event generation.

Full simulation of the detector response has been performed for all signal and background event topologies, within the ATHENA software framework which uses the GEANT4 [20] package for the description of the detector response. In addition, due to the large background production rates, it is necessary to increase the number of simulated events by means of the parametrized fast detector simulation (Atlfast [21]). The presented analyses are based on the combination of both simulation types. The samples obtained with the detailed simulation have been used for the tuning of the parametrized description of the detector performance in the fast simulation. The tuning procedure provides a very good agreement with the full detector simulation. Any remaining differences are treated as systematic uncertainty.

Process	Generator	$\sigma \times BR$ [pb]	Filter efficiency	Number of events	Simulation type
$t\bar{t}$ ; $2\mu$ -filter	MC@NLO	833	0.072	500 000	full sim.
$t\bar{t}$ ; $1\ell$ -filter	MC@NLO	833	0.556	600 000	full sim.
$(Z \rightarrow \mu\mu)+0$ -3 light jets	SHERPA	2036	0.490	5 000	full sim.
$(Z \rightarrow \mu\mu)+1$ -3 b-jets	SHERPA	52.3	0.914	5 000	full sim.
$b\bar{b}(Z \rightarrow \mu\mu)$	AcerMC/PYTHIA	45	0.788	280 000	full sim.
$ZZ \rightarrow b\bar{b}\mu\mu$	PYTHIA	0.151	0.724	10 000	full sim.
$WW$	PYTHIA	116.8	0.35	50 000	full sim.
$t\bar{t}$ , no filter	MC@NLO	833.0	1.0	100 000 000	Atlfast
$(Z \rightarrow \mu\mu)+0$ -3 light jets	SHERPA	1165.9	0.855	30 000 000	Atlfast
$(Z \rightarrow \mu\mu)+0$ -3 b-jets	SHERPA	52.3	0.914	1 000 000	Atlfast

Table 1: Background data samples with corresponding NLO cross-sections.

All mentioned data samples have been simulated assuming there are no additional  $pp$ -interactions per event. However, at luminosities of  $10^{33} \text{ cm}^{-2}\text{s}^{-1}$  one expects to have 2-3 such pile-up interactions superimposed to the hard scattering. In addition, the neutron and photon background of the muon spectrometer (so called cavern background) may increase the muon trigger rate and degrade the muon reconstruction performance [22]. In order to study the impact of the pile-up and cavern background on the analysis performance, dedicated  $b\bar{b}A$ ,  $t\bar{t}$  and  $Zb\bar{b}$  data samples have been simulated with the realistic pile-up and cavern background contribution. The simulated cavern background is assumed to be five times higher

than the prediction of GCALOR [23] and FLUKA [24] simulations, to account for the uncertainty of the calculation.

## 4 Detector performance

A detailed description of the ATLAS detector and its performance is given in Ref [25]. The details of the detector layout, the software framework used for the Monte Carlo production, as well as the details of the reconstruction of fully simulated events can be found in Ref [26]. In this Section, the performance of the reconstruction algorithms is shortly described, concentrating on the key objects for the analyses: muon identification and momentum measurement, jet reconstruction, b-tagging and the measurement of the missing transverse energy ( $E_T^{miss}$ ). First, the results obtained in absence of pile-up and cavern background in the detector are shown. These are subsequently compared to the results obtained when both pile-up and cavern background are taken into account.

### 4.1 Reconstruction performance without pile-up and cavern background

In ATLAS, the muon reconstruction is performed by combining the information of the muon spectrometer and the inner detector. Staco and MuTag [22] reconstruction packages are used for the study. The average muon reconstruction efficiency is  $(97.15 \pm 0.04)\%$ . This is reduced to  $(95.44 \pm 0.05)\%$  if a match between the muon spectrometer track and the inner detector track is required. The momentum resolution of low- $p_T$  muons is mostly dominated by the inner detector performance, while the high- $p_T$  muon reconstruction is more sensitive to the muon spectrometer performance. The average muon momentum resolution is better than 3%, which allows for an excellent dimuon mass resolution, as shown in Figure 2 for the A-boson ( $m_A=200$  GeV) produced via the associated  $b\bar{b}A$  and the direct  $gg \rightarrow A$  production mode. As expected, the experimental dimuon mass resolution does not depend on the Higgs production mode. Table 2 summarizes the dimuon mass resolutions obtained for different A boson masses.

Figure 2: Dimuon mass distribution for the  $b\bar{b}A$  and  $gg \rightarrow A$  signal samples with an A boson mass of 200 GeV and  $\tan\beta=30$ . The distributions are fitted by the Gauss function.

Characteristic of the  $b\bar{b}A$  signal are the b-jets with generally rather low transverse momenta, as shown in Figure 3(a). Since the efficiency of the b-jet reconstruction decreases with the  $p_T$ , the number of reconstructed b-jets will in general be smaller for the signal than for the  $t\bar{t}$  or  $ZZ \rightarrow b\bar{b}\mu\mu$  backgrounds, where the b-jets are more energetic (see Figure 3(b)). A detailed study was performed to identify the

(GeV)	A boson mass (GeV)					
	110	130	150	200	300	400
Natural width	2.16	2.48	2.80	3.60	5.61	8.46
Reconstructed $\sigma$	$2.59 \pm 0.02$	$3.83 \pm 0.03$	$4.11 \pm 0.04$	$6.29 \pm 0.05$	$10.2 \pm 0.2$	$15.0 \pm 0.3$
Reconstructed mass	$109.818 \pm 0.006$	$129.738 \pm 0.005$	$149.796 \pm 0.006$	$199.589 \pm 0.005$	$298.82 \pm 0.04$	$399.37 \pm 0.04$

Table 2: The natural width of the  $A$  boson and the expected width of the dimuon resonance based on Monte Carlo simulated data are shown for the  $b\bar{b}A$  signal at different mass points and with  $\tan\beta=30$ .

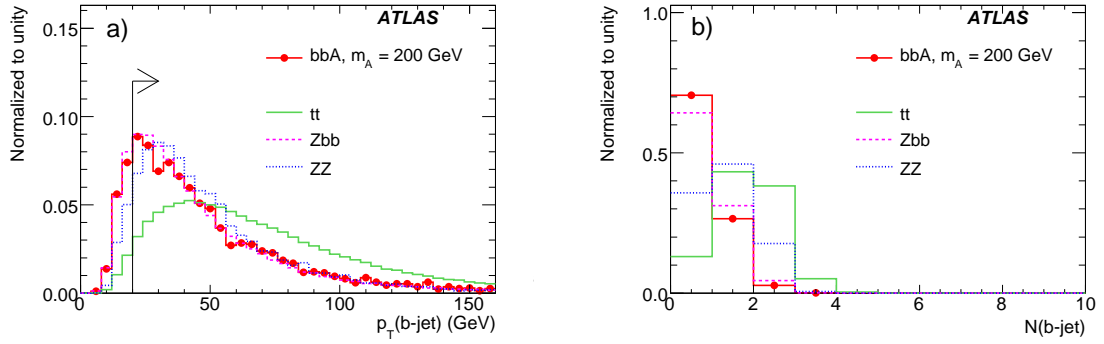

Figure 3: a) Transverse momentum  $p_T$  of the b-jets in the  $b\bar{b}A$  signal and the dominant background processes and b) the number of reconstructed b-jets per event. The selection criteria for the b-jets are described in the text.
